228. "2nd. If we evaporate a solution of silver in cyanide of potassium to dryness, and heat the residue to redness until the mass is in a state of quiet fusion, and has assumed a brown colour, there remains, when we wash the mass with water, metallic and porous silver. The wash-waters, when filtered, still contain a little silver in solution; because, if hydrochloric acid be added to them, it will produce a precipitate of chloride of silver. In evaporating and calcining a solution of gold in cyanide of potassium, the result is the same—we obtain metallic gold. The wash-waters, acidulated with hydrochloric acid, give, when treated with sulphuretted hydrogen, a brown precipitate of sulphide of gold; and, with the salt of tin, a violet precipitate purple of Cassius—a proof that these liquids still contain a little gold in solution.

229. "3rd. If we pour upon finely-divided silver—for instance, silver-leaf, or silver precipitated in the porous state by zinc from a solution of silver—a concentrated solution of cyanide of potassium, at the ordinary temperature, and shake it frequently, the liquid, at the end of a certain time, exhibits silver in solution; and by adding hydrochloric acid to it, we produce an abundant precipitate of chloride of silver. This experiment explains why, in the wash-waters of the various combinations of gold or silver with cyanide of potassium, we can still demonstrate the presence of gold and silver, after the most minute separation.

230. "4th. When hydrochloric acid, or ordinary sulphuric acid, is added to a solution of cyanide of copper and cyanide of potassium, until the liquid exhibits an acid reaction, there results a reddish-white precipitate, which is a cyanide of copper in the anhydrous state. If the precipitate be well washed and boiled in potash lye, protoxide of copper will be separated, of a beautiful red colour; and if to the filtered alkaline liquid we add a solution of green copperas (sulphate of iron), a dirty-blue precepitate will be obtained. A solution of carbonate of soda furnishes the same results, and yields, with the copperas, the same dirty-blue precipitate. If the reddish-white precipitate be dissolved in pure nitric acid, and a solution of nitrate of silver added to it, an abundant white precipitate will be produced, which, when washed, dried, and calcined, yields silver in the metallic state—a proof that the precipitate is cyanide of silver.

231. "The reddish-white precipitate is soluble in an excess of hydrochloric acid, in nitric acid, and in aqua regia; it is also soluble in aqueous ammonia, and in a solution of cyanide of potassium.

232. "5th. If we pour hydrochloric acid into a very pure solution of gold in cyanide of potassium, there will be slowly formed, at ordinary temperatures, and immediately on the application of heat, a yellow precipitate, which is cyanide of gold; the filtered liquid which has given this precipitate, still contains a little gold in solution. In evaporating to dryness, fusing, dissolving, and filtering afresh, there is found upon the filter the remainder of the gold.

233. "When a solution of silver prepared for silvering articles of bronze or of brass, has been employed a certain time for that purpose, the precipitate produced in it by the addition of hydrochloric acid, is not pure white, but reddish, in consequence of the reddish-white cyanide of copper which is precipitated with it; for we know that those silvering liquids which have been used for some time, contain copper in solution. The same thing occurs with the solutions for gilding, in which articles of silver, copper, bronze, and brass, have been gilded for a long time; the liquid contains, after a certain time of service, not only gold, but also silver and copper. This case presents itself especially when gilded articles of silver, containing copper or other alloys of silver, are in the solution of gold; then the precipitate of cyanide of gold, produced by the addition of hydrochloric acid, does not possess its proper pure yellow colour. It has happened to me to observe a precipitate of this kind, which, instead of being yellow, was green; and, in fact, articles of iron have been gilded in a solution, and the precipitate contained, besides cyanide of gold, Prussian blue, so as to be demonstrated in an examination, which consisted in boiling the green precipitate in aqua regia, filtering to separate the dirty-green residue, evaporating the filtered liquid to dryness, and dissolving the dry salt in water acidulated with hydrochloric acid; the addition of sulphate of iron to this new liquid gave a brown precipitate, and the salts of tin a reddish-brown precipitate. In treating by aqua regia, the cyanide of gold was then decomposed, and converted into chloride of gold.

234. "Based upon the preceding facts, we may found several methods for recovering all the silver and gold of old cyanide of potassium solutions. The extraction of these precious metals may be effected either by the wet or by the dry process.

235. "*Extraction of Silver by the Wet Method.*—Add hydrochloric acid until the liquid exhibits a strongly acid reaction (230). The precipitate of chloride of silver which is thus obtained, will be, as we have already said, of a reddish-white colour, because of the cyanide of copper which is precipitated with it when the solution has

been used a long time for silvering objects containing copper. In this precipitation by hydrochloric acid, there is hydrocyanic acid gas set free, therefore the operation should only be performed in the open air, or in a place where there is good ventilation. If the precipitate be very red, it must be treated with hot hydrochloric acid, which will dissolve the cyanide of copper. The chloride of silver having been washed with water, must be dried, fused with potash in a Hessian crucible, and then coated with borax, in the ordinary manner for obtaining metallic silver.

236. "This method is very simple in its application, and very economical, considering that, by the aid of the hydrochloric acid, all the silver contained in the solution of cyanide of potassium is precipitated, and there remains no trace of it in the liquid. But the large quantity of hydrocyanic acid gas which is disengaged, is a circumstance which must be taken into serious consideration when operating on large quantities of silver solution, the vapour of which is most deleterious; and nothing but the most perfect ventilation, combined with arrangements for the escape of the poisonous gases, will admit of the process being carried on without danger to the workmen: when, however, we have taken the precautions dictated by prudence, the method in question may be considered as perfectly practical. The liquid should be poured into very capacious vessels, because the addition of the acid produces a large amount of vapour.

237. "*Extraction of Silver by the Dry Method.*—The solution of cyanide of silver and potassium is evaporated to dryness, the residue fused at a red heat, and the resulting mass, when cold, is washed with water. The remainder is the silver in a porous metallic condition. There still remains in the wash-waters a little silver, which may be precipitated by the addition of hydrochloric acid.

238. "*Extraction of Gold by the Wet Method.*—A solution of gold and cyanide of potassium, which has long served for gilding articles of silver alloyed with copper, may still contain, as we have already remarked, independently of the gold, both silver and copper, and perhaps iron. In order to obtain these metals we operate in the following manner:—

"The liquid, the same as with the solution of silver, is acidulated with hydrochloric acid; in which case there is produced hydrocyanic acid gas, which requires the same careful ventilation. This addition of hydrochloric acid causes a precipitate, which may, according to circumstances, consist of cyanide of gold, cyanide of copper, and chloride of silver. The precipitate, washed and dried, is boiled in aqua regia, which dissolves the gold and copper in the form of metallic chlorides, and leaves the chloride of silver unaffected. The solution, containing the gold and the copper, is evaporated nearly to dryness, in order to drive off any excess of acid; it is then dissolved in a small quantity of water, and the gold precipitated from it by the addition of protosulphate of iron, in the state of a brown powder. The chloride of silver is reduced to the metallic state by the usual means. The liquid from which we have precipitated the cyanide of gold, &c., by hydrochloric acid, may yet contain a little gold in solution. I refer to section 232 for its further treatment.

239. "This method is distinguished by the great simplicity of the operation, and we may repeat for it all that we have already said respecting the extraction of silver by the wet method.

240. "*Extraction of Gold by the Dry Method.*—The solution of cyanide of potassium, which contains gold, silver, and copper, is evaporated to dryness; the residue fused at a red heat, cooled and washed (the wash-waters still containing a little gold and silver; and this occurs most often when the solution of either metal contains a very large excess of cyanide of potassium). The residue, after washing, consists of gold and silver in a metallic porous state, and carbide of copper resulting from the decomposition of cyanide of copper by the heat. The metallic residue is treated by aqua regia, which forms insoluble chloride of silver, and contains the chlorides of gold and copper in solution. In order to obtain these metals in the metallic state, we must proceed in the manner previously indicated.

241. "If we operate according to the method of Professor Bœttger, *i.e.*, if we fuse the dried residue with its own volume of litharge, in a covered crucible, the regulus we obtain in this case consists of gold, silver, and lead. In treating this alloy by nitric acid of specific gravity 1·2, and applying heat, the gold remains in the form of a brown powder, whilst the lead and the silver are dissolved in the acid. This solution, after having been diluted with distilled water, may have the silver separated from the lead, by the addition of hydrochloric acid.

242. "These methods of extracting the silver and gold from old solutions of cyanide of potassium by the dry process, present this advantage, that the operator is not incommoded, while working, by the disengagement of vapours of hydrocyanic acid. In these operations the poisonous gases are not developed as they are in the process for extracting the metals by the wet process.

243. "After the experiments here reported, those who are interested in the subject may choose for themselves which of these methods appears the most suitable to the circumstances in which they are placed, and the object which they wish to attain.

244. "*Means of Recovering Gold or Silver by M. Bolley.*—Cyanide of gold dissolved in an excess of cyanide of potassium, resists all the means which we have tried to separate them; and hydrosulphuric acid, for example, does not produce a precipitate. By the wet way we cannot always precipitate the gold completely, and for that reason MM. Bœttger, Hessenberg, Elsner, and others, propose to evaporate the liquid to dryness; mix the residue with its own weight of litharge; fuse the mixture at a strong red heat; then dissolve the lead from the alloy by boiling it a long time with dilute nitric acid, which leaves the gold in the form of a light sponge.

245. "M. Wimmer has more recently proposed to evaporate the solution to dryness in a water bath, then mix the residue with one-and-a-half times its weight of saltpetre, and introduce the mixture by small portions at a time into a Hessian crucible, heated to redness in order to cause explosions; and to continue this until the entire mass is in a state of quiet fusion.

246. "The first of these two processes does not give room for any objection, except the employment of a great heat, and the use of nitric acid; the second process is, on the contrary, disagreeable, and very uncertain. We know that saltpetre never explodes with more violence than with cyanide of potassium; and, notwithstanding that the inventor of the process advises us not to add more than small portions of the mixture at a time, the explosions are so powerful that they cannot be caused without loss of materials.

247. "The following process is applicable, on the small scale, with a spirit-lamp and a crucible of platina:—Evaporate the solution to dryness; mix the saline mass with its own weight of sal-ammoniac, and heat it gently: ammoniacal salts decompose, as we have said, the metallic cyanides, and form cyanide of ammonium, which is itself decomposed by the heat and volatilised, whilst the acid of the ammoniacal salt (the body which salifies the ammonia) combines with the metals (passed to the state of oxides), which were previously united to the cyanogen. The sal-ammoniac, then, in this case forms chloride of potassium and chloride of gold, and, if the salt contain ferro-cyanide of potassium, chloride of iron in addition. The chloride of gold is easily decomposed; the chloride of iron is partly decomposed, and leaves oxide of iron in beautiful crystalline spangles. The undecomposed portion of the chloride of iron, like the chloride of potassium, may, after the decomposition is finished (which only requires a low red heat), be washed away with water, leaving the gold in the form of a light coherent mass, and the iron in small spangles, which may be removed by mechanical means.

248. "If we fear that a little of the gold remains mixed with the iron in a pulverulent state, we may dissolve it in hot aqua regia, and precipitate the gold from

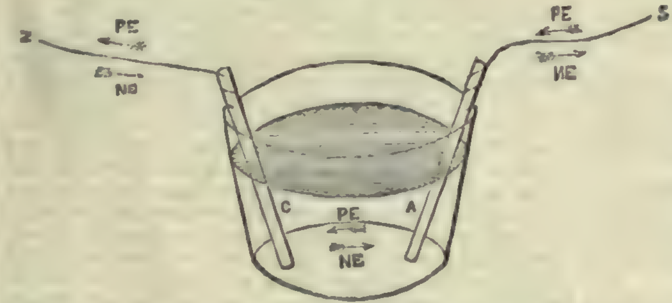
the resulting solution by adding to it a solution of protosulphate of iron; but this appears superfluous: and I am assured, by evaporation of given volumes of the same solution of gold, the evaporation and calcination of the sal-ammoniac, and other operations, that we have collected in a sufficiently exact manner all the gold of these solutions.

249. "The same process is applicable to the solution of silver; and independently of the oxide of iron (of the ferro-cyanide of potassium), we obtain chloride of silver, which is soluble in aqueous ammonia."

250. To further assist the reader in remembering the terms applied to the different parts of the electric circuit, and in understanding the action of electricity upon liquids, we repeat those terms, and append a diagram of the anode, cathode, &c.

S (Fig. 91) is a wire proceeding from the silver plate or positive plate of a battery; Z is another wire from the zinc plate or negative plate; the two wires are attached to two pieces of metal immersed in a depositing liquid. By the direction of the arrows, it will be perceived that the positive electricity circulates in one direction through the circuit, and the negative electricity in the opposite direction.

Fig. 91,



The immersed pieces of metal are termed "electrodes," meaning ways by which the electricity enters and leaves the liquid; the piece A is called the "anode," and is that by which the positive electricity enters the liquid; and C is the "cathode," or that by which the positive electricity leaves the liquid. In the ordinary depositing vat, the anode is that piece of metal which dissolves and supplies the solution; whilst the article or articles which are receiving a metallic coating or deposit, constitute the cathode. The liquid is termed an "electrolyte;" and whilst the electric current is passing through, it is said to be undergoing "electrolysis," to be "electrolysed," or suffering "electro-chemical decomposition." The elements of the liquid are termed "ions;" those of them which combine with, or are set free at the "anode," are called "anions;" and those which combine with, or are set free at the "cathode," are termed "cathions:" for instance—1st, in the electrolysis of a solution of sulphate of copper with copper electrodes, sulphuric acid is viewed as an anion, because it is the product which combines with the anode, and copper the cathion, because it is the element set free at the cathode; and, 2nd, in the electrolysis of the ordinary cyanide silver-plating liquid, cyanogen is the anion, and silver the cathion.

251. *List of Patents upon Electro-Deposition.*—The following is a chronological list of some important patents which have been taken out for subjects connected with electro-deposition.

Elkington's Patent.—June 24th, 1836: gilding copper, brass, and other metals; G. R. Elkington.

Elkington's Patent.—February 17th, 1837: gilding metals, and coating with platinum—apparatus described; H. Elkington.

Elkington's Patent.—December 4th, 1837: gilding and silvering certain metals—apparatus described; H. Elkington.

Elkington and Barratt's Patent.—July 24th, 1838: coating and colouring certain metals; G. R. Elkington and O. W. Barratt.

Elkington's Patent.—March 25th, 1840: coating or plating certain metals; G. R. Elkington and H. Elkington.

Parkes' Patent.—March 20th, 1841: production of works of art by electro-deposition; Alexander Parkes.

Barratt's Patent.—September 8th, 1841: deposition of metals; O. W. Barratt.

Fox Talbot's Patent.—December 9th, 1841: coating and colouring metals with other metals; H. H. Fox Talbot.

Zeeson's Patent.—June 1st, 1842: electro-deposition—with apparatus; H. B. Zeeson.

Tuck's Patent.—June 4th, 1842: coating metals with silver by electro-deposition; E. Tuck.

Woolrich's Patent.—August 1st, 1842: coating metals and alloys with metal; J. S. Woolrich.

Sturges' Patent.—August 10th, 1842: making plated articles; R. F. Sturges.

Fox Talbot's Patent.—November 25th, 1842: coating metals with other metals; H. H. Fox Talbot.

Moses Poole's Patent.—May 25th, 1843: deposition of metals—with apparatus; Moses Poole.

Barratt's Patent.—June 15th, 1843: gilding and plating metals; O. W. Barratt.

Schottlaender's Patent.—December 8th, 1843: deposition of metal upon felted fabrics; J. Schottlaender.

Parkes' Patent.—February 21st, 1844: deposition of metals and alloys; A. Parkes.

Parkes' Patent.—October 24th, 1844: depositing metals and their alloys; A. Parkes.

Parkes' Patent.—October 9th, 1845: coating metals and alloys; A. Parkes.

Lyons and Millward's Patent.—March 23rd, 1847: deposition of metals; Lyons and Millward.

Salzède's Patent.—September 30th, 1847: brassing and bronzing steel, iron, zinc, lead, and tin; Charles de la Salzède.

Fontainemoreau's Patent.—March 14th, 1849: coating metals and non-metallic substances; J. Fontainemoreau.

Russell and Woolrich's Patent.—March 19th, 1849: coating iron and other metals with metals and alloys; Russell and Woolrich.

Parkes' Patent.—March 26th, 1849: deposition of certain metals and alloys; A. Parkes.

Smith's Patent.—June 7th, 1849: depositing metals; S. B. Smith.

Roseleur's Patent.—March 23rd, 1850: tinning metals; A. G. Roseleur.

Steele's Patent.—August 9th, 1850: coating metals; Joseph Steele.

Ridgway's Patent.—April 20th, 1852: coating glass with metal by battery process; J. Ridgway.

Lyons' Patent.—October 7th, 1852: coating surfaces of iron; M. Lyons.

Morriss and Johnson's Patent.—December 11th, 1852: deposition of brass and alloys; Morriss and Johnson.

Junot's Patent.—December 28th, 1852: reducing metals by electricity and plating; C. J. E. Junot.

Power's Patent.—December 29th, 1852: silvering metals and glass; J. Power.

Newton's Patent.—July 29th, 1853: improvements in depositing metals and alloys of metals; W. E. Newton.

Newton's Patent.—August 5th, 1853: coating cast-iron with metals and alloys; W. E. Newton.

Person's Patent.—April 27th, 1854: electro-coating with zinc; C. C. Person.

Joubert's Patent for the Acierage of Engraved Plates.—In the preceding pages, we have repeatedly referred to the applications of electro-metallurgy in the art of engraving and printing. To them, M. Joubert has made a most valuable addition, in his method of coating engraved copper-plates with iron, by means of electro-chemical action. As the invention is of the highest importance, and as it has been extensively adopted by many engravers, we shall not hesitate to give an extended description of it, availing ourselves of the report furnished in the *Journal of the Society of Arts*, for

November 26th, 1852. M. Joubert describes his process as follows :—

"The last century produced many engravers of great merit ; and, in this country, foremost amongst them are Hogarth, Sir Robert Strange, and James Heath. The excellence of their works gave rise to such a demand for print impressions of engravings, that some forty years ago, when it was found that a copper plate could not yield a sufficient number of impressions for the demand, steel plates were introduced, for small plates only at first, and several editions of books were published containing plates most elaborately engraved on steel.

"Subsequently, when means were found to obtain a large surface of steel of pure quality, this metal was adopted for the style of engraving known as mezzotinto, which is now practised on steel plates, the result being a much larger number of impressions obtainable as compared with the old copper plates ; but historical or line engraving, for important subjects, was still entirely practised on copper, when the discovery of the art of electrotyping took place, about the year 1838.

"Several line engravings on copper were then multiplied by this process ; the result, however, was only attended with partial success, in consequence of the soft quality of the copper so deposited, which will yield but a very limited number of good impressions, and soon wears away : this caused the process to be almost abandoned for artistic engraving ; but for commercial purposes it is still practised extensively, and has been often successfully applied in cases where a large number of impressions is not required.

"Under the circumstances which I have described, it had become a desideratum to harden, if possible, the surface of a copper plate, and to protect it from wear while printing ; but it is only lately that this important object has been attained.

"In March last, my friend M. Jacquin, of Paris, took out a patent in this country for a method of coating plates with iron, which had already been successfully applied in France, and of which the merit is due to my friend, M. Henri Garnier, of Paris.

"I have myself had the advantage of co-operating with M. Garnier in the development of the invention, the principles of which I shall now proceed to describe.

"If the two wires of a galvanic battery be plunged separately into a solution of iron, having ammonia for its basis, the wire of the positive pole is immediately acted upon, while that of the negative pole receives a deposit of the metal of the solution. This is the principle of the process which we have named 'acierage.'

"The operation takes place in this way :—By placing at the positive pole a plate or sheet of iron, and immersing it in a proper iron solution, the metal will be dissolved under the action of the battery, and will form hydrochlorate of iron, which, being combined with the hydrochlorate of ammonia of the solution, will become a bichloride of ammonia and iron : if a copper plate be placed at the opposite pole, and likewise immersed, the solution being properly saturated, a deposit of iron, bright and perfectly smooth, is thrown upon the copper plate, from this principle :—

"Water being composed of hydrogen and oxygen ;

"Sal-ammoniac being composed of—

"1st. Hydrochloric acid containing chlorine and hydrogen ;

"2nd. Ammonia, containing hydrogen, nitrogen, and oxygen ;

"The water is decomposed under the galvanic action, and the oxygen fixes itself on the iron plate, forming an oxide of iron ; the hydrochloric acid of the solution acting upon this oxide, forms a hydrochlorate of iron, whilst the hydrogen precipitates itself upon the plate of the negative pole, and, unable to combine with it, comes up to the surface of the solution in bubbles.

"My invention has for its object certain means of preparing printing-surfaces, whether for intaglio or surface printing, so as to give them the property of yielding a considerably greater number of impressions than they are capable of doing in their ordinary or natural state. And the invention consists in covering the printing-surfaces, whether intaglio or relief, and whether of copper or other soft metal, with a very thin and uniform coating of iron, by means of electro-metallurgical processes. The invention is applicable whether the device to be printed from be produced by engraving by hand, or by machinery, or by chemical means, and whether the surface printed from be the original or an electrotype surface produced therefrom. I would remark, that I am aware that it has been before proposed to coat type and stereotypes with a coating of copper, to enable their surfaces to print a larger number of impressions than they otherwise would do ; I therefore lay no claim to the general application of a coating of harder metal on to the surface of a softer one, but my claim to invention is confined to the application of a coating of iron by means of electricity on to copper and other metallic printing surfaces.

"In carrying out the invention, the solutions of iron employed may be varied ; and such is the case in respect to the arrangement of the galvanic battery, or other source of electric currents used. I do not, therefore, limit the invention to the means hereinafter described, but I believe they will be found to be the best for the purpose.

"I would further remark, that it is important that a ferric solution should be employed which will not dissolve or corrode the plate intended to be coated ; for if it be attempted to use such a solution, though the iron will be precipitated, it will not only be in a non-coherent state, but the engraved surface itself will be liable to be attacked and injured. It may also be remarked, that the coating of iron admits of being removed from a printing-surface of copper without injury to the original plate ; hence the original plate may, after being coated and used for some time, have the worn coating removed, and then be recovered with an iron coating as often as may be required ; and if care be taken to remove the coating of iron before it has been entirely worn away, the engraved copper or other plate may be made to print a vast number of impressions, and yet remain in the original state it was in when it left the hands of the engraver, or was otherwise first produced : the only limit appears to be in the gradual change which takes place in the body of the printing-surface, by the compression to which it is subjected in the process of printing. Heretofore, in respect to plates engraved in intaglio, if of steel, they each yield, on the average, about 3,000 impressions without retouching : if of copper, they each yield, on an average, not more than 800 without retouching ; whilst electro casts of copper, obtained from the originals, will not, on an average, each yield even 200 impressions without retouching : in fact, such printing-surfaces are so easily worn, that, after the first 100 or 150 impressions, there is a considerable deterioration in the quality of the work produced. Therefore, for the supply of the number of impressions often required by art associations and others, it has been found necessary to multiply the electro casts very considerably. In such cases the invention is applicable with considerable advantage ; for I find that an electro plate, 40 × 22 inches, covered or coated with iron, has yielded 2,000 impressions without its being necessary to remove and renew the iron coating, there being no perceptible difference between the first and last impression ; the work on the plate appearing not to have suffered in the slightest degree. Hence, in future, by the application of the invention, it will only be necessary to multiply electro casts to such an extent as may be necessary to ensure the production of prints or impressions with the requisite speed, on paper, calico, or other fabrics. At the same time, an original engraving on copper would become, when treated according to the invention, more lasting than if engraved on steel. Although original surfaces engraved in relief, and also electro and other casts taken from them, yield a considerably greater number of impressions than those I have mentioned as obtained from plates engraved in intaglio—to which the invention has not been applied—nevertheless the invention is applicable, with great advantage, to such relief printing surfaces, whether of copper or other soft metal; for if they be coated with iron, according to the invention, they will yield almost an indefinite number of impressions, provided the iron surface be renewed as often as may be necessary, and the printing surfaces be again recoated.

"In carrying out the invention, I prefer to use that modification of Grove's battery, known as Bunsen's; and I do so because it is desirable to have what is called an intensity arrangement. The trough I use for containing the solution of iron, in which the engraved printing surface is to be immersed, in order to be coated, is lined with gutta-percha, and it is 45 inches long, 22 inches wide, and 32 inches deep. In proceeding to prepare for work, the trough, whether of the size above-mentioned or otherwise, is filled with water in combination with hydrochlorate of ammonia (sal-ammoniac), in the proportion of one thousand lbs. by weight of water, to one hundred lbs. of hydrochlorate of ammonia. A plate of sheet iron, nearly as long, and as deep as the trough, is attached to the positive pole of the battery, and immersed in the solution. Another plate of sheet iron, about half the size of the other, is attached to the negative pole of the battery, and immersed in the solution; and when the solution has arrived at the proper condition, which will require several days, the plate of iron attached to the negative pole is removed, and the printing surface to be coated is attached to such pole, and then immersed in the bath till the required coating of iron is obtained thereto. If, on immersing the copper plate in the solution, it be not immediately coated with a bright coating of iron all over, the bath is not in a proper condition, and the copper plate is to be removed, and the iron plate attached, and returned into the solution. The time occupied in obtaining a proper coating of iron to a printing surface, varies from a variety of causes; but a workman, after some experience, and by careful attention, will readily know when to remove the plate from the solution; and it is desirable to state, that a copper plate should not be allowed to remain in the bath, and attached to the negative pole of the battery, after the bright coating of iron begins to show a blackish appearance at the edges. Immediately on taking a copper plate from the bath, great care is to be observed in washing off the solution from all parts; and this I believe may be most conveniently done by causing jets of water forcibly to strike against all parts of the surface. The plate is then dried and washed with spirits of turpentine, when it is ready for being printed from in the ordinary manner.

"If an engraved copper plate be prepared by this process, instead of a comparatively limited number of impressions being obtained, and the plate wearing out gradually, a very large number can be printed off without any sign of wear in the plate, the iron coating protecting it effectually; the operation of coating can be repeated as many times as required, so that an almost unlimited number of impressions can be obtained from one plate, and that a copper one.

"This process will be found extremely valuable for electrotype plates, and also for photogalvanic plates, since they can be so protected as to acquire the durability of steel; and more so, for a steel plate will require repairing from time to time; these will not, but simply recoating, whenever it is found necessary: by these means one electro-copper plate has yielded more than 12,000 impressions, and was found quite unimpaired when examined minutely.

"It is easy to appreciate the importance of this invention, as applied to artistic or line engraving more especially; for a copper plate being once engraved, if submitted to the acierage process, will become a lasting property, not liable to deterioration by printing, and the public may expect to be supplied with the very best impressions at a more moderate charge; whilst, to the numerous branches of commercial engraving, for the ceramic manufactures and others, as well as to the vast number of old engraved copper plates existing in this country, this process is likely to confer an immense additional value.

"I need not say that copper is by no means the only metal to which the process is applicable, for the same principle will be found to answer in the case of other soft metals used for printing purposes; and I shall only add, in conclusion, that although the principle of electrotyping has been applied, up to the present date, in a variety of ways since it was organised by Thomas Spencer, in 1837; this is, I believe, the first time that an attempt has been successfully made to prepare an engraved copper plate with harder metal, with the view of increasing its printing capabilities; and I feel happy to have been the first to introduce so valuable a discovery into this, my adopted country."

THERMO-ELECTRICITY.

We have yet to draw attention to another source of electrical power, which of late years has attracted considerable attention from scientific men. In the previous pages, we have repeatedly noticed how frequently the disturbance of electrical equilibrium is attended with the production of other forces, such as heat, light, &c. These and other facts have led to the idea that each of the undulatory forces has a common origin—a theory which has already been enlarged on. We must now explain the methods by which electricity may be evolved by the action of heat on certain metals, and describe some of the phenomena which result therefrom.

As we have seen, electrical effects result, in some cases, chiefly from the action of intense electricity, or that which has the quality of exerting its effect at a distance from the source of power. To some extent, thermo-electricity falls under this category, but little quantity being noticed in its action. Our thermo-electric batteries, however, have hitherto been on a very small scale, and therefore we may yet perceive greater effects when larger arrangements are made.

A thermo-electric battery is easily constructed. It is composed of a bar of two different metals, generally bismuth and antimony. The bars may be united at one end, as represented in Fig. 92; whilst the others are left free. In the cut, *a* is supposed to represent the bar of antimony, and *b* that of bismuth. Now, if heat be applied at the point, *c*, a current of electricity will be produced; and if a number of these arrangements be connected together, as in Fig. 93, they will form a thermo-electric battery; the current induced passing in the direction indicated by the arrow.

Fig. 92.

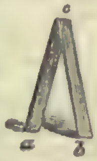


Fig. 93.

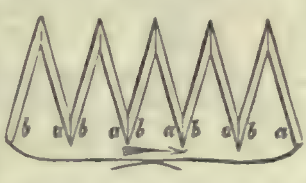
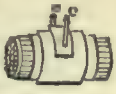


Another method of making a thermo-electric battery, is that of soldering, end to end, bars of bismuth and antimony, and of rolling them into a bundle, such as is represented in the annexed figure, in which *c c* represent the wires proceeding respectively from the last bar of each metal. The principle is precisely the same as that described already, but the arrangement is more convenient for many experiments. If wires be conducted from the extremities of the coil, they can be then attached to apparatus just as is done in some voltaic batteries, &c.

Fig. 94.



The cause of electric disturbance, although evidently dependent on heat, is not easily investigated in all its details. Extremes of temperature favour the development of the current; thus, if one metal be heated whilst the other is cooled by ice, a more powerful current is produced than by heating alone. It has been stated that difference of conducting power is partly the cause; and this is borne out, apparently, by the order in which the conducting power of metals is connected with that of thermo-electric production. The following table shows the thermo-electric relationship of some metals in reference to this question; the greater differences between them in position, the more powerful is the battery formed by their union; and hence the choice of the metals, bismuth and antimony, for constructing batteries.

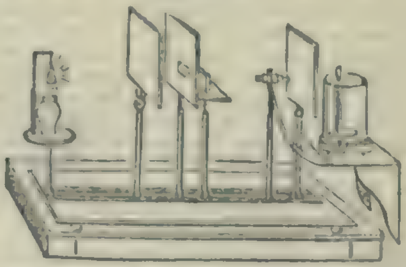
TABLE OF THERMO-ELECTRIC METALS.

Bismuth.
Lead.
Tin.
Copper.
Zinc.
Iron.
Antimony.

This singular method of producing electric currents has been of great value in many respects. In the section on *Heat*, we have already pointed out how it may be employed in measuring changes of temperature, far too minute to be appreciated by ordinary thermometric arrangements. But, besides these philosophical applications, thermo-electric batteries have been arranged with other apparatus, for a variety of practical purposes in daily life, one or more of which we shall have to allude to after our remarks on the Electric Telegraph.

The best method of showing the existence of a thermo-current, is to attach the wires of the battery to a galvanometer. As soon as heat is applied, in the way we have described, the needle is instantly diverged, just as if an electric current from a voltaic battery were passing. The method of applying a thermo-electric current for many experiments, in connection with radiant heat, is illustrated in the following cut; to the left of which we see the source of heat, which, passing through screens of substances under experiment, arrives at the battery. The current thus produced acts on the galvanometer, seen on the right hand of the engraving.

Fig. 95.



ADDENDA ON ELECTRICAL MACHINES.

We have already mentioned, at page 171, a plate electrical machine, which was, at one time, in the Royal Panopticon, London; and Mr. Warner, under whose superintendence it was constructed and worked, has favoured us with some interesting particulars respecting it.

The plate itself was ten feet in diameter, and the machine was provided with double rubbers and conductors. For the purpose of keeping the glass surface free from moisture, steam was allowed to pass into the rubbers, which were constructed of sheet iron. The entire machine was supported by plate-glass columns, so as to insure complete insulation; and the plate was driven by steam power. The number of revolutions averaged about forty per minute, for ordinary experiments; and the rubbing force, or friction, was regulated in the usual manner by screws, &c.

With respect to the force developed, we may observe that this machine never had a fair trial. It was, unavoidably, placed in the centre of an immense hall, round which currents of moist air were continually passing; and in front of the machine was a basin, from which many hundred gallons of water were forced per minute, twice each day, during the exhibition of the Chromatic Fountain. With all these disadvantages, the effects were surprising. Above two hundred feet of Leyden jar surface could be charged in a few seconds; twenty feet of steel wire could be rapidly deflagrated by the battery discharge; and other electrical phenomena were produced on an equally large scale. Under the best circumstances, in dry weather, a spark of upwards of two feet in length, and of great density, could be obtained from the prime conductor; and the usual class experiments with the direct spark, afforded brilliant results. On the breaking-up of the institution, this machine passed into the hands of its constructer; but it is to be hoped that, eventually, its powers will be more fully tested than they have yet been. Such would, no doubt, result in our acquiring additional facts in reference to the powers and effects of electricity produced by friction, and possibly lead to discoveries of great interest.

SECTION IV.

MAGNETISM, AND ITS APPLICATIONS.

CHAPTER I.

The subjects on which we have already treated, will have prepared the minds of our readers for the study of a very interesting class of phenomena, which, although of a restricted character, have yet the most important relations, both in a philosophical and social point of view.

There are few persons who have watched the oscillations of the mariner's compass, but who must have reflected that some unseen agent is incessantly at work maintaining the needle true in its polarity. Amongst all the curious facts which science or daily experience presents to our notice, none seem more extraordinary than that a small piece of metal should constantly point in one direction, if it have been previously endued with the magnetic force. Day and night it ceaselessly obeys some unperceived power: if undisturbed, it truly guides its possessor through the trackless ocean; and in it he puts an implicit faith, which can only be justified by the fact that Nature is never at fault.

It may not perhaps be too great an exaggeration if we remark, that many of the political, commercial, and social circumstances of the present age are due, to a large extent, to this application of magnetism. Without it our ships would be compelled to confine their voyages to the coast-line; our colonies in Australia, New Zealand, &c., would be inaccessible; the construction of railroads and the progress of mines, &c., would be most difficult; the intercourse of nations, separated by the ocean, would be impossible; and commerce itself, with our manufactures, would be confined, for want of raw material, to the narrowest limits.

Another application of the magnetic needle, to which we may here refer, has become of the most extreme importance in every respect. Thirty years ago, the earliest intelligence which could be obtained between our manufacturing districts and the metropolis, required at least twelve to eighteen hours for its transmission. At the present time, it is possible to receive intelligence of any event which has taken place in any capital of Europe, within a few minutes of its occurrence; and within the space of two or three years, there seems every probability that the whole of our Indian possessions will be, in respect to the power of the electric telegraph, within an hour's time of communication with London, or any city in Great Britain. We may also remark on the extreme importance which exists in those discoveries of science that have often been made without any apparent or immediate practical result. Scarcely forty years have elapsed since it was first noticed, that if a current of voltaic electricity were passed by a wire placed over and parallel to a magnetised needle, the latter would be diverged from its usual position, and, according to the direction of the current, the needle deflected to the right or left hand. But we are anticipating the subject on which we shall have to dilate more fully; and, without further preface, we shall proceed to investigate the laws of that force called Magnetism, which we shall subsequently find to be analogous to the other undulatory forces.

As a matter of convenience, we shall adopt the following plan in treating on the subject; and shall describe—

1. Natural Magnets.
2. Artificial Magnets.
3. Magnetic Attraction, Repulsion, and Polarity.

After which we shall enter into a variety of phenomena which are presented by terrestrial magnetism; and other phases of the force.

1. Natural Magnets.—The ancients were well acquainted with the fact, that a stone found in Magnesia had the power of attracting metallic iron; and from this substance, which has since been called the loadstone, the term "Magnetism" has arisen. It may readily be procured from the philosophical instrument-makers. It has a black colour, and a close texture; and if placed amongst iron filings, it immediately attracts them. If a piece of this natural magnet, which is an oxide of iron, be rubbed on a rod of steel, the latter immediately acquires the properties of the loadstone, and becomes, as it is termed, magnetic. There is a singular peculiarity in reference to the permanence of this force, when it is communicated to different kinds of iron. Soft iron is rendered magnetic only so long as it is in communication with a body permanently magnetic. On the removal of such influence, the magnetism immediately ceases. Steel, which is a compound of iron, carbon, and possibly of nitrogen also, has the power of retaining the magnetic influence, and thus of becoming a permanent magnet. Its power of retaining magnetism, depends, however, on its quality. If the steel be badly tempered, or of an inferior quality—that is, approaching the character of soft iron—its retentive power is greatly diminished. In fact, this power of retaining the magnetic force may, to some extent, be employed as a test of the quality of steel; it being borne in mind, that the degree of hardness of the metal also affects the result.

Cast-iron—which is what we may term an analogue of steel—may be often rendered permanently magnetic. Its composition is, however, so varied as to leave us in constant doubt as to its character. Indeed, some specimens of cast-iron far exceed in hardness those of steel. This is owing to a process of cementation, or partial conversion into steel, which the external surface undergoes when in contact with the coal and coke used as moulds in casting the metal. We have seen specimens of this nature which were hard enough to cut glass. An artificial loadstone may be prepared by making a paste of oxide of iron: this, however, deserves notice simply as a philosophical curiosity.—We shall now proceed to the second and more practical division of our subject.

2. Artificial Magnets.—The most simple manner by which an artificial magnet can be produced, is that of rubbing a piece of the loadstone on a common sewing-needle. It will thus acquire two properties: first, that of attracting any piece of iron; and, secondly, of possessing polarity, or a tendency to point in the direction *nearly* of the pole star, in the constellation of Ursa Major. It hence appears that magnetism can be communicated to any extent; and not only from a piece of

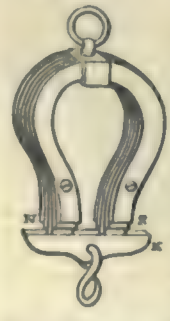
natural loadstone—but if the magnetised needle be rubbed against another one, the latter will also exhibit similar properties to that from which it acquired them.

The extent of magnetic force so communicated, depends on the size of the loadstone and of the piece of steel which is magnetised. In every instance in which force of any kind is communicated to any body, there is a definite relation between the body possessing and that receiving a force, with respect to their mass. This is a natural consequence of the constitution of any mass, because its atoms have, either chemically or dynamically, a fixed amount of attractive power, which they can exert on any proximate atom within their influence. This power can be mathematically calculated. The circumstances may vary considerably, but the laws are in every case constant; and the attraction of gravitation is perhaps the best illustration which we can adduce to prove our position. For instance, we may suppose that any body exerts an attractive power on another near to it. Such a power must necessarily have some relation to the mass or other qualities of the body which it attracts, and the distance existing between. This relation or comparative effect of force may be ascertained in a variety of ways. In the case of gravitation, the time occupied by any body in falling from any height, may become a measure of the force. But in the case of magnetism there is no such opportunity of calculating the value or amount of its force. There exists a kind of antagonism in the magnetic effect, which the earth, and the electric currents which circulate around it, exert. It is true that we can, by the oscillations of a magnetic needle, approximate towards an idea of the amount of magnetic attraction which may exist between terrestrial magnetism, and an artificially induced magnetic arrangement. But still we are left in doubt as to the exact proportion; and the varied affections which may exist between the two phases of the same force, interfere considerably. For instance, there is a daily variation in the polar direction of the magnetised needle. This alone is sufficient to show that a considerable uncertainty exists between the indications afforded by our best arrangements, and the permanent, or continuous and regular, indications which the earth affords of its magnetic intensity.

These remarks may at first sight seem impertinent to the subject on which we are treating: but such is not the case; because we shall have to examine into the comparative power of various magnetic arrangements, and the causes which influence it.

We may here remark, that a straight or bar magnet has two ends, which exhibit the greatest amount of magnetic force; and that the point half-way between the extremities seems entirely destitute of magnetism. Hence, in making an artificial magnet, special attention is paid to these extremities, or poles, as they are frequently termed. A horse-shoe magnet is simply a bar magnet bent into the form of a horse-shoe; and the advantages which this form presents is, that the two poles are brought near to each other, and can so exert simultaneously their power on any object presented to them.

Fig. 1.



When a number of horse-shoe magnets are bound together, they form what is called a compound magnet. One of these is illustrated in the annexed engraving, in which N and S represent respectively the north and south poles of the magnet, and K is what is called the *keeper*. This is a piece of soft iron placed at the poles of a horse-shoe magnet, for the purpose of preventing any loss of power. We may here remark, that either straight or horse-shoe magnets should always have a piece of soft iron, or a quantity of iron filings, at the poles; which, by their reaction on the magnet, prevent its losing its attractive force.

There are two modes of making magnets;—the one by touch we have already alluded to: that by means of voltaic electricity we shall describe under the head of Electro-Magnetism. The simplest mode of making a bar magnet, is that of rubbing a piece of good steel, continually, by means of a compound horse-shoe magnet, such as we have just described. This, however, must be done in a proper manner; the steel being placed on a level table so as to be rubbed from its centre towards its extremity by one pole of the horse-shoe magnet; and this will induce in it a magnetism of an opposite character. The other extremity is then to be rubbed in a similar manner, from the centre of the steel, by the other pole of the horse-shoe magnet; and this is to be repeated until the bar is rendered as magnetic as possible. This, as we have already mentioned, will depend on the quality of steel, and the strength of the magnet employed. Bar magnets are best kept in pairs, and the north pole should be marked on each. In laying them aside, the north pole of one should be in contact with the south pole of the other—a plan which, like that of the keeper, prevents a loss of power.

3. Magnetic Attraction, Repulsion, and Polarity.—We have already had to refer, in our previous observations, to the fact, that a magnet has the power of attracting pieces of iron or steel towards it. We have also mentioned, that the extremities of a magnet are termed "poles." We shall now enlarge on these matters, and investigate some interesting phenomena, and applications depending on them.

If a piece of steel, in the shape of a long rod or bar, be magnetised, and then hung by a silk thread so that it may move freely, it will be found to take up a position pointing nearly north and south, if no disturbing cause be present. This result indicates that some force must act on the magnetised needle; and such is the magnetism of the earth itself. If, while the bar is thus hanging, another magnet of equal power and size be presented to it, pole to pole, the first needle will be either repelled or attracted. If a north pole of one be presented to the south pole of the other, or *vice versâ*, then these will attract each other. If, however, the north poles or the south poles be presented to each other, then they will repel instead of attracting, as in the last case.

From this experiment we learn that similar poles repel, whilst dissimilar poles attract each other; and this law holds good in every shape or form which a magnet may possess.

The simplest mode of trying this is by magnetising two sewing-needles, and floating one of them in water, which is easily done by gently laying it on the surface. The film of air always attached to polished surfaces enables it to swim on the liquid. The poles of the other needle may be alternately presented to either end of that swimming on the water, and the phenomena of attraction, repulsion, and polarity conveniently studied.

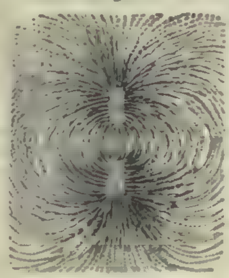
It will be found, that as the distance between the two needles is increased, the effect they mutually exercise is also decreased; and the ratio of this decrease will, for any two points in each magnet, be, like all radial forces, as the square of distances. It must, however, be borne in mind, that we refer here to two mathematical points, rather than to the extension of a magnetised surface: for it is evident that the magnets, being of considerable length and breadth, the force they exercise will be given off in many directions. Could we obtain a magnet in the form of a sphere, then we should doubtless find that the force obeyed the laws above-mentioned; but as, in all ordinary forms of magnets, the length exceeds the breadth—and hence the laws of force must be of unequal length—so the law of radial forces will not have an exact application practically. These observations apply equally to the attracting and attracted body.

It must also be kept in mind, that the poles, or chief attracting portions of a magnet, are not at its extremities. They exist at a short distance nearer to the centre, and equi-distant from that point; and thus, if the two ends of a horse-shoe or bar magnet were slightly hollowed out between the two sides, the chief centre of attraction would be more nearly reached by any body exposed to their action.

The attractive and repulsive powers of a magnet are equal to each other; and, indeed, they may be regarded as the opposite conditions of one force. In this consists the analogy between magnetism and the double electrical theory adopted in reference to frictional electricity. Just as we presume that the inside and outside of a charged Leyden jar[*] are in opposite states of electrical excitation, and yet that such are exactly equal in amount; and, again, as similarly electrical bodies repel, and dissimilar attract, each other[†]—so we have identical conditions and affections of the magnet. We may also illustrate the condition of a magnetised body in a similar manner to that adopted in instances of electrical excitation; for as the alternate sides of the atoms of an electrified body are supposed to be in opposite states of electricity, so the particles of steel composing a magnet, have respectively, on their opposite sides, a north and a south pole—the whole magnet being built up of such until the two extremities form the two opposite poles.

A very beautiful illustration of the effects of magnetic attraction, is afforded by placing a sheet of writing-paper on the poles of a horse-shoe magnet, and sifting over it some fine steel or iron filings. The paper is then to be gently tapped, when the filings will arrange themselves in various forms and at different distances, producing what are termed magnetic curves, the appearance of which is illustrated in the annexed engraving. The same effect may be produced by a bar magnet. Artificial magnets produced by the rubbing process, never exhibit so great an attractive power as those produced by soft iron when surrounded by a voltaic current, and hence termed an electro-magnet. We shall, however, defer speaking on this point until we treat on the subject of Electro-Magnetism.

Fig. 2.



Pieces of steel acquire the power of magnetic attraction, repulsion, and polarity, if they are kept in some positions for a considerable time. A poker will thus often be found magnetic if it be kept in a position nearly due north and south. Old iron window-frames are similarly affected. In fact, masses of cast-iron and steel are frequently found to have acquired magnetic properties from such causes. This results from the inductive action of the magnetism of the earth, which, like electricity, can induce its effects in bodies at a distance from its source.

Nickel and cobalt have decided magnetic properties under certain circumstances; but such are extremely feeble compared with those possessed by iron and its compounds. The magnetic force exercises its influence through bodies which are incapable of being acted on by it. Thus, if a magnetised needle be placed on the surface of water in a basin, and a horse-shoe or other magnet be brought near to it whilst the material of the vessel intervenes, it will be found that the attraction and repulsion are as actively exhibited, as would occur supposing that no substance was placed between the two magnets. Most solids, liquids, and even gases, may, however, be affected by the magnetic force. This we shall more fully explain when we treat on Dia-Magnetism.

THE MARINER'S COMPASS AND THE DIPPING-NEEDLE.

WE have preferred to introduce our readers to a general knowledge of magnetic attraction and polarity, before directing their attention to the very interesting subjects of the Mariner's Compass and the Dipping-Needle, because these depend on a special application of the laws we have just explained.

We have, however, hitherto confined our attention to the artificial magnet, or the loadstone: we must now extend our ideas beyond such limits, and transfer all the powers and laws we have examined, to the earth, as the great source of magnetic attraction. We may conceive, in fact, the earth to be an immense magnet, having polarity, attraction, &c., as have the feeble instruments we employ in our researches into the nature of this force. Indeed, all development of magnetism which we observe, is due to the inductive power of the earth on the bodies we find magnetic. The magnetic poles of the earth vary, from its natural polarity. The north magnetic pole is situated in long. 96° 45′, and lat. 70° 5′. The magnetic equator is therefore, of course, not coincident with that of the earth.

The mariner's compass consists of a bar of steel which has been well magnetised—mounted on a pivot, so that it can move as freely as possible in a horizontal direction. Attached to, or placed beneath it, is a circular card, on which are engraved the different points of the compass. This card is divided into thirty-two parts. Each of these parts, or points, are subdivisions of the four cardinal points—north, east, south, and west; and the intermediate points between any of them, acquire their joint names; such as north-east, south-west, south-south-east, &c.

Generally speaking, at least two compasses are carried on board a vessel, so that in case of any damage to either, another may at once supply its place. The greatest care is observed to place the compass in a position in which any external object shall have as little effect as possible upon it, as any derangement might lead to the most serious results; of which we shall speak more fully as we proceed.

The needle, as we have already stated, does not point due north; that is, it does not lie in a plane parallel to the meridian of a place—which, of course, is due north and south. This deviation is termed the *variation* of the compass; and it is undergoing constant, although gradual change. This variation also differs for different places on the earth's surface. About 300 years ago, the needle pointed 11° east of north. In 1657, it pointed due north and south; and at the present time its variation is about 23° west of north; each of the above referring to observations made in London. Tables are constructed, giving the variation of the needle for different places; and we need scarcely remark that such are of great importance to the mariner.

But besides the horizontal motion of the magnetic needle, a bar of steel, if properly balanced, so as to be capable of a vertical motion, will, on being magnetised, lose its balance, and bend at an angle towards the earth. Such an arrangement is called a *dipping-needle;* and the variation from a horizontal line is called the dip. At the present time, the dip for London is about 67°; and, like the horizontal direction of a needle, is constantly varying. If a needle were placed in lat. 70° 5′ north, and long. 96° 45′ west, which is the position of the magnetic pole of the earth, it would then assume a vertical position.

Apart from any accidental influence, the needle varies daily in its indications; the maximum being during the day, and the minimum during the night, in any locality. It has hence been assumed that the sun has a definite action on it; and some have gone the length to suggest that that luminary is the great source of magnetic force. When, however, we discuss the influence of electric currents on a magnetised needle, we shall find abundant reasons for the effects we have named. There are other disturbing causes which act on a magnetised needle occasionally. It has been noticed, for instance, that the appearance of the aurora borealis has a decided influence on the direction of a needle; causing it, at times, to fluctuate considerably. Indeed, the needle indicates the presence of that splendid phenomenon, when, from any cause, it is invisible to the eye.

The diurnal variations of the needle have been made the subject of anxious investigation by most of the leading astronomers in the observatories of Europe and

---

[*] See *ante*, p. 179.

[†] See *ante*, p. 175.

America; and a vast fund of valuable information has been acquired. At the present time the observations are registered by means of photography;* and thus the incessant care required on the part of observers, and the chance of erroneous results, are entirely avoided. There is also the great advantage of no intermission being required, as, by means of properly prepared paper, a lamp with a reflector, and a clockwork arrangement, the indications print themselves, and the photograph, on removal from the instrument, shows precisely all the variations which have taken place, and the exact moment of the occurrence. One of the best instruments of this kind is that which was constructed by Mr. Brooke, for the Greenwich Observatory.

Returning to the subject of the compasses of a ship, we may notice some special influences to which they are subject, and the remedies which have been employed to obviate such. They may be divided into accidental, local, and, possibly, atmospheric.

It would be impossible to enumerate the accidental circumstances which may arise, to cause the derangement of a ship's compasses. Articles of iron placed near them are a frequent cause; and an intelligent captain once informed us, that, for four hours, he had been steering, on a dark night, out of his course, owing to the stupidity of a cabin-boy, who had placed *a box of knives* close to the compass.

The local influences to which the needle is liable on board ship are of great importance, and depend on the nature of the material of which the ship is built, the cargo, the engines of a steam-vessel, and the position of the two latter in reference to the compass.—As soon as the ship is completely loaded, she is taken to any convenient place in which she can turn round in an entire circle—being held by her anchor—as the tide rises and falls. In this process the direction of the needle is carefully watched in reference to any distant and fixed object, and the variation, if any, is noted. Her compasses are then adjusted—that is, magnets are placed near, so as to entirely counteract all the influences which may affect them on board, and to which we have just alluded. If the cargo be undisturbed until the vessel reach her final destination, and no accidental or atmospheric influence be exerted, such adjustment would be a sufficient safeguard for the whole voyage. If, however, a portion of the cargo be discharged at intermediate ports, it may happen that the adjustment previously effected will become a source of danger; because the disturbing element being removed, its intended remedy necessarily becomes a source of disturbance itself. This is a matter of common occurrence on board coasting vessels: we observed an instance of this, some years ago, in a steam-vessel which had left port with a large cargo of iron on board. This was discharged at an intermediate port; and the needle was thereby affected to the extent of between two and three degrees. It is highly probable that many of the shipwrecks which annually occur round our coast, may owe their origin to this constantly-occurring circumstance.

With respect to atmospheric influences, especially as regards fog, great diversity of opinion exists. Many persons insist that the needle ceases to act in a dense fog; whilst others equally deny its influence: and thus when any vessel is lost during foggy weather, the evidence offered as to the cause, is always accompanied with the special views of the witnesses on each side. In the absence of any reliable data, we shall mention two instances of our own observation, taken within a few days, on the east and west coasts of England and Scotland.

In a voyage from London to Edinburgh, in an iron screw steamer of about 600 tons burthen, and with a general cargo, a dense fog set in immediately after leaving the Pool. This continued for twenty-eight hours; during which, for safety's sake, the speed was never allowed to exceed five miles per hour, and the anchor was cast frequently, owing to the positive danger of proceeding at all. There were three compasses on board—one at the stern, another on the hurricane deck, and one in the cabin. The writer compared their indications, repeatedly, each hour during the time mentioned; and in no case did either, or all of the compasses, vary from each other to the extent of one degree. A pocket compass, the needle of which was delicately hung, agreed with the average of the ship's compasses. There was not the slightest motion of the vessel, except from the vibration of the screw. So far, no indication of the action of fog was afforded. In another instance, however, which occurred in a voyage between Ayr and Campbelton, at the mouth of the Clyde, very different results were noticed. The voyage was commenced in a dense fog, and no special cause of disturbance was on board, the vessel being built of wood, and no iron was contained as cargo. After steering direct westward towards the Isle of Arran for about an hour, with the intention of calling at a port at its *southern* end, it was discovered that the vessel had been steered gradually towards the north, although the compass had indicated a westerly course. The needle, in fact, varied about 90° from its proper indication; and this increased until the setting sun appeared in the north-east, instead of slightly south of west. During the whole time the compass had been shaken so as to cause the needle to move freely; besides, the vibration from the paddles ought also to have been quite sufficient for that purpose. At the end of about two hours' time from the commencement of the voyage, a brisk wind sprang up, and almost immediately afterwards the compass-needle veered round to its proper direction, and gave no more cause for anxiety. In the former, and in this instance, the circumstances were exactly the same; for a breeze sprung up and cleared away the fog at the end of the twenty-eight hours, yet the compasses showed no change of direction from that which they had indicated previous to the clearing-up of the weather. The observations in each case were conducted with great care, and with that scrupulous hesitancy as to theoretical opinion, which the study of experimental science makes a habit; and we could not find, on free conversation with the captain of each vessel, that any extraordinary circumstance of any kind was present which could vitiate the result.

We may, however, state, that three or four iron vessels have been lost between the Isle of Arran and the west side of the coast of Argyllshire, near Campbelton, since the above observations were made. In each case the cause was assigned to the fog acting on the compasses. We may venture to suggest that there may be some local cause in the constituents of the rocks, &c., of that neighbourhood, especially as we learned from an intelligent scientific observer, that one or two masses of rock near Campbelton, have a decided effect on the magnetic needle. However, we merely throw out the idea as a suggestion rather than as expressing any opinion on the matter, which, of course, can only be decided by minute and scrupulously exact observations.

The effect of electrical currents we have already referred to; and we shall have to enlarge considerably on the subject in the next chapter. They are scarcely of much moment during the voyage of a vessel, because, being local with respect to extraordinary occurrence, and the position of the vessel continually varying, their force and intensity can be practically, except in very special cases, of little consequence.

---

* See *ante*, p. 163.

CHAPTER II.

ELECTRO-MAGNETISM.

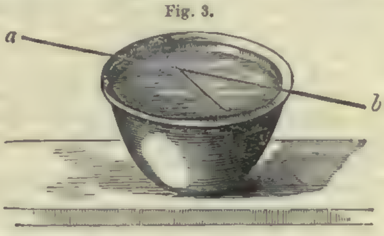
No branch of experimental science has made such rapid progress as that to which we shall now direct attention. This is chiefly owing to the discovery of voltaic electricity, by means of which we have the power of obtaining any amount of current force of great quantity, which is an essential point in all electro-magnetic researches. For most of the experiments which we shall adduce, but little apparatus is required, and such can easily be constructed by attention to the directions we shall give. A voltaic battery of either Daniell's, Smee's, or Grove's form, will be required; one cell, however, being sufficient for most purposes. When larger arrangements are needed, we shall mention the fact as we proceed. A quantity of copper wire, covered with cotton or silk, of No. 16 and 22 gauge; a strong horse-shoe magnet, and some good steel needles, will also be requisite for the majority of the experiments. With these the student may make an extended investigation of the leading laws and phenomena of electro-magnetism, and thus acquire a competent knowledge of the subject at a trifling expense.

In studying the facts of which we shall have to speak, several difficulties may arise in the minds of those of our readers who are not prepared to take an independent view of the action of two forces, which, whilst seeming to be antagonistic, are really due to the same cause. For instance, we shall show that a current of electricity which produces magnetic phenomena, in some cases acts in opposition to the force it may generate. This difficulty, however, if carefully examined, will prove rather an advantage than otherwise to a careful and attentive student, because it will call out his reasoning and observing powers, and so add, as far as he is concerned, an additional interest and value to this branch of philosophical pursuit. We must, however, remark, that all such opposition of the forces to which we refer, is more apparent than real, and results from the direction of the electro-current being modified in reference to the plane of the magnetic force: this, however, we shall fully inquire into as we proceed.

Perhaps the most convenient and instructive course which we can take in introducing our readers to the laws of electro-magnetism, is that of proving, in the first place, that a current of voltaic electricity affects the magnetic needle when certain particulars are observed in carrying out the experiments which illustrate this fact. This may readily be ascertained by means of the following arrangement, which we suggest as one of the simplest which can be used for the purpose:—

Experiment 1.—Fill a basin nearly to its brim with water, and float on its surface a magnetised sewing-needle.* When the needle has ceased to vibrate, and is therefore quite at rest, place over, and exactly parallel to it, a straight copper wire, at a distance of about a quarter of an inch from the needle, so that the two shall lie on the same straight line. Now, so long as no current of electricity passes by the copper wire, the needle will not be deflected from its position; but if a current of electricity be sent from one cell of any form of the voltaic battery, then the needle will instantly be moved from its position, and be deflected right or left, according to the direction of the current. A voltaic battery, for this experiment, is easily made by soldering a wire to a small piece each of zinc and copper. These metals are then to be placed in a vessel containing water, to which a tenth part of its bulk of sulphuric acid has been added. On the terminal wires being brought in contact with the wire placed over the needle, the deflection of the latter will be immediately observed. Of course the two plates of metal must not be allowed to touch each other. The following engraving illustrates the arrangement we have described, and shows the deflection of the needle during the passage of the current by the wire.

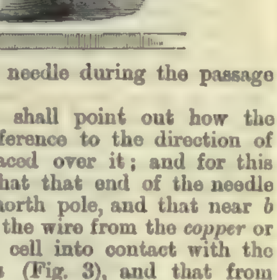
Fig. 3.



Experiment 2.—We now shall point out how the deflection takes place in reference to the direction of the current by the wire placed over it; and for this purpose we shall consider that that end of the needle nearest *a*, in Fig. 3, is its north pole, and that near *b* to be its south pole. Bring the wire from the *copper* or *platina* plate of the battery cell into contact with the wire over the needle at *a* (Fig. 3), and that from the *zinc* end of the cell into contact with the wire at *b*. The current of electricity passes *in* the battery from the zinc to the copper, and thence by the wire from *a* to *b*. In this direction it will deflect the needle towards the *right* hand of the observer, supposing that he looks at the needle from its south, towards its north pole. Afterwards, remove the wires of the battery, and adjust the needle so that it may again be at rest, parallel to the wire passing over it on the basin. Then allow the current from the battery to pass from *b* to *a* by placing the wire from the copper plate at *b*, and that from the zinc plate at *a*. The needle will now be deflected towards the observer's left hand, the current passing from *b* to *a*.

This will be still further illustrated by means of the annexed diagram; in which No. 1, Fig. 4, represents the current as passing downwards from *a* to *b*, in the direction of the arrows; whilst, in No. 2, it is passing in the direction from *b* to *a*. The north pole of the needle is thus diverged to the right in No. 1, and to the left in No. 2, owing to the reversal of the current in the latter case. It is of the greatest importance that the student should bear in mind these laws of deflection, as they exercise great influence in all the phenomena of electro-magnetism; and, although our engravings are explicit enough to explain the facts, it is far better that the experiment should be frequently repeated in the simple manner we have just described, as that will certainly impress the truth more firmly on the memory than any amount of study could do. We may here add, that when we describe the form of electric telegraphs in common use in this country, we shall presume that the facts we have thus illustrated have been fully understood by our readers.

Fig. 4.



No. 1. No. 2.

From these experiments we can readily deduce the first law of electro-magnetism; which is, "That a current of electricity affects the magnetic force at right angles to the direction of the current itself." In applying the law practically to the two last experiments, we observe, that as the current passes by the wire, the magnetic needle assumes a direction approaching that of a right angle to the wire. With a powerful battery the right angle is nearly completed.*

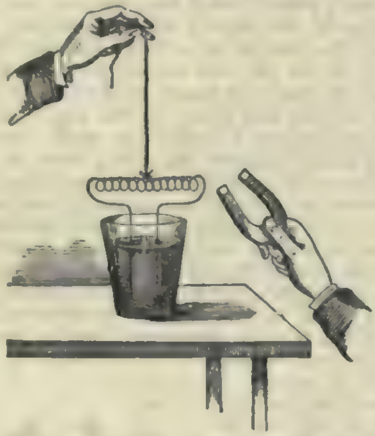
---

* See *ante*, p. 244.

Whenever a wire conducts a voltaic current, it manifests magnetic tendencies in a direction at right angles to that of the current: in other words, supposing that a current of electricity be sent through a copper wire in a direction from north to south, or *vice versâ*, the magnetic effect will be observed on its east and west sides, and, in fact, all round the wire in any position at right angles to the course of the electric current. By extending this principle practically, we may make a voltaic conducting wire, although of copper, to present all the phenomena afforded by an ordinary piece of magnetised steel; that is, it will be subject to the laws of attraction, repulsion, and polarity,† just as if it were an ordinary magnet. The following experiments will illustrate the fact. We shall choose two simple pieces of apparatus, which may readily be constructed by the reader, and for which we shall give full directions.

Experiment 3.—Solder to a piece of covered copper wire, of about eighteen inches in length, a narrow strip of zinc and one of copper—one at each end—and then twist the wire into a spiral form, so as to leave the strips of metal hanging beneath it. Let these dip into some sulphuric acid and water, and suspend the spiral by means of a piece of thread, so that the whole arrangement may freely move in any direction. Its entire appearance is represented in the following engraving.

Fig. 5.



It will be found that the spiral wire will have become powerfully magnetic. It will assume a direction of nearly north and south, just as a magnetic needle would do; and if a horse-shoe magnet be presented to it, the poles of the spiral and the magnet will either repel or attract each other, dependent on the poles which are experimented on, and according to the laws which have been previously explained when treating on magnetism.‡

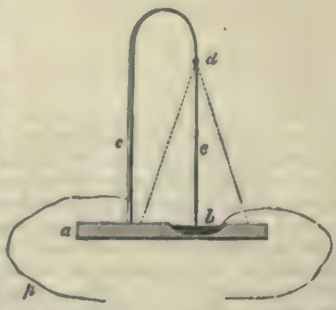
It is thus evident that a most intimate connection exists between magnetic force and a current of electricity; and the next experiment will still more familiarly prove the fact.

Experiment 4.—Immerse a wire conveying the voltaic current in some iron filings. It will be found that so long as electricity passes, some of the filings will adhere to the wire—indicating the existence of magnetic attraction on its surface.

A great variety of apparatus has been invented for the purpose of illustrating this mutual action of electric currents and magnetised bodies, by means of which motion may be readily produced by their opposition or attraction of each other. We may select two of these as still further illustrative of the laws we have been speaking of; and we have chosen such as may be readily constructed by our readers.

Experiment 5.—Fix in a wooden foot, which may be six inches long and three broad (*a*—Fig. 6), an upright brass or copper wire, *c*, which must be bent round at the top, so as to hang over a hollow trough cut out of the foot, as seen at *b*. From the wire *c* suspend another, so that it can move freely in all directions, and fill the trough *b* with mercury, so that it may touch the extremity of the wire *e*, suspended from *d*. Now, of course, as such has no force acting on it, it will remain perpendicular. Attach one of the wires of a cell of a voltaic battery to *c*, and dip the other wire into the cistern of mercury *b*. A current of electricity will now pass through the wires—say from *p* to *d*, thence by *e* to *b*, and so back to the battery. If a horse-shoe magnet be now placed on the wooden foot, so that one of its poles shall be on each side of the suspended wire *e*, that will be instantly put into motion, and will be rapidly jerked out of the mercury. By this, contact with the battery will be broken; and as all effects are thus stopped, the wire will fall back into the mercury. Contact and a complete current will be again established; and the wire will be again jerked from the cistern. The direction of this motion, as indicated by the dotted lines, will depend on that of the current and on the position of the poles of the magnet, and it may be continued so long as the battery power is sufficiently maintained.

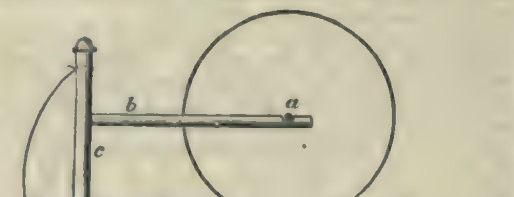
Fig. 6.



We may just observe, that for the success of all electro-magnetic experiments, it is highly necessary that the ends, &c., of the wires be kept perfectly clean. This is best effected by dipping them into a little nitric acid, and then into mercury. By this they will be slightly amalgamated, and much disappointment will be prevented, which, at all times, arises from carelessness as to this particular.

Experiment 6.—The arrangement we are about to describe, actson precisely the same principles as the last one; but instead of a jerking motion, a circular one is obtained. In fact, we may regard the wheel we shall mention, as made up of an infinite number of wires, or radii, proceeding from a common centre, instead of being suspended from a hook, as shown in our last engraving. To construct this arrangement, cut a circular wheel out of thin sheet copper, and through its centre solder an axle of copper wire, as at *a*, Fig. 7, so that it may freely turn thereon; and supported by a brass arm, *b*, which is to be fixed to an upright, also of metal, *c*. This may stand on a wooden foot, hollowed out at *e*, as in our last arrangement; and the rim of the copper wheel should just touch some mercury contained in the trough *e*. One wire of a battery is to be attached to the upright *c*, and the other is to be immersed in the mercury in the cistern. On placing a horse-shoe magnet, with its poles resting on the foot, on each side of the wheel, the latter will begin to rotate, and will maintain its motion so long as the current of electricity passes.

Fig. 7.

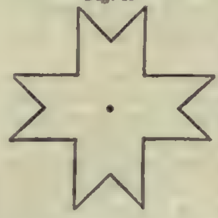


This arrangement may be modified by using a wheel with spokes, instead of the circular form we have described. Such will combine the principles of construction illustrated in our two last engravings; for, whilst it has a rotary motion, each spoke, as it leaves the mercury, is, as it were, similarly jerked out in the way we mentioned in the case of the wire. The annexed cut will assist our readers in making a wheel of this kind: all other matters are the same as in that form of instrument we have just noticed.

---

* See *ante*, p. 195. † *Ante*, p. 244. ‡ *Ante*, p. 244.

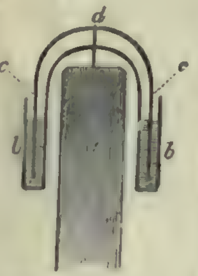
Fig. 8.



If a small voltaic battery be suspended round each of the poles of a horse-shoe magnet, the metals of which it is composed will revolve rapidly round the magnet, and in reverse directions at each pole. These arrangements are exceedingly ingenious, but very troublesome in use. In the following engraving one of them is illustrated. They are sold at the instrument-makers; and give an additional proof, when in action, of the mutual influence of electric currents and magnets.

In Fig. 9, *a* represents a pole of a powerful circular horse-shoe magnet; *b* is a copper bucket, suspended at *d* on the top of the magnet, round which it may freely rotate; *c* is a zinc cylinder which hangs inside the copper one. The latter is to be filled with some acid and water, when a voltaic battery is at once formed. As soon as this is charged the cylinders turn round rapidly on their axes at *d*, which action is due to the same laws as those we mentioned in connection with our three last experiments.

Fig. 9.



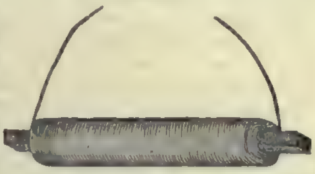
Whilst referring to the magnetism of the earth, we spoke of electric currents as affecting the magnetic needle;* and also, when describing the dipping-needle, we mentioned that there existed magnetic poles. Mr. Barlow, many years ago, invented a most ingenious arrangement, which consisted of a number of wires (corresponding with the circles of latitude on a globe), which were wound round a wooden ball, and were intended to represent the direction of electric currents as they pass round the earth. If a current of electricity be sent from a voltaic battery round a ball so arranged, and a vertical magnetic needle be presented to it in different parts, the various inclinations or dips are at once produced. Such an arrangement forms a curious and instructive illustration of the production of magnetic phenomena by means of a voltaic current, and also affords to the mind an idea of the effects which occur on the large scale in nature.

ELECTRO-MAGNETS.

We have hitherto confined our attention to simple instances of the mutual action of electric and magnetic currents; and shall now proceed to point out how, by applying the laws already discussed, we may produce an immense development of magnetic attraction in soft iron, by means of properly directed voltaic currents. If a piece of steel be rubbed by means of an ordinary magnet, of any form, it retains a portion of the magnetic force; but soft iron does not; and it ceases to exhibit any sign of attraction so soon as the magnet which had induced it is withdrawn. In fact, the result is simply one of induction, and, therefore, ceases on the inducing power being removed. The same holds good in reference to the magnetic force induced by electricity; as we shall discover in trying any of the following experiments:—

Experiment 7.—Twist some covered copper wire round a roller, so as to form a spiral of a few inches in length, and, removing the roller, insert in its place a rod of soft iron. Connect the two ends of the spiral with the wires proceeding from a voltaic battery. Immediately that the current of electricity passes round the iron, it induces, at right angles to its direction,† magnetism in the rod; and if some nails or iron filings are presented to the extreme ends, they will be powerfully attracted. The annexed cut illustrates this simple arrangement. At each end of the coil the iron rod is seen projecting; and the wires terminating the coil are also shown.

Fig. 10.

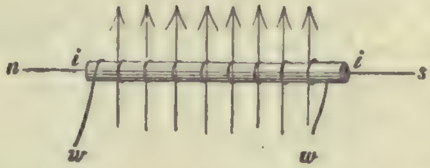


Experiment 8.—So long only as the current of electricity passes, does the iron exhibit magnetic attraction; for, on removing either of the battery wires, the iron nails will at once fall down, and the iron rod returns to its normal condition.

We must here note the fact, that the magnetic effects are induced at right angles to the direction of the electrical current; and to assist the student, we introduce the following cut.

Fig. 11 represents a skeleton view of the spiral coil and iron rod: *n* and *s* show the poles of magnetic force induced in the bar of iron *i i*. Now, the direction of the current of electricity from one of the wires, *w*, to the other on its return to the battery, is indicated by the arrows; and if the spiral be wound quite straight round the rod, then it and the current will necessarily be at right angles to the iron which they encircle. We have already seen that the sides of a spiral are magnetic when it conveys a voltaic current;‡ and it follows that the iron enclosed therein partakes of that change or effect. Indeed, the simple arrangement illustrated in Fig. 11 is quite of sufficient power, when in action, to induce magnetism in a small soft iron wire, if such be placed in its centre; and thus the application of the laws of which we have so repeatedly spoken, is evident.

Fig. 11.



This law, however, may be made more special in the instances to which we are now referring, by stating, "that a current of electricity passing round soft iron, converts the metal into what is termed an electro-magnet, when its direction is at right angles to the iron.

We have seen that the magnetic effect produced on soft iron is but temporary; that is, provided that the metal be perfectly pure. But this is rarely the case, because iron is mixed with other substances which affect its nature. Carbon is invariably present to a small extent, and hence the metal does not lose its magnetism instantly on the current being withdrawn. The magnetic effect remains for some time; and this is called *residuary magnetism*, which frequently becomes a source of great difficulty and annoyance in many of the applications of electro-magnetism. A perceptible interval of time is required to produce the highest effect of magnetic induction; and as in the case of ordinary magnets, the poles do not exist exactly at the extremity of the metal rod. We shall now examine the effect produced on steel by the voltaic current as it passes round a rod of that metal.

Experiment 9.—Place inside a coil of covered copper wire (which, for this purpose, may be wound round a paper or gutta-percha tube), a bar of good steel, which has been previously tested, so that the absence of all magnetism has been proved. As soon as a current of electricity passes over it, the steel will become magnetic, as may be shown by holding any piece of iron near it. But it will be noticed, on the current ceasing to pass by the removal of the wires from the battery, that the metal does *not lose* its magnetism. On the contrary, it has been converted into a permanent magnet. Herein, therefore, exists a similar difference between soft iron and steel in reference to electric as in magnetic induction; and both, doubtless, are due to the peculiar molecular constitution of steel, arising from the presence of carbon, and most probably, also, of nitrogen in it. Knives, needles, and any other steel object having two ends, may thus be at once rendered magnetic.

---

* See *ante*, p. 245.

† See *ante*, p. 247.

‡ See *ante*, p. 248.

Before describing electro-magnets of large size, and electro-magnetic engines, which have been constructed with a view to the production of motive power, we will inquire into the circumstances which tend to increase or diminish the effects which can thus be produced by electricity on iron or steel.

These may be epitomised as follows:—

1st. The length of the coil, and the thickness of the wire composing it.

2nd. The number and size of the plates of the voltaic battery employed.

3rd. The purity of the metals used in respect to the copper wire and the iron core.

1st. *The Length, &c., of the Coil.*—It is a rule in electrical science, that the longer the conductor, the greater is the resistance afforded to the passage of a current; and it is equally true, that the greater the transverse area of the conductor—or, what is the same thing, its thickness—the less the resistance afforded by the same length of wire. It has been found, that a copper wire, of No. 16 gauge, has a conducting power of 100; whilst a thinner one, of No. 18 gauge, has only a power of 65. The following table, for which we are indebted to an able work by T. Shaffner, Esq., of Kentucky, *On the Electric Telegraph*, illustrates the fact of the difference of conducting power in wires of various thicknesses. The experiments were tried at the Gutta-Percha Company's Works, in London, on wires each 100 miles long; and these were submerged in the Regent's Canal—every care having been taken that the external coat of gutta-percha was faultless. The figures indicate the deflection of the needle of a galvanometer* for each gauge of wire employed.

No. of Battery Plates.	No. 18 Gauge.	No. 16 Gauge.
3 pairs	29°	39°
6 ,,	50°	59°

We thus observe how much the resistance is increased by a deficiency in the size of the conducting wire; and it follows that a great length may be, to some extent, compensated for by an increased thickness of conducting material.

2nd. *The Number and Size of Battery Plates.*—The remarks we have just made, and the table quoted, lead us to consider the effects produced by the size and number of the voltaic batteries which may be employed; and we must here point out that *quantity* of electricity is produced by *large plates*, irrespective of the number; whilst *intensity* results from the *number* of plates, rather than their size.

Now, the amount of magnetic effect produced on iron by electricity, depends, *theoretically*, on the quantity of the current alone; but this is only true on the supposition that the conductor offers not the slightest resistance to the passage of the current. But, in practice, we know that such never can occur; for the longer the wire, the greater the resistance afforded; and as each successive coil increases the amount of inductive effect, we are necessarily compelled to employ long wires in constructing all electro-magnetic arrangements. To overcome the resistance of the wires as to their length, we are therefore under the necessity of using, not only large plates, but a number of them. The size of the plate affords the necessary quantity of electricity; and the number of the plates assists that quantity, by their intensity, to give out the full force which one large plate would do were no resistance to be overcome. It therefore follows, in practice, that both size and number of plates must be considered in all attempts to produce the greatest amount of electro-magnetic induction under most circumstances. We always presume that copper wire is used in our experiments; as, for various reasons, none other, in most cases, is admissible.

3rd. *The Purity of the Metal used in both Coil and Core.*—This is a point which has not received that attention which it deserves. Indeed, the experiments necessary to afford accurate data, would require to be of the most elaborate and extensive kind; and the results, although of the greatest interest in a philosophical point of view, could rarely have a practical application for telegraphic and other purposes, owing to the great expense and trouble which would have to be incurred. Almost each length of copper wire which we may accidentally meet with, varies in this respect. Indeed, we have found, that the longer the same wire has been used as a conductor for powerful batteries, the worse is its power of conduction. It undergoes a molecular change; becomes hard, and frequently breaks into pieces with the slightest touch. Iron is subject to the same influence; and, like copper, it becomes completely "rotten" after having undergone lengthened electric action. We have frequently had occasion to remark these facts whilst experimenting with apparatus in which an intense current was employed; and shall refer again to the subject as we proceed.

HORSE-SHOE ELECTRO-MAGNETS, AND ELECTRO-MAGNETIC MACHINES.

Having explained the principles on which electro-magnets are constructed, and the conditions which affect their power, we proceed to make a practical application of our remarks in reference to horse-shoe electro-magnets and electro-magnetic machines, which have been invented for the purpose of obtaining a motive power by employing voltaic electricity. It will not be necessary for us to enter into any further theoretical considerations: we shall therefore confine ourselves chiefly to the mechanical details of the instruments to be described.

A horse-shoe electro-magnet has a similar advantage to that we mentioned as possessed by the permanent steel horse-shoe magnet;† for it has its two poles in close proximity, which, therefore, act in concert, and so produce a large development of attractive power. The ends should always be planed or ground as level as possible, so that any object presented to them may come into as close contact as possible. We shall give directions for making them, and leave the question of size to the choice and means of our readers. The copper wire must either be covered with cotton, worsted, or silk; the first material being the cheapest, and answering every purpose. It is also necessary that the wire should always be as soft as possible, so that it may accommodate itself to the curves of the iron. Each turn should be brought tight up to that preceding it, so that there may be no loose or "kinked" places throughout the convolutions. The iron part of a small electro-magnet may be a piece of rod iron, eighteen inches long, and an inch and a-half in diameter. It is to be bent so that its two ends may be brought within from two to three inches of each other, in the manner represented in the following engraving. The winding-on of the wire is to be commenced at the top of one end or pole, and to be continued for a depth of four or five inches towards the bend. It may then be wound back towards the top of the pole again, and returned until the lower end is again reached. One side will thus receive a coating of three coils of wire. This may then be passed over to the end of the rod nearest the bend, care being taken to bind the wire on it in the same direction as on the first arm; in fact, just as if the wire had been continuously wound on a straight rod. Now, because the centre point between the two extremities of a magnet does not exhibit externally any magnetic effect, it is unnecessary to wind any wire on it. Indeed, great advantage accrues by "condensing" the wire on the poles of the magnet, or, rather, near to the outer extremities of the iron, by winding extra coils on those parts. It is there that the greatest inductive power is manifested, and where, therefore, the greater effect should be produced. It may here be remarked, that electro-magnets, like ordinary magnets, have their poles at a distance from their extremities; hence the coating of covered wire is never carried to the extreme end of each arm.

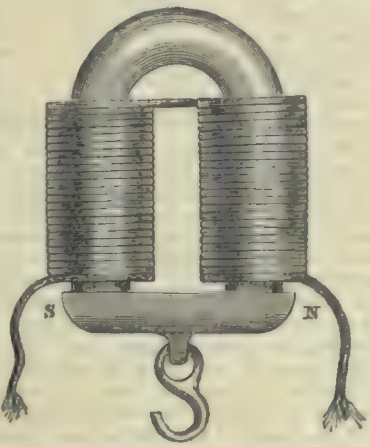
---

* See *ante*, p. 195.

† See *ante*, p. 244.

The following engraving illustrates the appearance of an electro-magnet when complete. Right and left are its poles, N and S. Beneath them is the keeper, to which a hook is attached, and to which heavy weights may be hung. From N and S proceed the two wires, which are to be attached to the wires of a voltaic battery when the electro-magnet is in use; and by means of which the current passes to the coils, round the iron. When very large magnets are made, it is usual to divide the coil into separate portions, and to collect the various ends of the coils together, so as to form one terminal for each end of all the coils. By these means the current of electricity circulates as many times round the iron as there are convolutions of wire placed round it, but has not to travel in one continuous length for the whole distance. By this arrangement the resistance of great lengths of wire is done away with, and yet the full effect of the quantity of the battery power is advantageously employed.* The end wires of the electro-magnet should never be twisted about, as they soon get very brittle; and if the wire be once broken close to the iron, and inside the coil, the magnet becomes useless, and must be recoiled by the wire. It is a good plan to fold some coarse brown paper, or a thin sheet of gutta-percha, on the iron arms before coiling on the covered copper wire, as this prevents contact between the metals, in case the covering is in any part defective. The coils may be bound on wooden cases, and these can then be slipped on to the iron arms of the electro-magnet, and removed when done with. As, however, the thickness of the wood removes the covered wire from the iron, and so increases the distance of the inductive power from its surface, a loss of power necessarily results from this arrangement. The attractive, or holding power of an electro-magnet, depends on its size, and on the strength of the battery employed. Such an arrangement as we have described, although small, will sustain at least one hundredweight, when a current from twenty cells of Smee's, or four to eight cells of Grove's battery, is sent through the wires.

Fig. 12



The largest electro-magnet which we have yet seen, and perhaps the most powerful which has been made, was one which we purchased from the Panopticon, at the public sale of effects, for the Polytechnic Institution in Glasgow. The wire and iron had been made of the purest metal which could be procured, and both were well annealed. The wire was a quarter of an inch thick; and the total quantity employed weighed nearly two hundred weight. The iron, which was of the usual horseshoe form, weighed about half a ton; and each arm was three feet high, and six inches in diameter: the remaining length of the iron rod formed the bend. We have repeatedly employed fifty and 100 cells of Grove's battery as the source of the voltaic current; and, under such circumstances, we have attempted in vain to remove the keeper from the poles by opposing a weight of over three tons. When two hundredweight of iron nails, each of which measured six inches long, and of the usual substance, were cast on the pole, every nail was so powerfully attracted, as that they could scarcely be pulled apart, and could not be pushed away from each other.

But there is a most remarkable fact in reference to all magnets; which is, that the attractive power decreases in a most rapid ratio. In the case of the large magnet we have just described, the attractive force, at three inches from either pole, was very trifling—not exceeding a few ounces. Thus we observe that the decrease in three inches distance from its source, was, beyond all comparison, greater in ratio than that of any other force with which we are acquainted; and this, unfortunately, has to a large extent prevented this agent from being employed as a motive power. In all kinds of magnets, the attractive power is greatest in those which have the longest arms; and this we should naturally expect, from the fact that the force diminishes to nothing as we approach to a point equi-distant between the poles. It is therefore better, in making an electro-magnet, to employ the wire so that it may cover the poles, rather than the whole length of the arms; and the neglect of this in the construction of the large magnet of which we have been speaking, doubtless prevented its maximum of power being obtained.

Electro-Magnetic Engines.—We shall now give a general outline of some of the attempts which have been made to obtain a power for driving machinery, &c., by means of electro-magnets: but before doing so, it is to be remarked, that the best-constructed arrangements have hitherto been complete failures in an engineering and economic point of view. This has arisen from three causes.—1st, the extremely small distance at which the attraction acts, and its rapid ratio of decrease, which we have already discussed; 2nd, the interference of residuary magnetism,† which prevents an instantaneous change in the direction of the attractive power; and, 3rd, the expense of voltaic batteries—not in their first cost, but in maintaining their power. In days such as our own, when inductive and experimental science, together with mechanical skill, are found in so high a degree of perfection, it seems most extraordinary that no success has as yet attended the numerous efforts which have been made to procure it.

When we compare the progress which has been made in steam machinery, with that which has attended that of the electro-magnetic arrangements, we can find no approximation in the latter. The mechanical difficulty results chiefly from the fact, that the rapid diminution of the attractive power of an electro-magnet, does not permit of any of the ordinary appliances for converting force into motion to be used. For instance, the stroke of the piston of the steam-engine may be of any length which the engineer chooses to employ. All he need do is to lengthen the cylinder, or supply the steam—each of which can be effected to any extent which may be desired; and the piston can be driven to and fro, acting on a crank of half its length. Now, in electro-magnetic engines, the greatest direct stroke which can be employed between two electro-magnets, cannot exceed (without the intervention of levers) a quarter to half an inch; and, of course, a crank of half that length, and of the necessary strength, is a physical impossibility in an engineering point of view.

It does not matter in what form the motion is obtained by any of the inventions which have been made, for still the rapid ratio of the decrease of force is constantly active. We fear, that unless some means may be discovered by which this power can be extended in a greater linear or radiating influence from its source, a good and useful engine, driven by electricity, will remain to be sought after.

---

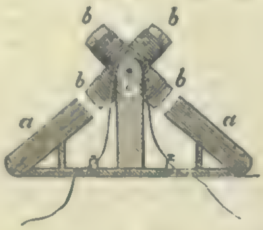
* See *ante*, p. 250.

† See *ante*, p. 249.

Having stated these difficulties, we will now describe some of the engines which the sanguine but disappointed inventors have patented, and brought more or less into public notice. In doing so, we shall not pay any heed to their chronological order, but rather to that of the principles on which they are constructed. We may divide them into two classes—namely, those, 1st, in which the motion is as a tangent in its direction to the lines of force; and, 2nd, such as, like the ordinary power of the steam-engine, have a reciprocating motion. There are other forms, to which we shall also allude in general terms, which claim attention rather for their ingenuity than their value.

Those machines in which motion is obtained in a tangential arrangement of permanent and electro-magnets, have been of numerous forms, according to the ideas of their inventors. The permanent magnets are always stationary; and the electro-magnets are made to revolve so that their poles may be nearly in contact with those of the former kind. The annexed engraving gives a view, in section, of this kind of machine, and shows the relative position of each kind of magnets. The less important parts are omitted, as is also the arrangement, by means of which contact is broken between the electro-magnets and the battery; for such varies so much in form, whilst the principle is the same in every instance.

Fig. 13.



In the above figure, *a a* are two permanent and compound horse-shoe magnets,* which are fixed on a wooden foot; *b b b b* are the four terminals, or poles, of as many electro-magnets, made in the usual manner. The wires of the ends of each electro-magnet are attached to a suitable arrangement, by means of which a current of electricity from a few cells of a voltaic battery is conveyed by them. As each pole of the electro-magnets approaches those of the permanent magnet, the current of electricity, producing magnetism in the soft iron, causes a powerful attraction. As the pole passes a little beyond the centre of the permanent magnet, the supply of electricity is cut off, and the soft iron thus returns to its normal state. Of course, the same happens to each electro-magnet as it approaches either of the permanent magnets, and thus a rapid revolution is produced. Very little power is afforded by this arrangement, which may be taken as a type of its class. In some of these machines a permanent magnet is placed, so as to be opposite each electro-magnet—one during each revolution; and the number of both may be increased to any extent. These may be arranged to revolve on their axis (*c*, in Fig. 13)—as often as from 300 to 500 times per minute; but owing to the attractive force diminishing in so rapid a ratio as each magnet passes on, the motion of the machine may be stopped by the slightest obstacle applied to the arms of the electro-magnets. When machines of this kind are constructed on the large scale, and used for driving lathes, &c., the speed of the driving-wheel, or that which communicates its motion to the machinery, is diminished below that of the electro-magnets by the interposition of variously sized cog-wheels.

The next form of electro-magnet to which we shall direct attention, is that wherein a crank is employed, which is moved by means of levers placed over the electro-magnet, and attached, at their other extremity, to a fulcrum. These machines are generally constructed with two sets of electro-magnets, &c., and the cranks are placed at right angles to each other on the crank-shaft; so that when one is on the dead points, the other may be in full action. This form of machine, like that which we last described, has been the subject of numerous modifications: its type, however, is illustrated in the annexed engraving. In Fig. 14, the general arrangement will be seen of one side of these machines: *a* is the electro-magnet; *b* is a soft iron keeper, attached to the lever *c*—this having a fulcrum at *d*. The lever is attached to the crank at *e*, which is again fixed on an axle of the fly-wheel, *g*, at *f*. The other cranks, &c., are not shown, so as to avoid confusion of detail. When a current of electricity passes round either electro-magnet, the attraction induced draws down the keeper, and so, by means of the lever, produces a rotary motion through the crank fixed on the shaft. As one keeper rises, the other one falls, and thus the general action resembles that of a double-cranked, &c., steam-engine. The contact between the electro-magnet and the battery is broken by means of any form of contact-breaker, attached either to the crank or lever. By means of this form of machine, a greater amount of power is obtained than that produced by the one we last described; but still the result, in an engineering point of view, is comparatively trifling. An effective modification of this kind of electro-magnetic engine—the invention of M. Froment, of Paris—is represented in the following engraving.

Fig. 14.

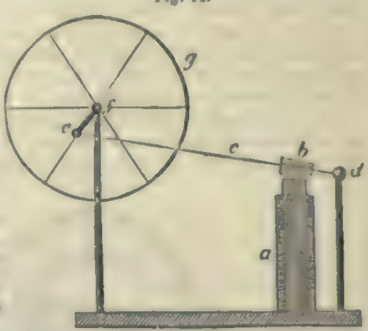


Fig. 15.

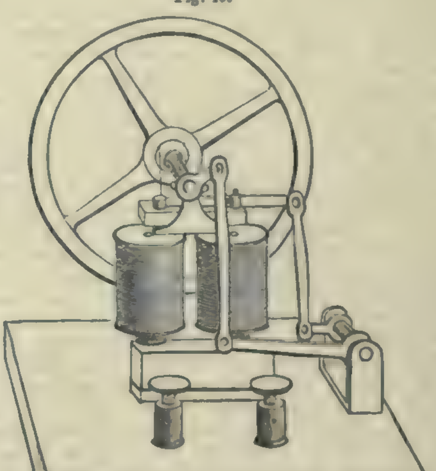

It will be impossible for us to describe the various arrangements which have been proposed by numerous inventors. M. Jacobi, of St. Petersburg, Messrs. Joule, Sturgeon, Davenport, Davidson, and many of the leading electricians and philosophical instrument-makers of this and other countries, have applied an immense amount of theoretical and practical knowledge to the subject. One of the best arrangements we have seen, is that invented by Mr. Allan, of the Adelphi, London; who has devoted himself, with great ardour and success, to the pursuit of every branch of electrical science. He employs a number of circular plates, placed over as many electro-magnets. Through each of these plates a rod runs; at the lower part of which is a pivot. The upper end of the rod is connected to a crank; and a set of plates and electro-magnets are placed vertically over

---

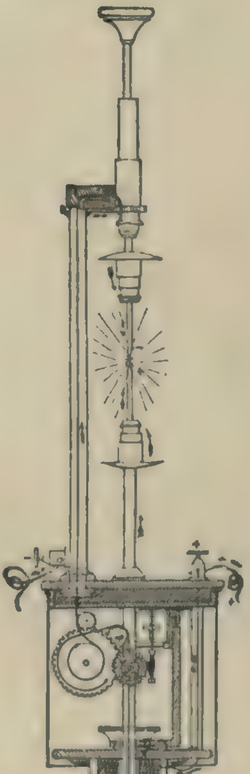

Fig. 3.—Duboscq's Electric Lamp.
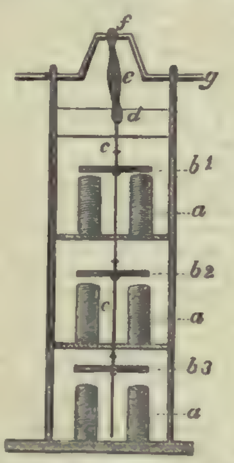
(See pages 139 and 191).

each other. The electric current is successively admitted to each electro-magnet, commencing with the top one. This pulls one plate down, and so moves the crank-shaft a little: each electro-magnet does the same to its super-imposed plate; and so the crank is gradually moved. Five series of these arrangements are placed side by side; and, by their successive action, a rotatory motion of a shaft is produced. Each plate has to move not more than an eighth of an inch, and is, therefore, always in close proximity to the electro-magnet beneath it. As soon as these have done their portion of the work, the current is cut off and directed to the neighbouring series. One of these machines produces a considerable amount of force, and, in our opinion, is a decided improvement on their predecessors. Fig. 16 will give an idea of Mr. Allan's arrangement; but we have only shown one frame out of four or five, which are placed side by side, and connected with one crank-shaft. Mr. Allan also uses five sets of electro-magnets instead of three; at least, so his model, which was deposited in the London Polytechnic, was constructed: *a a a* are three electro-magnets, firmly fixed in a frame; b^1, b^2, and b^3, are three soft iron circular plates, loosely resting on pins, which are fixed on the vertical rod, *c*. It will be observed, that each plate varies in the distance from its electro-magnet. The rod *c* is attracted at *d* to another, *e*, which again is connected with the crank *f*, fixed on the shaft *g*. When a current of electricity is sent round each electro-magnet successively, they attract, one after another, the plates over them, and so, by a succession of pulls, produce a rotary motion. In this, as in every other electro-motive machine, the residual magnetism[*] is a constant source of difficulty; and if a powerful battery be employed, some of the plates become fixed to their subjacent electro-magnets, after the current has been cut off. The mode of breaking contact we have not shown: it is, however, extremely simple—cutting off the current from each electro-magnet with great precision.

Fig. 16.



Having thus endeavoured to acquaint our readers with the principles on which electro-magnetic machines are constructed, we shall dismiss the subject, with an expression of regret, that so little success has, as yet, rewarded the efforts of those who have devoted their attention to it.

Electro-Magnetic Clocks.—Numerous attempts have been made to accommodate clockwork to the arrangements which afford electric and induced magnetic currents. These inventions have, in almost all cases, proved to be failures. Such, however, have not been owing to a fault in the principle, so much as the defects which occurred in the practical details. We need scarcely say that electro-magnetism supplies a power which is constant so long as a voltaic battery gives what we may term the initiative; but it is not simply on the electric current that the success of the clock arrangement depends. There are many other details which interfere; and although minor in their character, their effect is none the less felt. For instance, we will presume the case of a clock of the highest class of manufacture, which has the necessary arrangements for carrying out the purpose to which we have referred; that is, the indication of exact meridional time at any place within reach, by means of conducting wires of an electro-voltaic current. Such an instrument will only afford accurate indications of time so long as the wheel, which is ordinarily connected with the detent of the pendulum, vibrates or passes any fixed point on the clock-face, corresponding to the original whence it first obtained its motive power. Now, this is carried out by means of a wheel, the spokes of which are alternately made of a conductor and non-conductor. A current of electricity is conveyed to the wheel; and from it is stretched a wire, which reaches a similar wheel in a distant clock. Another wire from this or an earth-current arrangement (which we shall describe hereafter) is also employed, so that the current from a battery may circulate completely between the two clocks. Each clock is furnished with an electro-magnet; and as a current passes from one to the other, it simultaneously sets each magnet in action. By so doing, a detent acts on the usual clockwork arrangement, just in a similar manner as is observed in the arrangement of the pendulum and first wheel of the common clock. Now, supposing there are sixty alternate conductors on the wheel of the first or primary clock, it is evident, that as each of these sends a current of electricity to the distant clock, its electro-magnet will be acted on, and its mechanism will be put in motion. Each minute is thus indicated on the clock-face by a movement of the minute-hand, which corresponds with that of the wheel moved by the electro-magnet. It is also evident that any number of clocks may be similarly worked by one primary; and so exact time could be indicated at any station distant from a central point.

This, however, whilst appearing perfectly easy on paper, is a very different affair in practice. It was proposed thus to regulate all the clocks on the railways of the United Kingdom, by an extension of wire from a central clock at Greenwich Observatory. This was, in part, carried into practice at the telegraph station at Charing-cross, London. Like many preceding attempts, however, it failed. In the folio plate, Figs. 1 and 2 will give a general idea of the construction of electro-magnetic clocks. The arrangement of vibrating levers, electro-magnets, detents, toothed-wheels, connecting wires, &c., will easily be understood, in connection with the above remarks. In our future pages, we shall refer to other inventions, which will be better included with the telegraph, the electric time-ball, &c.

SECONDARY INDUCTION—THE COIL MACHINE.

In all the instruments we have hitherto described in connection with electro-magnetism, we have merely noticed the magnetic effect which is produced when a current of electricity is conveyed by a wire. We shall now investigate a different class of phenomena, in which a second current of electricity is induced by the primary current in any wire near to, but not in contact with, that attached to a voltaic battery.

For the purpose of trying the experiments we shall introduce, the reader will require two or three cells of any form of voltaic battery, and a supply of covered copper wire, of two sizes—namely, No. 16 and 22, or a finer gauge; and, to prevent circumlocution, we may here state, that when we employ the term *primary* to a wire, we mean that which *conveys* the current of electricity from the battery; and the *secondary* wire, is that in which a current is *induced* by its proximity to the primary one. Electro-magnetic induction is analogous to that of frictional electricity; but differs from it in one respect—namely, that the two phases of electrical conditions are simultaneously produced by the first inducing cause. Thus, if any glass surface be charged with frictional electricity,[†] its opposite side assumes one opposite electrical state only; but when a wire suffers electro-magnetic, or secondary induction, one of its ends exhibits a positive, and the other a negative electrical state; and, so far, this phenomenon much resembles that of ordinary magnetic induction. There is, however, this peculiarity about that of electro-magnetism—which is, that it is instantaneous in its existence; and occurs, in the secondary wire, only at the moment that contact is made or broken between the ends of the primary wire and the poles of the voltaic battery, which is its source of electricity. The following experiment will introduce the reader to some facts in connection with the subject.

---

[*] See *ante*, pp. 249 and 251.

[†] See *ante*, p. 180.

Experiment 10.—Wind about ten yards of No. 16 gauge covered copper wire on a hollow tube of gutta-percha, or paper, which may be an inch in diameter, and about eight inches long. On this coil wind one of the fine wires above-mentioned, in the same direction, but of a length of thirty or forty feet; and let the ends of each coil be kept separate, and extended about a foot or eighteen inches from the coil. Two coils will thus be formed, one on the other—the primary one being inside, and the secondary, or finer coil, covering it. The two ends of the secondary coil are then to be attached to the terminals of a galvanometer.* If the ends of the *primary* coil are then placed in contact with the plates of a voltaic battery—at the moment they touch, a current will be induced in the secondary wire, which will be evidenced by the deflection of the needle of the galvanometer. This deflection will speedily cease; but if contact between the primary coil and the wire be broken, then the needle of the galvanometer will again deflect; and, as often as these processes are repeated, a current of induced electricity will be produced in the secondary wire, the direction of which will depend on, but be contrary to, that of the primary one.

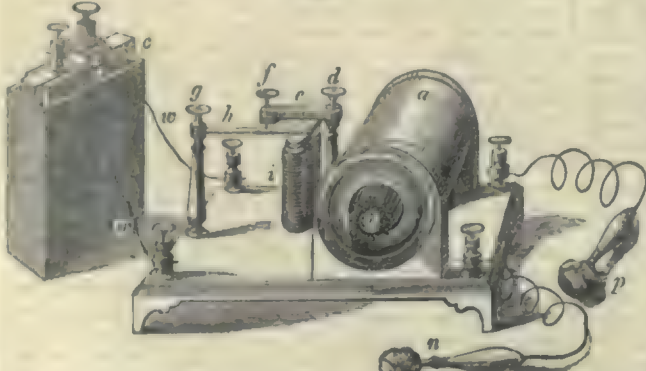
Experiment 11.—If a rod of soft iron be placed inside the hollow cylinder, surrounded by the coils, and the same process be repeated, it will be found that the deflection of the needle in the galvanometer will be much greater, and the iron itself will become magnetic. A double phenomena is thus presented—namely, the induction of a secondary electric current, and also magnetic effects.

It will thus be seen that a current of voltaic electricity, when passing by means of a conducting wire, has the power of producing another current in a conductor lying near it; and this takes place when the two wires are stretched straight, side by side, equally as well as when they are coiled up in the form we have named.

There, however, exists a great advantage in the coil form; which is, that each successive layer or coil of wire increases the intensity of the current produced. Indeed, by extending the length of the secondary coil, most astonishing effects of intense electricity can be produced. In Rhumkorf's coil (which we shall presently describe), a length of two or three miles of wire is used; and all the phenomena of frictional electricity can be procured from it.

Perhaps the most convenient mode of illustrating the various effects of electro-magnetic induction, will be that of explaining the construction, &c., of the coil machine; a common form of which is illustrated in the following engraving.

Fig. 17



The apparatus consists essentially of two parts—the coils and the contact-breaker. In Fig. 17, *a* represents the cylinder on which the primary and secondary coils are wound; *b* is a bundle of iron wires, placed in the centre of the coil; and *n* and *p* are the two terminals of the secondary coil. The primary generally contains about 100 feet of No. 16 gauge covered copper wire; and the secondary has often so much as 300 or 500 feet of No. 22 or 24 wire. One wire of the primary coil is attached to one of the binding-screws, in which a wire, *w*, from the battery *c* is fixed; and the other wires, of both the battery and coil, are in connection with the contact-breaker, which next deserves our attention.

By means of this apparatus, the current proceeding from the battery is suddenly passed to, and cut off from, the primary coil. This is effected by means of a small electro-magnet, *i*: over this is placed, at a small distance, a soft iron keeper, which is connected, by means of a steel spring, *h*, with a brass pillar, *g*. A wire is fixed under the instrument—passing from one of the binding-screws; which holds one of the battery wires. The other end of the primary coil is attached to the pillar, *d*; and from this stretches an arm, *e*; at the end of which is a screw terminating in a metallic point, *f*. The electro-magnet, *i*, however, forms part of the circuit, by means of wires arranged beneath the foot of the instrument. Now, if a current of electricity be made to circulate through the coil by the means we have named, the electro-magnet immediately attracts the keeper placed over it, and, by drawing it down, removes the spring to which it is attached from being in contact with the metallic point terminating the screw, *f*. As the coil and battery are, electrically speaking, only brought into connection when the spring, *h*, and the point, *f*, are in contact—it follows, that the moment they part, the current is at once cut off from the coil. On this happening, the electro-magnet, *i*, loses its magnetism, and, therefore, ceases to attract the keeper over it. The spring, *h*, then acts, and again brings itself in contact with the end of the screw, *f*. The coil is thus again in connection with the battery, and the electro-magnet is magnetised. The previous conditions are repeated; and thus the contact between the battery and the coil may be made and broken with great rapidity.

As we have already stated, a secondary current is induced in the fine coil each time when contact is made and broken between the primary coil and the battery; and as this is easily done 500 times per minute, as many induced currents are simultaneously produced, and a torrent of electricity afforded. There is, however, a great difference between the character of the two currents. That of the primary, which is derived from the battery, has all the characteristics of the voltaic current; whilst that afforded by the secondary coil presents effects precisely similar, in many respects, to the phenomena of frictional electricity; and this identity is developed just in proportion to the length of the coil employed—all other circumstances remaining the same.

In our engraving, the terminals of the fine coil are attached to two handles; and if these be grasped by the hands, previously moistened with salt and water, a most powerful shock may be obtained. If the secondary coil be very long, and the battery attached to the primary be in good action, the effects on the muscles of the arm are so powerful, as to make it impossible for the person receiving the shock to leave hold of the handles; and the pain produced is most excruciating. In fact, considerable caution should be observed in this respect, especially with young persons and females, as serious consequences may result from inadvertence. It is better to place the end wires of the secondary coil in two basins of water, into which persons desirous of receiving a shock can immerse the hands; and from which they, generally speaking, far more quickly withdraw them. Two or more persons can jointly receive the shock by joining hands together. The effect, however, rapidly diminishes as the number is increased; and varies very much according to susceptibility of each individual.

This form of machine is largely used for the purpose of administering electricity in rheumatic, paralytic, and other nervous diseases; in cases of asphyxia, from inhaling carbonic acid gas, drowning, &c. The power of the shock may be regulated by the removal from, or gradual introduction of, the iron rod into the hollow of the cylinder on which the coil is wound; by means of which the magnetic effects of induction are lessened or increased. Another plan, having the same result, is that of interposing a column of water between one of the wires of the secondary coil and the handle; for as the liquid conducts to a much less extent than the metal, the intensity of the shock received is readily proportioned, by the length of the liquid column, to the condition of the patient.

---

* See *ante*, p. 193.

If one of the wires of the secondary coil be attached to a file, and the other be drawn quickly over its surface, bright sparks will be produced; and if the ends of the wires are immersed in acid water, or a solution of sulphate of copper, decomposition of the liquid ensues. But both the chemical and luminous effects of the secondary current are very feeble; its characteristics being great intensity and the absence of quantity.*

We have confined our description to one form of the coil machine; but may observe, that they are made in various ways by the instrument-makers, both as to the arrangement of the coil itself, and the other parts of which it is composed. We shall now proceed to describe a most valuable modification of this instrument, which has been invented by M. Rhumkorf, and by whose name it is generally known in scientific circles.

RHUMKORF'S COIL.

PERHAPS one of the most interesting instruments which have been introduced to the notice of the experimental philosopher during the present century, is the coil constructed by M. Rhumkorf, of Paris, and improved lately by many eminent electricians. It has afforded us a complete connecting link between frictional and voltaic electricity, and so has removed many difficulties which had previously existed between those two branches of electrical science, in respect to their general laws and facts.

The description we have already given of the ordinary coil machine, will prevent the necessity of describing some portions of M. Rhumkorf's instrument. It has a primary and secondary coil, and a contact-breaker, which, however, is of a peculiar construction. The principal points of difference between the two machines are, that the Rhumkorf coil has a very great length of secondary wire, extending to many thousand feet—it being of extreme fineness; and also a "condenser," which is not found in the common instrument.

Each layer of the secondary coil is insulated from its neighbour by a thin sheet of gutta-percha, or other non-conducting material. This prevents a great loss of intense electricity, which otherwise would occur. The condenser consists of a large sheet of tinfoil, enclosed in sheets of oiled silk. It is attached to the primary coil; and has the effect of increasing the intense effects of the secondary coil, by modifying the quantitive nature of the primary one.

At one end of the instrument two glass upright pillars are placed; into the top of each of these the terminals of the secondary coil are fixed. From these, wires may be extended, which can be connected with any apparatus to be employed in the course of experiments.

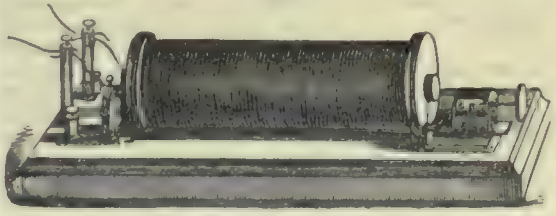
We may remark, that in all our experiments with Rhumkorf's coil, or its modification, the greatest effect has been obtained when the contact-breaker has been so regulated as to give a minimum of currents per minute. We have previously remarked, that it requires an appreciable interval of time to render a rod of iron magnetic by means of the voltaic current;† and in the coil of which we are speaking, another element must be considered; which is, the great length of the secondary coil, and the resistance which it may afford to induction, &c.

Four cells of Grove's battery, with platinas, each exposing an active surface of sixteen square inches, afford, so far as we have seen, the best effects with the instrument. Care must be taken not to use too great a battery power, lest the primary coil be heated. This frequently occurs if a large battery be employed with the coil already described;‡ and it would certainly injure a Rhumkorf arrangement, and perhaps render it useless. In the ordinary coil, the battery is directly connected with it; but in M. Rhumkorf's apparatus, a commutator is provided, by means of which the current can be turned on and off as required, or be reversed in its direction, which is frequently necessary in some experiments. Another advantage is secured, which is of no mean importance. As the handle of the commutator is insulated from the battery and coil, the experimenter runs no risk of receiving any shock. Those who have accidentally received one from a Rhumkorf, will not easily forget its effects. The writer was twice unfortunate in this respect, and suffered for some days after their occurrence. The outside of the coil is as highly charged as the terminals; and long sparks may be obtained from it, just as may be taken from the conductor of an electrical machine. If a wire proceeding from the outer extremity of the secondary coil, or from its external surface, should happen to fall on the table on which the instrument may be standing, a powerful shock is often experienced if the operator touch any part: indeed, it is impossible for us to urge too strongly, that the greatest care be observed in handling the instrument, or in avoiding neglect with respect to the management of the wires proceeding from it.

Since the first introduction of the Rhumkorf coil, it has undergone numerous modifications, which have consisted in the extension of the condenser, improved insulation of the coils, &c. A spark of half an inch in length was considered a great achievement; but we lately observed in a periodical, that M. Rhumkorf had succeeded in obtaining one seventeen inches long, between the terminals of the secondary coil.

Having thus explained the construction of M. Rhumkorf's coil, and of its modifications, we may suggest a few experiments, which will illustrate some of its peculiar powers; and for this purpose we shall choose such as will show how far it connects the phenomena respectively afforded by frictional and voltaic electricity. The following engraving represents a Rhumkorf of the form usually sold at the instrument-makers.

Fig. 18.



Experiment 12.—Having attached the wires of the battery to the coil at the proper binding-screws, fix, in the two pillars holding the terminal wires of the secondary coil, a platina wire in each, so that their two points may be within ⅜ths of an inch of each other; turn on the commutator, and a constant stream of purple-coloured fire will be produced between the two points.

Experiment 13.—It will be noticed that one wire will become red-hot, whilst the other remains comparatively cool. But reverse the direction of the commutator, and immediately the effects of heat will also be changed—that wire which had been previously cool, becoming heated.

Experiment 14.—Separate the two wires to a distance of an inch from each other; taking care, however, in this, as in all other experiments, that the current from the battery has first been turned off. On again turning-on the primary current, no sparks will pass between the secondary wires; but if the flame of a spirit-lamp be placed so that each wire may enter, then the spark will at once dart through the heated air, although it will not through the atmosphere in its ordinary state.

---

* See *ante*, p. 251.

† See *ante*, p. 249.

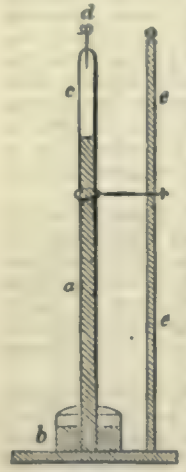
‡ See *ante*, p. 254; Fig. 17.

Experiment 15.—Employ the apparatus used for sending the electric spark in a vacuum, described under the section of Electricity[*]—attaching the outer wire of the secondary coil to the ring of the rod, and the inner wire to the metal plate of the pump. A rich purple-coloured flame will pass, which, however, will depend for its length and beauty on the degree of exhaustion of the air in the receiver. If a good vacuum be maintained, then the flame will be of a most delicate purple or violet tint. If air be slowly admitted, the colour of the flame becomes gradually redder, and, eventually, a red wire-like spark will be produced.

We have repeatedly tried, at the same time, this experiment with the Rhumkorf, and a similar one with the large hydro-electric machine at the London Polytechnic; and the vacuum being equal, the effect in each receiver was precisely the same.

In 1855 and 1856, being engaged in a series of experiments with Rhumkorf's arrangement, we found the barometer tube of great service, as affording a complete vacuum; but, for this purpose, a platina wire must be soldered into the top of the tube before it is filled with mercury. This arrangement has already been referred to:[†] when it is used with the Rhumkorf, the outer wire of the secondary coil is to be attached, by means of a fine wire, to *d*, the platina wire; and the inner wire of the coil is to be dipped into the mercury of the cistern *b*. On passing the secondary current through the vacuum *c*, a beautiful lavender-coloured flame is produced.

Fig. 19.



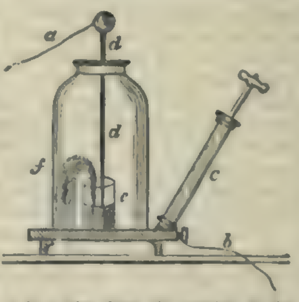
a is the glass tube, containing the column of mercury; *b*, the cistern of that metal; *c*, the vacuum; *d*, the platinum wire; and *e e*, a ring-stand to support the tube in a vertical position.

Experiment 16.—Amongst other results obtained, were many curious appearances, produced by passing small portions of the vapour of ether, bisulphide of carbon, &c., into the vacuum of either the air-pump or the barometrical arrangement. This is easily effected in the former by loosening the screw which admits air into the receiver, and holding against it a little cotton wool moistened with the liquid. The air must be again exhausted; the current may then be passed, when the diffused vapour left in the receiver will at once affect the normal colours of the discharge. Bisulphide of carbon is generally at once decomposed—a bright flash of flame being produced at first; after which sulphur is deposited on the surface of the receiver. Ether, naphtha, &c., produce a flame of a greyish-lavender tint. Some very interesting effects are also produced by passing the spark through rarefied atmospheres of hydrogen, carbonic acid, &c.

In trying these experiments, it will be noticed, that one pole presents a beautiful blue spangle of flame; whilst the other is of a red hue—the position of these appearances being altered on a reversal of the primary current being effected by means of the commutator; and we may add, that the appearances undergo constant variation as the vacuum of the receiver varies. We have met with few air-pumps which have been so well constructed as to permit of maintaining a sufficiently good vacuum for any length of time; indeed, to a practised eye, the colour of the discharge in vacuo we have been describing, is as good an indicator of the extent of exhaustion as is the barometric column.

A very pretty mode of exhibiting these results, is that of placing inside the receiver a small glass vessel, the inside of which has been partly lined with tinfoil. All the arrangements are to be carried out in a similar manner to those already described, with the exception that the conducting-rod fitting into the top of the receiver, is forced down so that its lower part may rest inside of the small coated jar, and with its end touching the coating. (See Fig. 20). A spark passed in such a manner, produces a fine cascade of flame, which presents a singularly beautiful appearance. We are indebted to Mr. Gassiot for this interesting mode of carrying out the experiment. Tables, and vessels of various shapes and materials, are sold by the instrument-makers, for the purpose of exhibiting these luminous effects in a variety of ways.

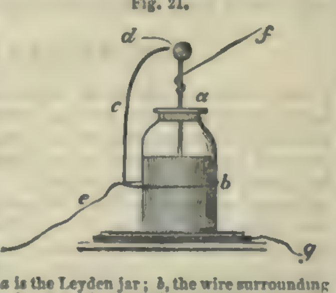
Fig. 20.



a is a wire from the outside of the secondary coil; *b*, a wire from the inside of the coil; *c*, the air-pump; *d d*, a brass rod fitting air-tight in the receiver, and resting on the coating of the jar *e*; *e*, the semi-coated jar, out of which the cascade of flame proceeds to the plate of the pump.

A Leyden jar may be easily charged and discharged, by attaching it to a Rhumkorf. For this purpose, a stout wire should be twisted round the outside coating of a jar; and one of its ends is to be bent up so as to be nearly in contact with the knob of the inside of the jar. The outside of the jar is to be attached by a wire to the inside of the coil, and the outside of the coil to the rod rising from the inside of the jar. (See Fig. 21). The latter is to be insulated by placing it on a sheet of glass, gutta-percha, or other non-conducting material. On passing the battery current through the primary coil, a series of brilliant discharges will take place from the secondary coil, between the knob of the jar and the external wire: these are attended with a loud snapping noise, and are repeated incessantly.

Fig. 21.



a is the Leyden jar; *b*, the wire surrounding it; *c*, a wire reaching nearly to the knob of the jar, but does not touch it; *d* is the interval between which the spark passes; *e*, the wire attached to the inside of the secondary coil; *f*, the wire attached to the outside of the coil; *g*, a gutta-percha plate, on which the jar rests.

Experiment 17.—If a card, or a few folds of paper, be interposed between the knob and the wire, they will be instantly perforated; and a thin sheet may be easily inflamed. A little naphtha, ether, or spirits of wine, if poured on to the knob of the jar, may also be readily ignited.

Many of the leading experiments of frictional electricity may be repeated by means of the Rhumkorf coil; amongst which are the following.

Experiment 18.—Suspend two pith balls, by means of a silk thread, from a glass tube, and attach to the top of the thread the wire from the outer end of the coil: the pith balls will at once diverge, owing to the charge of intense electricity—just as may be observed when a pair of pith balls are hung on the conductor of the ordinary electrical machine.

Experiment 19.—Hold a pith ball, suspended from a well-dried glass tube by means of a silk thread, near to the outside of the coil, in any part of its surface. The ball will be attracted to it, as if it were a charged conductor; and if a metallic ball, attached to a chain or wire, be also presented, sparks may be readily obtained from the coil. In trying this experiment, some risk occurs of injuring the silk covering of the wire of the secondary coil. In connection with the experiment, we may mention, that, in very dry weather, sparks often dart from the outside of the secondary coil, to the wires in different parts of the instrument; and a powerful shock can be obtained from that part as easily as from the terminal wires or poles. The reader will perceive, that in this fact exists another analogy between the electricity produced by a Rhumkorf's coil and that by friction.

Most of the other class. experiments exhibited in connection with frictional electricity, may be performed similarly by means of the Rhumkorf coil; and we shall leave the choice of such to those of our readers who may feel disposed to try them—referring them to those we have mentioned under the head of Frictional Electricity.

---

[*] See *ante*, p. 173; Fig. 6.

[†] See *ante*, p. 174.

We may here make a remark on some peculiarities in reference to the appearance, &c., of the spark produced on charging a Leyden jar by means of a Rhumkorf coil. The brilliancy of the spark, and the noise of the discharge, are affected by the size of the jar, to some extent, but in no comparison to that witnessed when frictional electricity is employed. We have charged, successively, twelve Leyden jars, each 28 inches high, and 50 inches in circumference, by the hydro-electric machine* and a Rhumkorf coil. The noise produced by the discharge of the jars, as excited by the machine, was truly deafening; whilst that of the Rhumkorf discharge scarcely exceeded a sharp rapping sound. Of course, the discharges and charges of the Rhumkorf are produced continuously and successively, at a very rapid rate—at least 200 per minute; whilst the machine charge did not exceed two in number during that time. We have also remarked, that the larger the jar charged by a Rhumkorf, the shorter is the length of the spark; but its lateral extension is, at the same time, increased. Its mechanical and calorific effects, however, do not seem to at all increase with the size of the jars; for a half-pint jar will perforate about the same thickness of card as the large battery we have just named.

Numerous experiments, analogous to those included under the head of Voltaic Electricity, may be repeated, but on a very small scale with a Rhumkorf. We have only succeeded in obtaining a most minute but brilliant spark from carbon terminals—similar to that produced by charcoal points, forming the poles of a powerful voltaic battery. We have rendered soft iron electro-magnets attractive by the coil current; and feeble, but decided decomposition of water, or of a solution of sulphate of copper, may be produced. In this experiment we employed two pieces of platina wire as the poles of the secondary coil. In repeating experiments of this kind, the ordinary voltaic apparatus, like the frictional, may be generally employed; but, as we have already remarked, care must be taken that the experimenter shall not receive an accidental shock.

As there are some interesting particulars attached, generally speaking, to the physiological effects of electricity, which are especially attractive to the general reader, we will make a few observations on the subject. The shock produced by frictional electricity has a sudden and, of course, transitory effect; because, the instant the jar is discharged through the body of the person, the effect can only be repeated by a fresh-charged jar. The shock from a voltaic battery, of high power, acts continuously on the muscles so long as the hands are in contact with the conducting wires; and if from 100 cells of Grove's battery, the effect is very painful. The ordinary coil machine acts in a similar manner; but being more intense, the effect is still more powerful. The physiological effects produced by the Rhumkorf coil, are, of course, far greater. The writer accidentally received a shock by the wire from the outer end of the coil falling on his chest. The sensation experienced was such as to create the idea that the whole of his body was a mass of light: no pain was felt; for the shock was so powerful as to produce almost instantaneous insensibility. After recovery, the digestive organs were considerably disordered for several days, and great languor and sickness were felt for some hours.

The best mode of receiving the shock from a Rhumkorf, is to immerse two wires proceeding from the terminals of the secondary coil, in separate basins filled with river or spring-water. The hands can be dipped in these; and the force of the shock is much diminished by the inferior conducting power of the liquid.

In reference to further comparisons, or analogies, between the effects generally produced by frictional and voltaic electricity, and those afforded by Rhumkorf's coil, we have already remarked that the latter affords a kind of link for the two former; and it may be useful to the student if we enter into further details.

The voltaic spark is continuous after being once produced (within certain limits); whilst that of the electrical machine is intermittent. The spark of the Rhumkorf holds a middle place. Again, the spark of the machine exhibits but trifling heating effects; whilst that of the voltaic battery affords us a greater amount of heat than any other source with which we are acquainted. Now, the two terminals of the secondary coil of a Rhumkorf exhibit very different results. One is always intensely heated, whilst the other remains comparatively cool.† A voltaic battery, unless of enormous size as to the number of its plates, rarely exhibits decided attractive power on pith balls, or on the electroscope. The Rhumkorf effects this result with ease, in a manner similar to the electrical machine. The latter but feebly produces chemical decomposition, as is the case with the Rhumkorf; which, however, depends for its action on the chemical decomposition going on in the battery, whence it obtains its primary current.

The electrical machine, even when of the largest size, affects but slightly any piece of iron or steel, in respect to the magnetic force; whilst the voltaic battery affords us a means of inducing magnetism to almost any extent we please. The Rhumkorf holds an intermediate position in this respect; and in this and many other results which our space prevents us enumerating, we may consider this coil as the connecting tie between the various phenomena and sources of electrical excitation and its effects; and as clearing away many difficulties which have hitherto stood in the way of their complete generalisation.

CHAPTER III.

MAGNETO-ELECTRIC INDUCTION.

We have considered it better to draw the attention of our readers to the production of magnetic effects by electric currents, before entering into the discussion of magneto-electric induction, because the apparatus employed, and the phenomena manifested, will be more readily understood by the perusal of our previous remarks. Hitherto, we have been drawing attention to the fact, that currents of great quantity, such as are produced by the voltaic battery, have, under certain conditions, the power of inducing magnetic force. We shall now show that magnetism can, by certain arrangements, produce all the calorific, luminous, chemical, and physiological results which may be obtained from the voltaic battery, the electrical machine, or Rhumkorf's coil.

Magnetism and electricity have a mutual action on each other. We noticed this when experimenting with a spiral, at the end of which a voltaic battery was placed, and to which a horse-shoe magnet was presented.‡ The electrified spiral exhibits magnetic effects just so long as the current from the battery passes by it; and such effects are exactly identical with those possessed by any kind of magnetised body. We have shown, that if a current of electricity be passed, by means of a wire, round a rod of iron, the latter at once exhibits magnetic properties; and, further, that these are only produced when the current passes in a certain direction.§ We shall now describe how, by using a similar kind of apparatus, magnetism may induce an electric current. In this experiment, as in that to which we have alluded, we shall find that the effects of the forces are produced at right angles to the direction of each.

---

* See *ante*, p. 179.

† See *ante*, p. 255.

‡ *Ante*, p. 248.

§ *Ante*, p. 249.

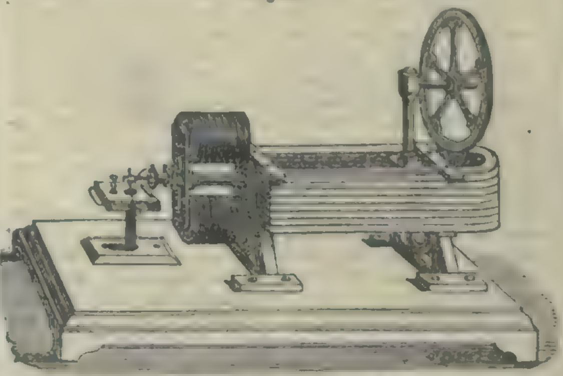
Experiment 20.—Coil about one hundred feet of No. 22 or 24 covered copper wire, round a paper or gutta-percha tube, ten inches long, and one inch in diameter; and attach its two terminals to the binding-screws of a galvanometer.* Then introduce one end of a rod, or bar magnet, suddenly; and at the moment this is done, it will be noticed that the needle of the galvanometer diverges. It will, however, speedily regain its old position. If the magnet be now suddenly withdrawn from the coil, the needle will immediately diverge in an opposite direction to that which it previously took.

This experiment shows that a current of electricity is immediately induced in the wire by the magnet, on its introduction into, and withdrawal from, the coil; and, further, that the effects are produced only when these movements take place; for no result follows if the magnet be kept permanently in the coil after its introduction is effected. This is highly analogous to the phenomena of secondary electro-induction, for we notice that the current was produced in the secondary coil, only when contact was made and broken. This fact, which was first discovered by Dr. Faraday, is of the most interesting kind; it establishes a chain of analogies between each branch of electrical science, and that of magnetism; it opens out a wide field for the exercise of inductive generalisation, and establishes a definite connection between the causes which tend to produce all the varieties of electric and magnetic disturbances, and other phenomena, whether as witnessed in our laboratories, or in the more magnificent and boundless one of nature.

The experiment which we have named will be a sufficient introduction to our subject, inasmuch as the student can easily repeat it, and personally ascertain the results we have called attention to. We shall, therefore, proceed to describe the best forms of magneto-electric machines, such as are employed at the present day. The simplest of the kind is that sold at the instrument-makers, as an American invention, for the purpose of giving shocks. It consists of a single horse-shoe permanent magnet; opposite to which are two small rods of iron, which revolve close to the poles of the magnet—being turned on their axis by the ordinary multiplying-wheel arrangement. In this instrument the magnet is not inserted in the coils, but the iron in them becomes magnetic by induction, as it passes either pole of the magnet. If these rods, or armatures, as they are called, were made of steel, they would become permanently magnetic; but being of soft iron, they instantly lose their magnetism on getting beyond the range of induction; and their rapid revolution and consequent successive appearance before, and on leaving the permanent magnet, answer exactly the same purpose as that of inserting and removing the bar magnet, as explained in our elementary experiment. These armatures are covered with a great length of fine covered copper wire, which is coiled in a similar manner to that we have already described in connection with various electro-magnetic instruments. Two sets of armatures are provided in large machines; one being of thick wire, for the purpose of producing the effects of quantity (light and heat)—the finer being employed for various effects of intensity, such as giving of shocks, &c. The ends of these wires are attached to a contact-breaker, which consists of alternate pieces of wood and brass, against which two springs rest. From these springs the two wires proceed, ended by binding-screws; and the various experiments are conducted by means of other wires attached to these screws.

The larger kinds of these machines have had chiefly two forms; in one of which the armatures revolve at the ends, and, in the other, at the face of the poles of the magnet; and, in such, the magnet consists of a number of the horse-shoe kind, forming a compound arrangement of great power. The following engraving illustrates the appearance of one of these instruments.

Fig. 22.



The power of these machines depends on the size and number of the magnets; the distance of the armatures from them; the length and thickness of the wire wound on the armatures; and the rapidity with which these are made to revolve in face of the magnets. The form of instrument used for the purposes of electro-plating has been already illustrated and described;† and as its several parts are the same, in principle, in all instruments, although they vary in form, we shall refer our readers to what we have already stated on this part of the subject.

Mr. Holmes, who has been very successful in applying magneto-electricity for the purpose of obtaining the electric light, uses a very different arrangement to any we have described. His armatures are fixed with their coils on a cylinder; over these the magnets are made to revolve face to face; and they are driven by steam power. The appearance of his machine is represented in the folio plate. It has been engraved to illustrated one which was shown in operation at the International Exhibition of 1862. To the left of the cut an ordinary electric lamp is seen; and on the right, a polyzonal lens, such as was employed for some time at the South Foreland lighthouse, with one of these engines, in place of the ordinary oil lamps, which it far exceeded, in the clearness and brilliancy of its illuminating power.

It will be unnecessary for us to suggest any experiments with the magneto-electric machine. It will be sufficient for us to state, that all those we have mentioned under the head of Voltaic Electricity, Electro-Metallurgy, and Electro-Magnetism, may be as readily performed by it as by voltaic batteries; the success and brilliancy of course depending on the size of the instrument. Its chief use, at the present time, is for electro-plating, &c.; medical purposes; and, to a limited extent, as a substitute for the voltaic battery in electro-telegraphy. This application we shall enter into in our next chapter.

As a philosophical instrument, the magneto-electric machine is of great interest: in its commercial application, it is also of great value; for as nothing but motion is required to put it into action, all the expenses and annoyance of liquids, &c., used in exciting voltaic batteries, are obviated.

HOLMES' MAGNETO-ELECTRIC LIGHT APPARATUS.

CHAPTER IV.

THE ELECTRIC TELEGRAPH.

Having explained the chief laws and facts in connection with magnetism and electro-magnetism, together with the lesser branch of magneto-electricity, we shall now lay before our readers an exposition of the principles of Electro-Telegraphy, and include a description of some of the instruments which have been most generally adopted, in different countries, for telegraphic purposes.

It will be only necessary for us here to call the attention of our readers to the remarks, experiments, and illustrations which we have already made in connection with this interesting subject. We before stated, that we presume the student to have mastered the various facts on which we have treated. This will prevent unnecessary repetition on our part, and will save both time and trouble to our readers.

The earlier modes of telegraphy were of the simplest description. Fires lit on the tops of high hills, at different stations, served, by means of preconcerted signals, to convey intelligence of any event to a great distance. In more modern times, the semaphore answered a similar purpose; and even birds—as the carrier-pigeon—were employed to carry messages between correspondents. There is scarcely a doubt that our railway system has been the chief means of perfecting the present mode of telegraphy. Without it, it would be impossible that we could attain that regularity and high speed, combined with safety, which are the characteristics of railway travelling and conveyance at the present time. In fact, the discovery of Oersted laid dormant for nearly twenty years before it was used in its present application; and we are indebted to Messrs. Cooke and Wheatstone for the perfection to which our telegraphic system has arrived.

We shall not attempt to give any historical details of the subject, as our pages are intended chiefly to convey and explain facts and laws, rather than to uphold the views, opinions, and interests of those persons to whose ingenuity we owe so great a debt. Hence, we shall only introduce their names and inventions as may best suit our plan, leaving our readers to consult other works which are specially devoted to the subject, and its numerous and minute details. We shall commence with the needle telegraph—that being the most common form of the instrument employed in this country; and, afterwards, shall proceed to describe other arrangements which are in use on the continent and in America.

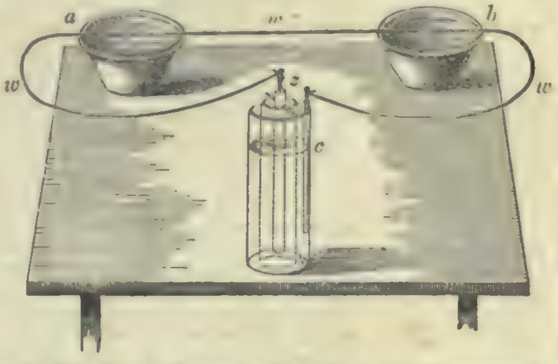
We have shown,* that when a current of voltaic electricity is passed, by means of a conducting wire, over and parallel to a magnetic needle, the latter is diverged right or left of its meridional plane, according to the direction of the current; and we also have seen, that that direction may readily be reversed, or, regulated, by the most simple means. But whilst our readers will easily understand the experiment and engraving which illustrated our remarks, they may not be able to understand how the divergence of the needle, and the consequent transmission of a message, is effected, when the station to which it is sent is at a distance from the source of power; and, further, they will also have a difficulty in finding out, how these divergences can be so managed as to indicate the wishes or instructions which they are intended to convey. It will be our business, therefore, to explain both these points; and we shall thus, we hope, in a clear and simple manner, remove all mystery in reference to this most interesting subject.

1. The Conveyance of a Message.—The first thing required for conveying a message between any two stations, is a sufficient conducting medium, by means of which the current of electricity can pass, so as to effect a divergence of a needle, at a distant station which shall agree with that produced at the place from which the signal was sent. We cannot adopt a better plan to explain the principle than that of an experiment; and shall therefore introduce a plan of illustration which we have generally used, and which may be easily arranged by the student.

Experiment 21.—Place, at the ends of a table, a basin of water, and on the surface of the liquid of each, float a magnetised sewing-needle.† Over, and parallel to the needles, place a copper wire; and, at either end of the table, have ready a small voltaic battery of any sort in action. Bring the ends of the wire close to the battery. Now, so long as no current of electricity passes, the needles will maintain their polarity, and suffer no divergence. But if the ends of the wire are connected with the zinc and copper of the battery, then a current of electricity will pass from the copper plate, by the wire, over the needles, and back to the zinc; and, during its passage, the needles will *simultaneously* be diverged from their previous direction, according to that of the current, in a manner we have already explained.‡

Now, it matters not how long the conducting wire may be. For instance, the experiment may be tried with one basin and needle, at one end of a garden, with the other at any other place; or from room to room in the house. In its passage, the wire may be twisted, or fastened, in any part, so that it be continuous throughout its length; because no mechanical action, like drawing or pulling the wire, is required. All that is wanted is, that the wire shall be of sufficient size to conduct the current freely, and that the current itself shall be sufficiently powerful to traverse the entire length of the conductor. The mode of carrying out this experiment is illustrated in the following engraving.

Fig. 23.



In Fig. 23, we observe each part of the arrangement. The vessels *a* and *b* have, floating on the water, each a magnetised sewing-needle. Over these, and parallel, are portions of the wire, *w w w*, the ends of which are connected with the zinc *z*, and the copper *c*, of a single cell of a Daniell's battery.§ Any other form of battery, or even a slip of zinc and one of copper,|| will answer equally as well.

After having thus noticed the simultaneous divergence of the two needles in one direction, they should then be allowed to come to rest—first removing the wires from the battery, so as to stop the passage of the electric current, or the divergence of the needles would be maintained. The wires should then be changed as to their connection with the plates of the battery. That which had been previously in contact with the copper should be applied to the zinc, and *vice versâ*. On this being completed, the

---

† *Ante*, p. 241.

‡ *Ante*, p. 247; Fig. 3.

§ *Ante*, p. 188; Fig. 40.

|| *Ante*, p. 186; Fig. 37.

needles will instantly diverge in a direction contrary to that which they had previously done.

We may sum up, as follows, the facts taught us by the last experiment, and those to which we have also referred in our previous pages: for we learn—

1st. That an electric current diverges a magnetic needle, under certain conditions.

2nd. That the direction of the divergence depends on the direction of the electric current.

3rd. That these results can be obtained at any distance in two instruments, providing a sufficient conductor intervenes between them.

4th. That the divergence occurs at the same moment (in almost every instance) in each instrument. Practically, there is scarcely any exception to this rule in land telegraphs; and its occurrence in submarine telegraphs will be duly noticed.

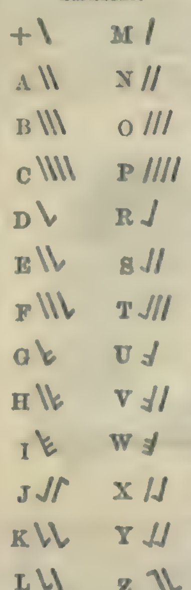
Having thus established the principle on which a message may be conveyed, we shall now explain how the divergence of the needle is used as a means of indicating the message sent by the wires. For the sake of simplicity, we shall omit all other considerations as to mode of conducting, obstacles, earth currents, &c., &c., until we have made the second question clear to our readers.

2. **The Decipherment of the Message.**—We stated that there are only two divergences from which the message can be read, if one needle alone be used at each station; and, for the present, we shall confine ourselves to the examination of the single needle arrangement. It is obvious, however, that even with the deflections of one needle, numerous signals may be transmitted between any two stations, if such deflections are taken singly or together.

The following diagram illustrates the code which has long been established; and which, although at first sight it may present some difficulty to the uninitiated, is, after all, very simple in its construction. The lines indicate the direction in which each divergence of the needle takes place; and the letters next them are those represented by the deflection. The small lines, in some signals, indicate that a combination of deflections, in different directions, is used. Thus, two to the left represent the letter A; whilst one to the left and one to the right \ represent the letter D; and so on. For the annexed, and some of our future illustrations, we are indebted to Mr. Shaffner's work on the Electric Telegraph.

It is thus evident that this combination of deflections may be employed to spell out any message which may be required to be sent from one station to the other. It is true that such a simple arrangement as we have described in our previous pages,* would be quite unfit for this purpose; because, the needle, after having been once deflected, would require a length of time before gaining its primary polar position. At the same time, our readers may easily try to effect the deflections in a leisurely manner, and so gain a practical knowledge of the working of the more perfect kind of instruments, which we shall presently describe.

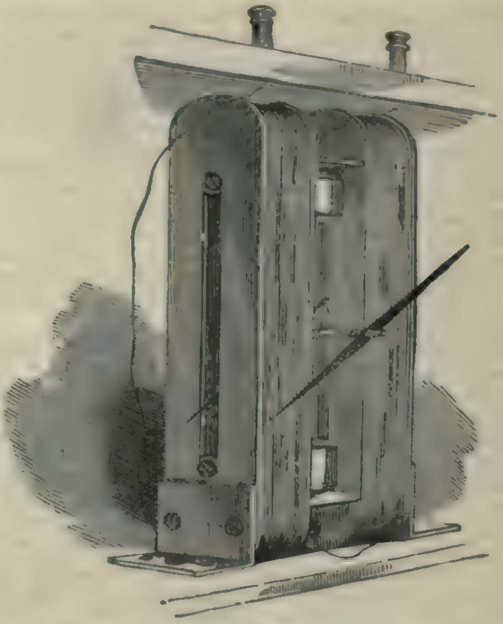
THE SINGLE NEEDLE ALPHABET.



We have gone so far as to show, that a message, or a series of signals, may be transmitted, by means of a conducting wire, from one place to another; and that such signs may, by a preconcerted arrangement of signals, be subsequently deciphered, and rendered available for telegraphic purposes; the deflections of the needle, in any specified direction, being employed for that purpose. We shall now advance another step, and explain the instruments which are actually used; commencing with the single needle telegraph, and afterwards describing the double needle, which is most generally adopted throughout Great Britain.

Instead of a needle floating on the surface of a liquid, one is suspended on pivots in a suitable frame; and, over this, wire is coiled, so as that each convolution may be parallel, and in as close proximity as possible, to the magnetised needle, in the manner illustrated in the following engraving.

Fig. 24.

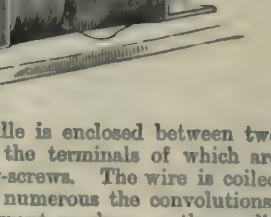


In the above cut, the needle is enclosed between two coils of fine covered wire, the terminals of which are connected with two binding-screws. The wire is coiled on a frame; and the more numerous the convolutions, the greater effect will the current produce on the needle itself. The reason of this we have already explained when we described the arrangement of the ordinary electro-magnet.†

The external needle is simply an index, which oscillates to and fro before a card on which the symbols or deflections are represented; and thus the person watching the instrument can at once see the deflections of the needle, and the code of signals which he has to follow.

As we are anxious to make our readers practically acquainted with the working of the telegraph, we shall suggest the construction of a model, which, for a trifling expense, will enable them to actually practise the telegraphic code. The following engraving illustrates a simple instrument, which we have often used for public illustrations of this subject. It consists of an upright board, on which is fixed a small coil of covered copper wire, to the ends of which are attached two binding-screws, at the foot of the instrument. Inside the coil a magnetised steel needle is suspended on pivots, so that it may freely move right or left. It should be hung a little out of its centre, so that the lower part may, by its weight, restore the needle to a perpendicular position after a signal has been sent, and the current withdrawn. Two of these instruments are required; and they can be made at an expense of three or four shillings each.

Fig. 25.



A wire must be attached to one of the binding-screws of one instrument, and be extended to that of the other; and a wire from each instrument is to be brought to the battery, which may be a single cell of any kind.

---

* See *ante*, p. 259.

† See *ante*, p. 250.

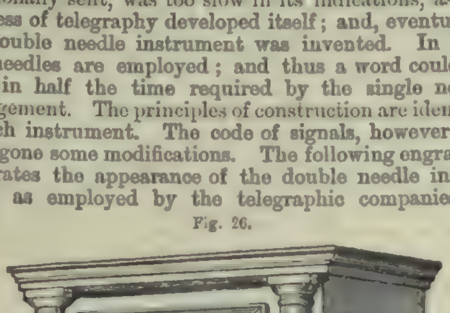
The connection of the wires is precisely similar to that illustrated in the arrangement shown in a previous page.* The ends of the wire proceeding from the coil, may be immersed in two cups containing a little mercury; and the battery wires being held in the hand, they can be dipped in either cup, so as to send the current in any direction that may be desired. Now, by this arrangement, the needles of each instrument can be simultaneously deflected; and if the code of signals already given be pasted on either side of the coils of each model, a complete single telegraph arrangement will be produced.

If one instrument be placed in any part of a house, and the battery and the other model be placed in another apartment, and two wires be extended between them, telegraphic signals can be just as easily transmitted, as is done, in the usual way, by the ordinary telegraphic arrangements; and our readers will learn more practical knowledge of the subject in half-an-hour, than a perusal of works on telegraphy can possibly afford them.

Many persons are much surprised and puzzled at the extraordinary rapidity with which the signals are read by the persons in charge of the telegraphic instruments at a station. We may, however, easily illustrate the readiness thus exhibited, by reminding our readers, that any musical instrument is rapidly performed on, solely from continued practice of the musician. He has had at first to learn the notes—a slow and laborious process: eventually, however, he learns to read and play music at sight. In the same way, the telegraph clerk gradually acquires a proficiency in reading the indications which the deflections of a needle afford. Practice in this, as in all other matters, alone makes perfect; and we may venture on a paraphrase of a well-known quotation, to illustrate our remarks—"No one suddenly became an expert telegraphist."

It was found that the single needle apparatus, although sufficient for stations between which messages were only occasionally sent, was too slow in its indications, as the business of telegraphy developed itself; and, eventually, the double needle instrument was invented. In this, two needles are employed; and thus a word could be spelt in half the time required by the single needle arrangement. The principles of construction are identical in each instrument. The code of signals, however, has undergone some modifications. The following engraving illustrates the appearance of the double needle instrument, as employed by the telegraphic companies on most of our railway lines—omitting the code of signals on the face of the instrument.

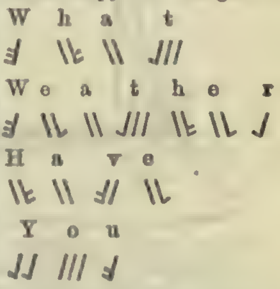
Fig. 26.



In the above engraving, we observe the two indexes which are connected with the needles inside the instrument. Pegs are placed on each side of them, to restrain their deflections; and at the lower part are two handles, by the movement of which the current of electricity is readily sent in any direction.† These handles have wires attached to them, which come in contact with those of the battery and the telegraph instrument; and according as the current is directed by them over the coils, so the needles are deflected right and left. On some lines of railway an alarum is used, which, by means of an electro-magnet, sets a bell in action, and so calls the attention of the telegraph clerk. A portion of the current is diverted from the needle coils; which, by moving a detent on clockwork, rings the bell. This continues until stopped by the attendant.

Before proceeding to explain a variety of practical details, we will illustrate the manner in which a message sent from one station is indicated and deciphered; and, for this purpose, shall employ the code of signals adopted in the single needle instrument already shown at a previous page; because, by so doing, we shall avoid any confusion which might arise in employing the two-needle code for our purpose. We shall presume that each attendant is at his station, and in front of the instrument; that the bell has been rung by the sender, and heard by the receiver. For example's sake, we may suppose the inquiry made—"What weather have you?" The sender moves the handle of his instrument so as to produce the proper deflection of the needle for each letter of the message, as seen beneath.

Now, to illustrate this more fully, we will give a literal explanation of the first word of the message—"What." For the "W," there are one deflection to the right, and three to the left. For "h," two to the left and two to the right. For "a," two to the left: and, for "t," three to the right, and one to the left.—Now, in the double needle instrument, the combinations of both needles are used at the same moment, and so much time is saved.



It is customary to shorten the message as much as possible by leaving out unnecessary words and letters; but these are practical details which scarcely concern the general reader. Each station on the line has a definite signal; so that, although the bells may be ringing, and the needles working at intermediate stations, the attendant at the intended station can at once perceive that *his* attention alone is required. The clerks have also an abbreviated code of signals for special and constantly recurring circumstances; and it is usual to transmit a special signal from and to each station when a word or sentence is completed, to signify that the same is, or is not, understood.

With respect to the rapidity of transmission of a message, we may observe, that it depends on the quickness of perception and intelligence of both receiver and sender (except under circumstances over which neither have any control, and of which we shall presently speak). From 60 to 100 letters may easily be sent and read per minute.

Most persons are curious to know how long it takes to send a message by means of the electric telegraph; and independent of the number of words, there are other circumstances to which we must now draw attention. As we have sufficiently explained the construction and use of the needle instrument, we shall now refer to the conducting wires; and the observations we are about to make, are equally applicable to every form of telegraph which we shall hereafter describe. There are two methods of connecting distant stations by means of wires. The Electric Telegraph Company suspend theirs on poles raised at the side of the railway. The wire, which is of thick galvanised iron, rests, not on the wood of the poles, but on glass or porcelain supports, which are contrived to shoot off the water deposited by rain, dew, or fog, so as to prevent a loss of power by deficient insulation of the wires. The Magnetic Telegraph Company enclose their wires—first covered with gutta-percha, so as to keep them electrically separate—in iron tubes: these are deposited on the sides of the main road; and at different parts, the wires are raised above ground, in an iron post, so that they may be tested for any defect. This precaution is, of course, unnecessary when the wires are suspended in the air, because any fault can be at once both seen and remedied.

---

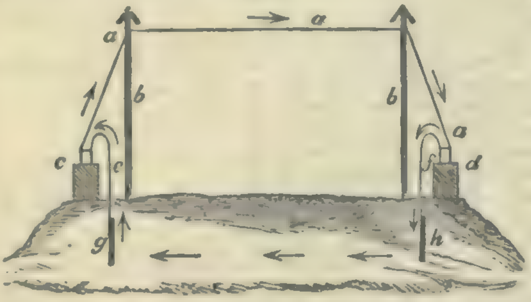
* See *ante*, p. 259; Fig. 23.

† *Ante*, p. 260

We must here remind our readers, that we have hitherto supposed that the circuit, or course of the electric current, is passed from one station to another, and back again, by means of a continuous or double conducting wire; but such is not done in practice. The *earth* is made to act as a conductor; and thus the expense of a second wire is saved. It is a most singular fact, that moist earth acts just as well as a solid wire in this respect; and if any number of instruments be working at the same time, and each using the earth for the purpose referred to, still each receives and indicates its message without the least confusion, providing an independent wire also joins the separated but corresponding instrument.

The following engraving illustrates the mode in which the earth is thus employed.

Fig. 27.



In the above engraving, *a a a* represent the conducting wire suspended on the poles, *b b*; *c* and *d* are two telegraph instruments, each of which is connected with the wire, *a*; *e* and *f* are wires which lead respectively from the instruments *c* and *d*; and at the ends of each of these wires, plates of metal, *g* and *h*, are affixed, which are buried at some distance beneath the surface of the ground, in moist earth. Now, supposing a current is passed from the station *c*, to a distant one, *d*—its course will be by the wire *a a a*, suspended on the poles; proceeding from *c* until it reaches *d*; and thence leaving the instrument by the wire, *f*, it passes into the earth by the plate, *h*: from this it then returns in the direction of the arrows, until it arrives at the plate *g*; by means of which it reaches the first station again by the wire *e*, into the instrument, *c*. A continuous circuit is thus established between the two, or, indeed, any number of stations; and, as we before remarked, it answers just as well as if a second conducting wire were employed.

Our readers will at once perceive the necessity which exists for maintaining a complete insulation of the wire from the earth; and in this is found one of the difficulties of telegraphing. It is almost impossible to keep the wires and poles completely dry during wet weather, although the glass or porcelain holders intervene. Now, moisture is a conductor of electricity; and as such, a portion of the current is often diverted from the wire towards the earth, in wet weather, by means of the wet poles. This circumstance is one, therefore, which interferes both with the speed of transmission and the distinct indication of a message, when rain, fog, or dew are prevalent.

It has been already mentioned, that the electric currents of the earth have a manifest influence on the magnetic needle; and in this is found another and serious source of annoyance to telegraphers. We have frequently noticed the needles of instruments, at stations far apart, working with all the vigour which would be seen if the clerks were engaged at the moment in sending a message by the wires. The needles oscillate in a most irregular manner, and not with that decision of appearance which is noticed when a message is actually being sent. The currents of atmospheric and terrestrial electricity vary constantly in their intensity; and, in some cases, are of extreme violence. We have noticed them as especially prevalent on the Edinburgh and Glasgow line, which runs nearly due east and west; and have heard some curious details of such occurrences, from the operators on the instruments at the extreme stations. The same effects, however, are experienced on all telegraphic lines, in a greater or less degree.

Atmospheric electricity, when present in excess—as in the case of a thunder-storm—is another source of difficulty, and possibly of danger, to the operator; this, however, is chiefly confined to lines in which the wires are suspended on poles.

In a great extent of country, of course, atmospheric changes are constantly occurring; and, to some extent, these changes may, by means of the conducting wires of the telegraph, compensate with each other, so far as that instrument is concerned. For instance—we may readily suppose, that in a distance of 40 or 50 miles, the atmosphere may occasionally be charged, at different places, with electricity of opposite characters;* and if the amount of these be equal, no effect would result on the telegraphic wires extended between any two distant stations. But it may so happen, that at or near one of these, a local electrical disturbance may occur; and such is sure to be followed by derangement of the needles of a telegraphic apparatus, if no provision be made to obviate it. Sometimes the electricity, during a thunder-storm, has passed by the conducting wires into a station, and completely destroyed the whole apparatus; or, at all events, so affected the needles as to render them useless. At times their polarity is reversed; and instances have been met with in which the persons in attendance have narrowly escaped with their lives. The remedy, however, is comparatively easy of execution. It is unnecessary for us to remark, that the intensity of the voltaic current is infinitely less than that of the electricity set free during a thunder-storm. For whilst the former requires a continuous and good conductor, the latter will readily pass through a stratum of air, between two conductors, and so reach the ground, if proper arrangements are made for that purpose. This fact is taken advantage of to prevent the accidents to which we have alluded. In some instances the poles are provided with lightning conductors; a plan adopted by the London District Telegraph Company. In others, temporary arrangements are contrived; so that, in the event of a thunder-storm occurring near a station, the atmospheric electricity can be readily directed to the earth, by means of a conductor of sufficient size; in which, however, a slight break is made—enough to prevent the escape of a current passing from a voltaic battery. Some ingenious inventions have been applied for this purpose; which, however, are of special interest only to those engaged in telegraphic matters.

It is a remarkable fact, that although the greater portion of the telegraphic wires in this country are suspended on poles, and entirely unprotected, it rarely, if ever, happens that they are subjected to intentional or malicious injury. With all possible charity for the qualities of human nature, we can scarcely suppose that the immunity of the wires is due to the good feeling of all classes, especially of the juvenile members. We believe, so far as our experience goes, that a general impression exists, to the effect that a powerful shock would be obtained on touching or meddling with the wires; and most young people throughout the country, have, at one time or another, made acquaintance with this kind of electrical phenomena. There is, at all events, a general opinion entertained, that birds flying against the wires are instantly "killed by the electric shock;" although it has not the least foundation in fact; for it would be impossible for any creature to feel the slightest electrical influence under such circumstances. This, however, is an instance of many cases in which ignorance becomes a protection rather than a bane. Except in extraordinary cases, storms of wind do comparatively little damage to the wires; and as any accident can be at once reported by the guards and engine-drivers continually passing, little or no hindrance ever arises from this cause.

There are many other circumstances which tend to the annoyance of the operators on a line of telegraph; but such are not of general interest; and we shall, therefore, omit to notice them.

---

* See *ante*, p. 183.

With respect to the various uses to which the electric telegraph is ordinarily applied, it would be impossible for us to enter. Confining our attention to the operations of the companies working the instrument on land, we may observe, that there is no event occurring in daily life which is not constantly made the subject of a message. Politically, commercially, and socially, the electric telegraph has become an institution of the age. So great has been its development, that, at the present time, all London is intersected with underground wires, and the roofs of the houses passed over by those suspended on poles, for the purpose of accommodating the universal desire for speedy transmission of messages. Nearly every line of railway has its public and private telegraphic arrangements. Warehouses, in different parts of the metropolis and other cities, and the various parts of warehouses and other large buildings, are connected together by electric wires. A company has lately been formed for the purpose of supplying instruments and wire communication between any two or more private establishments in London. Indeed, we may sum up our remarks on this point by stating, that electricity is as effectually "laid on" in most of our large cities in Great Britain, as are gas and water; although its uses and advantages are not so largely availed of, or required, as the other articles we have named.

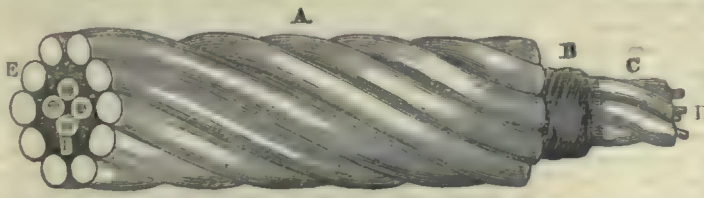
SUBMARINE TELEGRAPHY.

After it had been proved that communication could be satisfactorily and readily employed between any two or more points on land, it was but natural that an attempt should be made to connect countries separated by seas, &c., so that electric telegraphic messages might be dispatched from one to another. Of course, the difficulty of carrying out the idea chiefly rested in that of insulating the wire, and of giving it sufficient strength to resist all the accidents to which it might be subjected. The first obstacle—that respecting insulation—was overcome by using gutta-percha as an external coating to the wire; and the latter was conquered, in most instances, by the exercise of that mechanical ingenuity for which this country is generally so greatly renowned. We shall proceed to detail the various results which have been obtained in this interesting branch of electro-magnetic application, and so enable our readers to estimate and understand the triumph which science and skilled labour have accomplished, in this respect, during the last few years. For the purpose of making this subject as clear as possible to our readers, we shall divide it into three parts. Having no reference to the instruments which may be used to indicate the message, we shall chiefly confine our attention to the cable, which is, of course, the specialty of submarine telegraphy. We shall consider—

1. The construction of the cable.
2. Its submersion in the sea or rivers, &c.
3. The circumstances which interfere with its constant and successful working.

1. The Construction of the Cable.—A submarine cable requires that it should be sufficiently protected from any chance of injury by being rubbed against any hard or pointed substance after submersion; that it should have strength enough to resist the great tension it undergoes during submersion; and that the conducting wire should be so covered as to entirely insulate the current which passes by it, that such may not be diverted from its intended course. These points are secured in various ways, which will be better understood by the foregoing engraving, which is an illustration of the cable laid between Dover and Calais.

Fig. 28.



A, the iron wires surrounding the cable; B, the tarred rope surrounding the gutta-percha covered wires; C, the gutta-percha covering the wires; D, the four wires through which the message is sent; E, an end view of the covering of iron wire; F, an end view of the gutta-percha covering, and of the conducting wires.

In Fig. 28, we observe, that the outer portion of the cable consists of a coating of thick iron wires. These are twisted on by means of powerful machinery; and when this is well performed, they afford a sufficient protection to all that they enclose within their folds. The size of these wires varies according to the strength required, and the circumstances in which the cable may be placed. In shallow water, the external coat requires to be much stronger than in deep sea, because of the pebbles and broken rock against which it may rub. After a cable has laid for some time beneath the surface of sea-water, it acquires a curious coating, which has the power of affording it additional protection. This consists of the shells of small fish which attach themselves to it. It gradually increases, and sand, &c., soon become completely attached to the wires, forming an external surface of great solidity and strength. This, which, at first sight, seems to be a source of danger to a cable, becomes one of its most valuable protectors; and, instead of decreasing and wearing away, it accumulates continually. The dangers, then, of injury from such sources, peculiar to immersion in sea-water, occur only for some time after the cable has been laid, and decrease as the coating we have described accumulates. We observe, in Fig. 28, next to the external metallic coating, a covering of hemp, which is wound round the next coating of gutta-percha, enclosing the wire. The object of this coat is to allow of play between the covering of the conducting wires and that which forms the outside of the cable. The hemp is saturated with a mixture of grease and pitch, which, to some extent, tends to protect the gutta-percha from the attacks of marine insects; for any greasy substance is always avoided by them. Should the cable be accidentally bent at too acute an angle, the coat, by its elasticity, prevents the snapping of the fine internal wires.

We next observe a gutta-percha coat, which is, perhaps, the most essential of the three; for, being a non-conductor, it insulates the conducting wires which it encloses. When more than one wire is employed—and this, with few exceptions, is always the case—each wire is individually coated with gutta-percha; and thus the insulation of the entire number is more effectually arrived at. Much of the success which has been obtained in the use of submarine cables, is due to the application of gutta-percha: and the chief manufacture of the material, and its application to telegraphic purposes, is conducted by the Gutta-Percha Company, of Wharf-road, City-road, London; which has expended a large capital in perfecting this branch of the business. Whilst mentioning names of manufacturers, we must also include Messrs. Newall, of Newcastle-on-Tyne, and Messrs. Glasse and Elliot, of London, as those who have individually or collectively had the manufacture of all the cables which have been laid round our coasts.

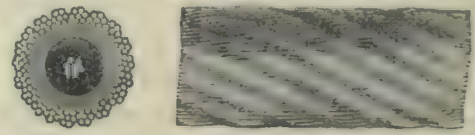
From late experiments—more especially since the failure of the Atlantic telegraph, of which we shall presently speak more fully—the opinion has gained ground, that gutta-percha is not so good an insulator as is to be desired. In fact, the process of its manufacture is such as to introduce chances of failure by the porosity of individual portions. Attention has therefore been directed to other materials. Amongst these is india-rubber, which has lately been highly recommended as a substitute for gutta-percha, for its insulating and non-porous character. Each material has its advocates; and extended trials are still required to afford accurate information on the subject. There is, perhaps, hardly any other substance in nature with which we are acquainted, so suitable to telegraphic purposes as those we have named; and the only advantage which has arisen, hitherto, in the search after substitutes for them, has accrued to the patent offices, in the shape of fees paid by inventors, who started forth in legions as soon as any defect in a submarine cable was discovered. On this point we may remark, that it would be a most merciful provision, on the part of the government, if a kind of committee were appointed, whose duty it would be to investigate and report on the various projects which are continually being patented. An immense amount of money and litigation would be saved; really good inventions would be reported as of value; and our insolvent courts and lunatic asylums cut off from a supply of broken-down and disappointed, but too sanguine inventors, who unwittingly, but surely, flock thither.

We next arrive at the conducting wires which always form the centre of a cable, and on which its value entirely depends. They are always made of copper, which combines elasticity, cheapness, and high conducting power. Various sizes are employed; but, generally speaking, that of No. 14 or 16 gauge is preferred, and is about equal to the tenth part of an inch in diameter. Occasionally, as in the Atlantic cable, a number of fine wires are twisted together, so as, electrically speaking, to form one; but we are not aware that anything is gained thereby, except, perhaps, a slight additional strength. We may here mention a circumstance which, we believe, often causes the failure in submarine cables. We have already noticed the fact, that copper wire becomes hardened, and eventually "rotten," after having long conveyed an electric current.* If it be enclosed in gutta-percha, the fact that the wire is broken cannot be discovered externally; and hence, during the laying of a cable, it is essential that its conducting power should be constantly tested. But the defect to which we allude does not occur until the cable has been some time in use, and its wire injured by the electric current passing by it. Our attention was first directed towards this point in 1856, when attempting to illustrate the explosion of the Russian infernal machines by means of the voltaic batteries.† After a few times of using the gutta-percha covered wires, which were the same as those employed for submarine telegraphs, they invariably broke on being bent to the least degree. The explosion of the powder would, of course, be prevented. But, strange to say, a broken wire would at times convey the current perfectly. This, however, is easily explained; for if, by accident, the broken wire were so bent whilst in use, as that the fractured edges were again brought into contact, the current would, for the moment, find a complete conductor, and so the explosion would take place. Now this is what frequently occurs in submarine cables. At times the current affords no indication of its passage: and we would suggest, that the cause which so continually hindered the success of our experiment, may just as likely be active in the case of submarine cables, more especially as far more intense currents are sent through their wires than those we employed. We observed, that, on submitting the edges of the fractured wires to a microscope, the metal had a decided crystalline appearance—proving that it had undergone a molecular change.

To those of our readers who may be engaged in practical telegraphy, we may state, that the "rottenness" of copper wire is produced the more rapidly as the intensity of current is increased; and, from our experiments, we do not consider that it matters of what thickness the wire is. We have employed copper wire, of a quarter of an inch in thickness, for conveying the current of from 50 to 100 cells (large size) of Grove's batteries; and the action on any portion of the wire may easily be noticed after they have been *constantly* in use for twenty or thirty hours. The readiest way of trying the experiment, is that of making some No. 22 gauge copper wire the terminals of a common or Rhumkorf coil. They will soon become as brittle as a piece of zinc or lead wire; and we have, in rare cases, seen a piece, ten inches long, break by its own weight after having been so employed.

The number of wires placed in any one cable, is regulated according to the amount of business expected to occur between any two stations. That laid between Ireland and Scotland, contains six wires: the Dover and Ostend cable, laid in 1853, has also six. The cable laid between the coast of Suffolk and Holland, has seven; which, however, have each an external coat of iron wire—the whole being twisted together to form one cable; whilst the temporary cable laid between Varna and Balaclava during the Russian war, and which served so many valuable purposes, was of small size, and contained but one wire, without any external covering. It will be unnecessary for us to enter into any special description of those we have named above; but we may here more fully describe the Atlantic cable, because so intense an interest has been attached to it. As we have already stated, it consisted of an external covering of iron wire, and a coating of gutta-percha; and, in the centre, seven fine copper wires, twisted together, formed the conducting medium. Its appearance is indicated in the annexed cut, both in section and in length.

Fig. 29.



Our readers will, doubtless, be surprised to find that such a comparatively slender cable (its actual size is represented in the cut) should have been employed. It must, however, be borne in mind, that, at great depths, the ocean is not liable to disturbance, as is observed on its surface. A dead and imperturbable calm always exists: so, if the cable stand the trial it has to undergo during submersion, it is liable to little subsequent injury from causes external to it.

The following table may be of value to many of our readers who take a general interest in the subject of submarine telegraphy. We have selected our information from various sources; and have chosen the leading cables now at work between different stations, or which have been worked and have failed.

Situation.	Date of laying.	Length in miles.	Number of wires.	Weight per mile, in tons.	Total weight in tons.
Dover and Calais......	1851	25	4	7	175
" " Ostend ...	1853	70	6	7	500 nearly.
Varna and Balaclava	1855	150	1	—	This wire had no metallic coating.
Varna and Constantinople................	1855	200	1	1	200
Atlantic Telegraph: Ireland and America	1858	2050	1	—	About 2,500 miles were used, and lost, in laying this cable. Its weight was about a ton per mile.

In the above table, the Red Sea and Mediterranean cables have not been included. The former has lately failed to work; and those laid in the Mediterranean are of various lengths and sizes. The cable between Malta and Alexandria is but just completed.

We may remark, in reference to the comparative weight of the different cables, that, in many cases, considerable material has been saved by laying a light cable in deep water, and attaching to it a stronger one near the shores where it terminates. The reason of this is obvious from our previous remarks; but we may add, that occasionally, cables are liable to accident from vessels anchoring near them. As the anchor is weighed, its fluke may catch the cable; indeed, some time ago, one of the Channel cables was thus accidentally fished up. The captain of the vessel whose anchor had caught

* See *ante*, p. 250.

† *Ante*, p. 193; Fig. 53.

it (being ignorant of its nature, it is to be hoped), was about ridding himself of the incumbrance by cleaving it with a hatchet; but one of the crew, more sensible than his commander, induced him to cast it overboard, and so to return it to its former resting-place.

2. THE SUBMERSION OF THE CABLE.—One of the most serious undertakings in connection with the submarine telegraph cable, is that of "laying it," as the operation is termed. Even when the finest and calmest weather is experienced, many difficulties arise. The cable is coiled in the hold of the vessel, and passed through an opening on deck. It is then wound two or three times round a large cylinder, to which is attached a break. The object of this is, that the cable may be "payed out" in an even manner; for, if it were allowed to pass from the stern of the vessel in an irregular manner, it would soon form knots and kinks, and most probably break. The regulation of its speed is a matter of great delicacy; for sufficient strain must ke kept on it to lay it straight, and yet care must be taken that it is not broken by too great tension, partly arising from the speed of the vessel, and from the weight of the cable itself. An ordinary speed of laying the cable is about four to five miles per hour. When, however, a storm occurs, the difficulties are enormously increased. As the vessel rises and sinks in the trough of the waves, the tension on the cable is suddenly increased or diminished; and, unless the greatest care be taken, its fracture is inevitable. Even while the cable may appear externally to be sound, it is possible that one or all of the wires inside it may be injured; hence telegraphic signals are constantly kept up between the vessel and the station whence it proceeded. In laying the Atlantic telegraph, the two vessels started from a place equi-distant from Ireland and America. The cables in each vessel were spliced together, and the portion between the two was gradually sunk. The steamers sailed then in opposite directions, until each reached its appointed port; and, during the entire voyage, the electricians kept up constant signals, acknowledged and received on each vessel, which, of course, proved that the conducting wire was perfect throughout. In the first attempt to lay the cable, the signals were interrupted, and could not be recovered, so that it at once became evident that the sunken portion had been by some means injured. This, of course, necessitated its loss, and both vessels returned to the port whence they had started.

We need not remind our readers, that the bed of the ocean, like the surface of the land, is often exceedingly irregular. Sometimes deep ravines are encountered, in which the cable quickly and suddenly falls. In other instances great elevations are met with, which diminish the rate of the cable's passage. All these, and many other circumstances, have to be minutely attended to; and without entering more fully into such details, we have pointed out sufficient to prove, that the laying of a submarine cable is a work of no ordinary difficulty and importance.

3. THE CIRCUMSTANCES WHICH INTERFERE WITH THE REGULAR WORKING OF A SUBMARINE CABLE.—It would be impossible for us to enter into a minute examination of all the circumstances which affect the regular working of a submarine cable. We shall therefore only touch on those which are either very important, or ordinarily found to be present. The numerous accidents, of a mechanical nature, to which all submarine cables are subject, have been already frequently noticed, and will not require further observation. There are, however, others of an electrical nature, which often produce serious consequences; and, at times, almost forbid all chance of communication between the two termini of the cable.

It was found, some time since, that if a short length of submerged cable formed part of a circuit between two land-lines, more disturbance occurred, in the regular indication of signals, than would have been the case had the entire line been on land, and suspended on poles in the usual manner. At first it was considered that this arose from defective insulation, or from injury to the conducting wire. Eventually, however, the fact was discovered, that an ordinary submarine cable acquired the character and qualities of a charged Leyden jar, whenever a current was passed through it: indeed, its construction is analogous to that arrangement; for we may suppose the wire to represent the inside of a charged Leyden jar; the gutta-percha to correspond with the glass of the vessel; and the external wires, or the water surrounding them, to answer the outer coating of a jar.* Now, the effect of this inductive action is not only to retard the passage of a current of electricity sent from a voltaic battery, but even to create an opposing force. In some instances, the current is all but destroyed: generally, its indications are irregular; and if a printing telegraph be employed, such as we shall shortly describe—it will be found, that, instead of an instantaneous signal being registered, such is, generally speaking, given in a slow and continuous manner, just as if the current were gradually conducted by the wire. This evil increases with the length of the cable. As we have already stated, even a short one shows such results; but in the Atlantic wire, the effect was, as might be expected, on a very large, and even alarming scale. It is a difficult matter to give a popular illustration of the actual results produced; but we may compare the retarded and opposed passage of a current to the position in which a vessel is placed on entering the mouth of a narrow river. The vessel may be urged forward by a fair or strong wind, whilst the water of the river is rushing towards the sea. The stream is urged into swelling waves, and on these the vessel tosses, making but little progress towards her destination. Now, similarly, the wave of voltaic current meets that of the induced cable-current, and the effect is that which we have described.

The question next arises as to what means can be adopted to overcome this difficulty; and the leading doctrine of Homœopathy—"*similia similibus curantur*" (*Anglice*—"Like cures like")—was called in to the aid of the telegrapher. It was considered that, if an intense current were opposed to an intense current, although produced from different sources, the strongest would gain the advantage, and more speedy signals would result. This plan was accordingly adopted on the Atlantic cable soon after it gave the first sign of defect. Powerful voltaic batteries, magneto-electric machines, and Rhumkorf's coil, or its modifications, were successively tried; but, alas! with no effect: and it is certain, that if the slightest break in the cable had existed, and a current had been transmitted, even for a few moments, from a Rhumkorf in good action, the fate of the cable would be for ever sealed by the combustion of the two edges of the fractured parts. The reason of this will be at once perceived by reference to our remarks on that coil, at a previous page.†

One effect of a fresh intense current, besides that of overcoming the resistance of a long conducting wire, is to neutralise the induction of the wire current, produced by a previously passing current; hence the employment of such means in the way we have just mentioned. Their want of success, in the case of the Atlantic telegraph, must not be ascribed to a defect in the principle of the doctrine, but rather to the peculiar circumstances in which it was applied. A section of the map of the bottom of the Atlantic, as prepared by Captain Maury and others, exhibited, as near as can be, just such a bed as would be found for a cable, if one were laid from Lombardy over the Alps, at the top of Mont Blanc—then into the valleys and plains of France, across the English channel, and so continued over the hilly parts of England and Scotland—concluding its career on the north side of Ben Nevis. For 500 miles from the Irish and American coasts, the cable was suspended on the tops of marine mountains, and hung in the deep hollow which intervened. Between these two localities, a level bed of sand, and the remains of shells, of nearly 1,200 miles in length, existed, on which the cable might have rested in undisturbed repose. The depth of the ocean there, was sufficient to prevent the least risk of injury from any cause whatever.

---

* See *ante*, p. 180.

† *Ante*, p. 255; Experiment 13.

The effect of ordinary terrestrial electric currents on the submarine cable, cannot be properly ascertained; for the position of a cable submerged in a liquid of tolerable conducting power, includes so many elements of disturbance, as to prevent the possibility of our acquiring accurate or reliable data.

The remarks which we have just made, apply equally to all submarine cables; and are modified by the difference of their length, the thickness of the conducting wire, and the number of them enclosed in the cable. It would be very desirable if a series of simultaneous observations were made, as to the retardation which is exercised on a current at the same moment, on cables laid in different directions, with respect to the compass. It would thus be seen how far electric or magnetic currents affected the conducting power, and whether such had a definite direction and action under all circumstances.

We shall now describe the construction of various kinds of telegraphic instruments which have been invented during the last few years, on principles entirely different to that of the needle apparatus.

ELECTRO-PRINTING TELEGRAPHIC INSTRUMENTS.

The remarks we have hitherto made, have referred entirely to the needle instrument, or to circumstances which affect every form of telegraph apparatus, so far as the conducting medium is concerned. We shall, therefore, pass on to examine a variety of arrangements in use in different countries, and also, to a limited extent, in our own.

The needle instrument only indicates, and does not record, a message. As we have fully explained, the signals are effected by means of alternate or combined deflections of a magnetised needle; and its use is practically confined to those who are accustomed to it, and can, therefore, readily translate its signs. This, to some extent, is an objection, and limits its use. If letters and words were imprinted by it, then its indications would be intelligible to any one; and its use would doubtless be more general. It is also liable to many derangements. The needles may lose their magnetic power, and, in certain instances, perhaps, at the very moment when they may be most required: a sudden flash of lightning inverts their polarity, and all attempts to employ them are futile. Earth currents, and atmospheric influences, also combine to effect their derangement.

These, and other reasons, have led to the invention of *printing telegraphs*; by means of which, the words of which a message is composed are spelt and printed on cloth or paper; or, which answers the same purpose, dots and dashes of various lengths are printed, according to a preconcerted code of signals.

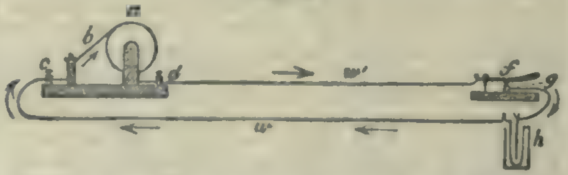
We shall first describe the general principles on which chemical printing telegraphs are constructed; then refer to the mechanism by which the plan is carried out; and shall best illustrate our subject by suggesting some experiments bearing on it.

Experiment 22.—Dissolve a little yellow prussiate of potass in warm water; and also, in a separate glass, some crystals of sulphate of iron (green copperas). Add these two solutions together: a blue precipitate will be produced, which is commonly called Prussian blue. Now, it is by the production of this colour on paper or cloth, that the printing of dots, dashes, or long lines, is effected in some kinds of telegraphs. The mode of printing may be illustrated as follows.

Experiment 23.—Moisten a piece of white calico with a solution of sulphate of soda; and, after wringing it, dip it into a weak solution of the prussiate of potass. Place the cloth, whilst damp, on a sheet of tinfoil, and to this attach the wire proceeding from the copper plate of a voltaic battery. Attach the wire from the zinc plate to a knitting-needle, and draw the end of the needle over the moist cloth. Wherever it touches the cloth, a blue stain will be left. If the needle just touch the cloth by the point, then a dot is produced; but if the point be drawn over the cloth, then a dash or long line is afforded. Now, on exactly similar principles, and by a simple modification of the plan, messages may be readily transmitted between any two stations—the printed paper or cloth kept, and the marks on it translated into ordinary language.

To familiarise the mind of our readers with the principal mechanical part of the printing apparatus, we will suppose that a pianoforte key, made of metal, and with one of its ends attached to the wire of the copper plate of a voltaic battery, is so arranged, as that, when pressed down, it shall enter a small cup containing mercury. From this cup we will suppose a wire to extend to a needle, placed so as to rest with its point against a metal roller covered with cloth, which has been impregnated with the prussiate of potass; and that the roller is connected with another wire proceeding from the zinc plate of the voltaic battery. It is evident, that when the pianoforte key is pressed into the mercury cup, a circuit will be established; a current will pass; and the point of the needle will instantly impress a blue dot on the cloth—thus, . If, however, the roller be gently moved, then, instead of a dot, a dash ——, or long line ————, will be produced; the length depending on the length of time the key is kept pressed down, so as to continue the passage of the current. The instant the key is removed from the mercury cup, the current will cease to pass, and no effect will be produced on the distant roller. Now, this is exactly what happens in most of the chemical printing telegraphs: but we may be better understood if we refer to the following engraving, which affords an illustration of the most essential part of the apparatus.

Fig. 30.



In the above cut, we have *a* representing the roller on which the prepared cloth is wound; *b* is the needle which imprints a dot, dash, or line; *c* is a binding-screw, to which is attached a wire, *w*, extending to the copper plate of the battery, *h*. A wire is attached to the zinc of the battery, and reaches to a small peg, *g*: *f* is a key, which, when pressed down on *g*, completes the circuit. The current will then travel from the battery by the wire *w*, to the needle, and thence by the roller to the wire, *w'*; returning again, through the key arrangement, to the zinc of the battery. Of course, no mark is made on the roller, except when the key, *f*, is brought into contact with the peg, *g*. The roller is gently turned by clockwork; or by hand, if for elementary experiments.

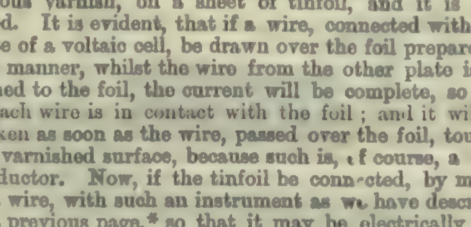
We have entirely avoided all mechanism used in the complete apparatus, so that our readers might gather a general knowledge of the *modus operandi*, and, if they so please, construct a model for their own use. Having thus illustrated the principle, we shall now describe the various forms of apparatus which have been, or are in use, constructed on such plans as we have explained.

Before doing so, we may call attention to a very ingenious piece of apparatus invented by Mr. Whitehouse, of Brighton, formerly the chief electrician to the Atlantic Telegraph Company; by which music could be printed as it was played on a pianoforte or harmonium, at any distance from the instrument, and accurate as to notes and time. Under each key of the piano a wire was placed, which extended to a needle fixed to an apparatus similar to that which we have just illustrated. On the roller a long strip of cloth was placed, on which as many needles pressed as there were keys on the piano. The cloth was marked with the lines and spaces for bass and treble, as is common in printed music; and by means of clockwork, or by the hand, it was gradually unwound from the roller. A current of electricity travelled from the piano to the needles; and as each key was pressed down, a mark was imprinted on the cloth by its corresponding needle; the length of the mark indicating the value of the note—such as a quaver, a crotchet, and so on. We have frequently played rapidly-executed music on a piano so fitted, and every note was thus printed as quickly and as accurately as it was performed. When the cloth was removed from the roller, the lines might immediately be read, or transposed into the ordinary form of musical notation. The instrument would be of great value to composers, because every idea, as it found expression on the piano, &c., would simultaneously be printed by the electric current. We believe that Mr. Whitehouse has not carried out his invention beyond making the model we have described.

BAKEWELL'S COPYING TELEGRAPH.

Perhaps the simplest and most interesting instrument constructed on the principles we have explained, is that invented by Mr. Bakewell; by means of which the handwriting of the sender of the message is faithfully copied by the electric current, at any distance from the station whence the message is forwarded. This certainly, at first sight, seems beyond belief; but by a little investigation, we shall find that it is only the result of a most ingenious application of principles, to which we have already very frequently drawn attention. The whole secret of the art consists in so arranging a conductor with a partial non-conducting surface, that, by means of the latter, the current of electricity may be intercepted; and this is managed after the following manner:—The message is first written, by means of a weak spirituous varnish, on a sheet of tinfoil, and it is then dried. It is evident, that if a wire, connected with one plate of a voltaic cell, be drawn over the foil prepared in this manner, whilst the wire from the other plate is attached to the foil, the current will be complete, so long as each wire is in contact with the foil; and it will be broken as soon as the wire, passed over the foil, touches the varnished surface, because such is, of course, a non-conductor. Now, if the tinfoil be connected, by means of a wire, with such an instrument as we have described in a previous page,* so that it may be electrically connected with the needle, and one wire of the battery be in contact with the roller of that apparatus—the wire from the other plate being passed over the written tinfoil surface—no mark will be made on the prepared cloth when the battery wire comes in contact with the varnish; but whenever it touches the tinfoil, a blue mark will be printed on the cloth. If the needle, instead of being stationary, is allowed to traverse from one side of the roller to the other, whilst the roller itself is quickly moved round by clockwork, the continuous straight lines will be printed when the circuit is completed; which, however, will be interspersed with white spaces whenever the circuit is broken by the interposition of the varnished surface. Supposing the varnished surface to be a straight line across the tinfoil, then the printed copy would present a number of blue lines, crossed by a white one—as is shown in the above diagram.

Fig. 31.

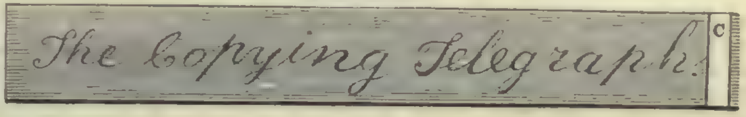


No. 1. No. 2.

No. 1, in Fig. 31, represents the tinfoil sheet, *a*, from which the signal is transmitted, crossed by the varnished line, *b*, which is the non-conductor; No. 2, *c*, is the cloth in which the signal is received and printed; *d* being the white space, unmarked with lines, and corresponding to the varnished surface of the tinfoil plate; and *c c* are the blue lines printed by the traversing needle, which receives the electric current from the foil. No. 2, in fact, gives a representation of the cloth as it appears when taken off the rollers.

Now, the principle being established, it does not matter whether the line on the foil be straight, curved, or of any form; hence, if such be ordinary writing, that would be copied on to the cloth in an exact fac-simile of the original, just as we observe in the copy shown in No. 2. This is just the plan adopted, and the result arrived at, by Mr. Bakewell's arrangement, provided that certain mechanical details are observed, to which we shall presently allude. The following diagram shows the appearance of the original, and printed, copy of a message, as illustrated by Mr. Bakewell, in his work on the subject.

Fig. 32.—No. 1.



No. 2.

No. 1, Fig. 32, represents the original, with the letters in black on the tinfoil; and No. 2 is the printed copy, having the letters in white intercepting the line produced by the needle. Our readers will thus perceive, that by this plan, an exact copy of the handwriting of any person may be transmitted by telegraph—a fact that makes Mr. Bakewell's invention rank very high as an instance of inventive genius. But, unfortunately, there is a very serious drawback to its utility, which is owing to the necessity that exists for both the transmitting and receiving-rollers to move at the same speed and at the same moment; and, consequently, through equal spaces in the same period of time. To effect this, Mr. Bakewell introduced regulating apparatus, worked by an electro-magnet, so that one roller could only proceed at the same rate as the other. In fact, in such an arrangement, the magnet acts in a similar manner to the pendulum of a clock. It is well known, that the weight or spring of a clock would quickly "run down" were it not for the action which a pendulum exerts on the seconds, or first wheel. A pendulum, thirty-nine inches long, beats about once in a second of time; and the spring of the clock is only required to keep up that motion. But two pendula never beat exactly together: thus they would not be effective as regulating arrangements in Mr. Bakewell's apparatus. Hence the employment of the electro-magnets, which necessarily act together, because their motion is mutually dependent. We are precluded from illustrating the mechanical parts which have been adopted; and this is not of so much consequence, because, although the invention is highly ingenious, it has scarcely ever been practically employed to any extent. Besides the difficulty to which we have alluded, there are others which also interfere with the result;—the receiving cloth may be unequally stretched; the two instruments may not commence work together, &c. Messages, however, have been sent accurately through a distance of fifty miles; and as many as 300 letters per minute can be printed by this interesting instrument.

Whilst referring to electro-chemical printing telegraphs, we may mention a very ingenious arrangement employed by Mr. Whitehouse, whilst he was engaged in trying experiments in connection with the Atlantic cable. The object he had in view, was to ascertain the speed with which a current of definite intensity and quantity passed through various lengths of conducting wire; and also to discover the retardation which the current suffered from the resistance arising from wires of different thicknesses. He employed an arrangement very similar to that we have already described in a previous page, and which is used in Bakewell's instrument. By these means, he found that the same current produced a dot through—say 200 miles; a dash through 500 miles; and a longer line through a circuit of 900 miles; and so on. It was to these experiments we referred when speaking of the influence which a gutta-percha coated wire has on the speed of signals transmitted through long cables.* We have first introduced Mr. Bakewell's copying telegraph, as being comparatively simple to some we shall have to mention; and shall now proceed to describe the inventions of Mr. Bain, and also of Mr. Morse, with others, which have been very extensively used for various purposes.

---

* See *ante*, p. 266; Fig. 30.

BAIN'S ELECTRO-CHEMICAL TELEGRAPH.

Amongst the earliest inventors in connection with electro-telegraphy, Mr. Bain is well known. We believe that he was one of the first to produce a printing telegraph, which, however, was constructed with ordinary types. These were moved by means of mechanism actuated by electro-magnets, and each letter was successively brought to its proper place by complicated arrangements. After being inked, it was pressed on a receiving surface, which, when finished, presented a similar appearance to ordinary printed matter. A model of this arrangement was first publicly produced and explained by its inventor, many years ago, at the Polytechnic Institution, Regent-street, London; but we are not aware that it ever came into extensive use. Mr. Bain was also well known for his ingenious arrangement of electro-magnetic clocks, one of which was for some time in operation at the above-named institution. His electro-chemical telegraph is constructed on somewhat similar principles to those we have illustrated already.† As in Bakewell's apparatus, Mr. Bain obtains marks on prepared cloth, intercepting the surface of the transmitting arrangement by means of non-conductors; producing, however, dots and dashes, instead of continuous lines. Combinations of the marks produce letters, as the following instance will illustrate.

A - —   D - - —
B - — -   E -
C - - -   F - — — — &c., &c.

It will be unnecessary for us to enter into detail with respect to the mechanical arrangement of the apparatus; for the principle is so fully illustrated by the elementary instrument already referred to: but we may add, that the continuity of the current is intercepted, and the letters represented, by means of perforated paper, each of which corresponds, in its perforation, to, and produces marks, such as those represented above. The message, in fact, is perforated in paper or cardboard by means of punches; and is then placed in the transmitting arrangement; after which it is sent, in the manner we have already described, to the receiving instrument at the distant station, and is then printed on the prepared cloth.

Various inventions have been brought into public notice—being improvements, modifications, or original productions—in the form of electro-chemical printing telegraphs; but we shall not enter into any investigation of them, as their use has not been adopted, to any extent. for telegraphic purposes.

MORSE'S TELEGRAPH.

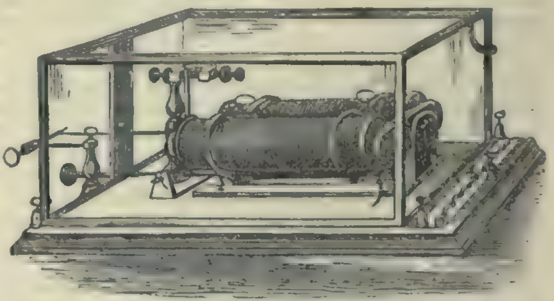
Amongst the great variety of telegraphic instruments which have been employed in foreign countries, that invented by Mr. Morse, of America, has been, perhaps, the most extensively adopted. In it, electro-magnets are employed in a similar manner to that of Mr. Bain's invention: in fact, the similarity of the two instruments is so great, as to have given rise to litigation in the American courts, which have had to decide on the respective rights of the inventors. Mr. Morse, however, seems to have been original in his ideas; and he has worked them out to a most successful issue; for nearly the whole of the American, and some continental, lines are worked under his patent.

In speaking of the needle instrument, we mentioned that its indications were effected by its deflections. Mr. Morse's arrangement is constructed on entirely different principles; and, except in some parts of the mechanism, the details are just such as we have described in Bain's instrument. The signals are transmitted in a similar manner, and the notation is that of dots and dashes of unequal length or interval. The following is a portion of the telegraphic alphabet employed by Mr. Morse.

A ·—   E ·   I ··
B —···   F ·—·   J —·—·
C ·· ·   G ——·   K —·—
D —··   H ····   L — &c., &c.

A larger amount of electric force is required to work Morse's arrangement than the needle telegraph, and hence the employment of "relay" magnets, by means of which the first current transmitted from a distant station, brings into operation another current at the station at which the message is received. The necessity of this will be at once seen if it be borne in mind, that, whilst a weak current will readily deflect a magnetised needle, it requires one of considerable force to convert a piece of soft iron into a magnet.‡ The arrangement of a relay magnet is illustrated in the following engraving.

Fig. 33.



With respect to the speed at which signals may be sent by this plan, its advocates maintain that it equals that of the needle system. It has other advantages; for, owing to the nature of its arrangement, and considering that the electro-magnetic force is generated at the moment it is required, there can be no risk of interference by atmospheric influence, which is almost always operating on the apparatus of the needle instrument.

Numerous modifications of the Morse principle have been made in America, and on the continent; but as we cannot enter into details, which, whilst interesting, invite no special novelty in principle, we shall not further refer to them than to state, that our readers may obtain full information in Mr. Shaffner's *Telegraph Manual*, from which our two last illustrations have, by his kind permission, been copied.

THE MAGNETO-ELECTRIC TELEGRAPH.

Amongst other instruments involving no great novelty in the indicating part of the arrangement, is the magneto-electric telegraph. Some years ago, a company was formed for the purpose of carrying out a system of telegraphy, in which a current of electricity, produced by magnetic induction, was to be employed in place of the old plan of voltaic batteries. It was urged that the new plan offered all the advantages of the old one, and saved the cost of chemicals, the wear and tear of plates, battery cells, &c.; that the current produced by magnetism had greater intensity; and, lastly, that the first was the only cost of the source whence electricity was to be obtained. Our readers have already been acquainted with the magneto-electric machine;* and we shall, therefore, not enter into any further detail, as the indicating instrument is simply a modification of the ordinary needle instrument. We were informed, two years ago, by the superintendent of one of the chief stations on the Glasgow and South-Western line, that the magneto-electric machine had been given up, and that the old plan of the voltaic battery had superseded it. If so, the distinctive character of the company no longer exists.

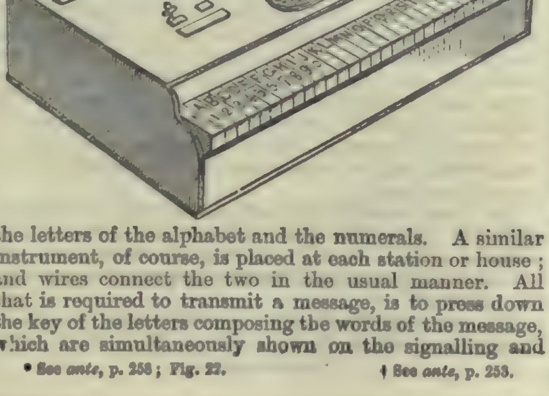
ALPHABETICAL TELEGRAPHS.

ONE of the earliest forms of electric telegraph, was that of a circular plate, around the edge of which were engraved the letters of the alphabet. An index moved in the centre; and, in fact, the arrangement was exactly similar to that of a watch, with the exception that letters were employed in place of figures. The index-hand was moved by electro-magnets; and, of course, the receiving and signalling instruments were constructed, in all respects, precisely alike—in the manner already described in connection with electric clocks.† The index had to be moved from letter to letter—passing over those which were not required in the word, and resting opposite to that which was included in it. It thus happened, in many words, that the index had to travel frequently over the dial-plate before a word could be spelt. Thus, supposing there were two "e's" in a word, the index would have to pass twenty-five letters before the "e" would be again reached; and so on. The plan, however, is remarkably simple, for any one can read the indications; and it requires no previous instruction for its successful employment. At the present time some of its modifications are in use; and an invention, by Professor Wheatstone, has lately been adopted by the Universal Private Telegraph Company—the object being to maintain electrical communication between, and in, private dwelling-houses.

Froment's alphabetical telegraph will assist our readers in understanding the principle of the arrangement of these alphabetical instruments. In front is a key-board, constructed similar to that of an ordinary pianoforte; and connected with this is a dial, on which are engraved the letters of the alphabet and the numerals. A similar instrument, of course, is placed at each station or house; and wires connect the two in the usual manner. All that is required to transmit a message, is to press down the key of the letters composing the words of the message, which are simultaneously shown on the signalling and receiving instrument. The apparatus, except with respect to its internal mechanism, is remarkably simple; and even a child may soon be taught its use. Fig. 34 illustrates the appearance of one of these instruments.

Fig. 34.



The alphabetical system of telegraphs has been partially applied to the purpose of railway signals; but instead of the entire alphabet being printed on the disc, separated signals, such as "train started," &c., are employed. An instrument is placed at each station on the line; and thus a system of constant signalling may be readily maintained. There is, however, considerable difficulty in keeping the signals identical at the same moment in each instrument; and in experiments we have tried with two such instruments, exactly opposite indications were received to those sent; a result which would be most serious in practice. On many of the railway lines, especially at the extremities of tunnels, the old needle system has been introduced; and as the number of signals is small, it is found the most convenient and certain plan.

The limits of this work prevent us extending to further telegraphic details; and we shall, therefore, now draw attention to some minor applications of the instruments we have described, and of the principles already explained; amongst which are the following.

WIND AND WEATHER REPORTS.—A complete system of telegraphy is now established, between the Admiralty Office and the Royal Exchange, London, with all the outposts and chief towns in this country and foreign parts; and it is impossible to over-value the results which have accrued. Since the discovery of the general law of storms, it has been most desirable to make simultaneous communication from a common centre, so that information may subsequently be diffused as to the kind of weather which may probably be expected. We have not yet arrived at such precision of information as will permit us to foretel, to an exactitude, the atmospheric changes which are continually occurring in a climate like ours; but we can, to some extent, approximate to truth; and, in many instances, the conclusions which have been drawn from the facts collected by the telegraph, have resulted in saving many lives, through timely notice which has been sent to different parts of our coasts.

Our readers will understand this better if we give a few facts in reference to the cause and indications of a coming storm. The most dangerous kind of tempest is that called the "cyclone;" which is an immense eddy of wind, having a calm centre and circumference. Vessels in any intermediate place are exposed to the full violence of the storm; but, from their position, the captain is unable to judge of its extent. Now, if we learn the direction of the wind over an extensive area of country, and also the rise or fall of the barometer (which is, at all times, a sure indication of coming atmospheric changes), we obtain data on which tolerably accurate conclusions may be drawn. Amongst those who have taken a lively interest in this matter is Admiral Fitzroy, whose remarks on the subject we shall quote. "I do not hesitate to affirm (and it is more than forty years since I bought Daniell's first work on Meteorology), that the peculiarities of our winds and climate are now sufficiently known to make it practicable to foresee every extensive storm; and, when no such change is impending, to give the negative information—often valuable—that no tempest need be feared."

On this matter we may remark, that much useful information might be afforded by private individuals undertaking the duty of keeping a register of the barometric indications, the direction of the wind, and other meteorological phenomena. These might be forwarded, periodically, to the secretary of the Meteorological Society, or to the Admiralty Office, London: and if a tolerable amount of accuracy were maintained by observers, the extent of our general information would be largely increased.

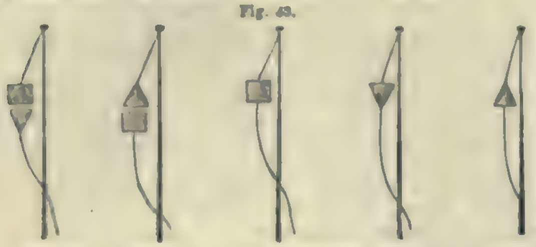
The necessary facts having been gained by means of the telegraph, the next step is to use that instrument for the purpose of diffusing the instructions from head-quarters; and this is followed by the employment of signals, which are hoisted at some prominent place on the coast, near each port. The following are the storm signals adopted by the Board of Trade.

---

* See *ante*, p. 258; Fig. 22.

† See *ante*, p. 253.

Fig. 63.



No. 1. No. 2. No. 3. No. 4. No. 5.

No. 1. Dangerous wind probably at first from the southward.—No. 2. Dangerous wind probably at first from the northward.—No. 3. Dangerous winds may be expected from nearly opposite quarters successively.—No. 4. Gale probably from the southward.—No. 5. Gale probably from the northward.

We will suppose, for instance, that the daily reports from all parts of the kingdom have been received at the usual hour of 9 A.M. A consultation is then held as to the chances of danger, and the probable direction of a storm, if one be likely to occur. Instructions are immediately telegraphed to those ports nearly adjacent to the probable locality of the expected tempest, to hang out the proper signals, so as to warn vessels within sight of their impending danger. In this way, at least, all that human foresight and intelligence can do has been attended to; and the rest can only be left to the discretion of the captains, who have thus been forewarned.

Electric Time-Balls.—Another valuable application of telegraphs, has been that of indicating the exact moment when the sun has passed the meridian of any place; or, what answers the same purpose, any exact interval of time which has elapsed. It is usual to hoist a large ball on the top of the Observatory of Greenwich, a little before one o'clock daily; and at the instant that the sun has passed one hour over the meridian (*i.e.*, one o'clock), the time-ball is lowered. The captains of the vessels in the Thames can thus daily check the rate of the chronometers they have on board, and so gain the most valuable information; because, on a correct knowledge of time, depends their discovery of the longitude during a long voyage. Within the last few years the system has been widely extended; and by an arrangement of telegraphic signals between Greenwich, London (Charing-cross), Liverpool, Glasgow, and other shipping ports, the time-balls at each of those places are lowered synchronously with that of Greenwich, and correct time is thus indicated. The telegraph has also been employed for ascertaining some interesting facts in connection with astronomical science—such as the longitude of two different places, &c.

Modifications of telegraphic apparatus have been employed for domestic purposes; amongst which we may notice the fire-alarum and house-bell. If wires be connected with the doors and windows of a house, and arrangements be made so that, on any of these being opened, contact shall be made between the wire proceeding from a small battery and an electro-magnetic bell, such may be readily applied for the purpose of warning the inhabitants of the ingress of persons; and as a protection against thieves. By means of a most ingenious arrangement of a thermometer and electro-magnet, a fire-alarum has been constructed. The thermometer is of peculiar construction; and the mercury it contains, is, in ordinary circumstances, at some distance from a little arm, which can connect an electro-magnet with an alarum-bell. If, however, the temperature of the room rapidly and greatly increase, then the expansion of the mercury in the thermometer raises the arm, and completes the connection between the battery and the electro-magnet of the alarum; and on this taking place, a detent is removed, and the bell at once commences to sound, and so gives the alarm to the inmates.

With this, we must now draw our observations and experiments, in connection with electro-telegraphy, to a conclusion. We have attempted to put our readers in possession of the leading facts of the subject; but have been compelled to omit many interesting particulars. It is impossible to regard the discovery of this mode of communication otherwise than as the greatest that has been made in this century, if all points are viewed. It has but one rival—photography; but that rivalry is more in the nature, rather than in the extent and value, of its applications. We may, for a moment, take a hasty glance at the advantages which accrue to residents in large towns; and, for example, we shall confine our attention to London, and its telegraphic connections. For a few pence, we can communicate our wishes to any part of the metropolis, and receive an instantaneous reply; the amenities of friendship, and the necessities of the household, can be simultaneously attended to, and communicated, over our housetops; and a conversation can easily be held between two friends, at any distance from each other, whilst both may be within their houses, if advantage be taken of the arrangements made by one of the telegraphic companies. The professional man can be called to the sick chamber at a moment's notice, or the relations and family friends suddenly summoned from all parts of the metropolis, to take a last farewell of a beloved one. The man of business has scarcely to conceive a new scheme, than all the arrangements necessary for its success can, in a few minutes, be made by communicating through the telegraph, to his agents in any part of Europe. Does he desire to receive even an amount of money, this the telegraph will send him. If he be anxious to change the intended destination of a vessel, to take advantage in a change of markets, this the telegraph can effect for him. A man can now as readily converse with his representatives in St. Petersburg, Vienna, Constantinople, Berlin, Madrid, and Paris, as he can with his neighbour in the next house to him. The politician can summon his adherents simultaneously from all parts of the kingdom and the continent, in cases of important divisions in the Houses of Parliament. The diplomatist may converse with his antagonist, and, at the same moment, receive instructions from his government, hundreds of miles away. Armies and navies, at the most distant places, can be commanded by the home authorities with as much readiness as by their commander on the spot; and, as we have lately seen, the two potentates of the two greatest nations on the earth—her Majesty the Queen, and the President of the United States—were enabled, by means of a slender wire stretched under 3,000 miles of the stormy ocean, to speak words of peace and good-will, as the representatives of two nations, using the same language, having brotherly ties, and divided, not in sentiment, but by position only. We may almost imagine that the triumphs of science can proceed no further. But we cannot forget that the realm of nature is boundless; and, despite all our successes and achievements, we have but entered the threshold of that storehouse in which are yet buried, but only to be discovered, wonders and truths, which, when brought to light, shall eclipse all our past discoveries.

DIA-MAGNETISM.

We shall now make a few remarks on an interesting branch of physical science, for which we are indebted to the researches of Dr. Faraday. In the early part of this work, we called frequent attention to the fact, that each of the undulatory forces had a distinct relation and connection with the rest; and the last link in this singular chain, is supplied by the facts of dia-magnetic phenomena. We shall find that even a ray of light may be subjected to magnetic influence; and thus our ideas of magnetism, and the objects to which it has affinity, will be much enlarged.

We have already explained, that a ray of polarised light has properties highly different to those found in common light. It will not obey the same laws; and presents, under certain circumstances, some very peculiar phenomena.*

If a ray of polarised light be sent through a mass of heavy glass—which, for this purpose, is made of borate of lead—it will, in ordinary circumstances, be transmitted; and if the glass be placed between the poles of an electro-magnet in an unexcited state, of course no change in any direction will be effected. The analysing plate is, however, to be so turned that the transmitted ray is nearly extinguished; and if the electro-magnet be then brought into action by the circulation of a voltaic current, the ray will instantly appear in full force. Or, supposing that, in the first instance, the ray had been in full force during transmission, and the electro-magnet be then excited, then the ray of polarised light would nearly suffer extinction. This fact at once shows that magnetism has a direct action on light, which, of all other agents, seems to have the least claim to be considered material.

---

* See *ante*, p. 80.

Dr. Faraday, however, extended his experiments, and was led to try how far a powerful magnetic force affected matter generally; and, in pursuit of this object, he discovered magnetic affection in numerous gases, liquids, and solids. These had a tendency of placing themselves in certain positions in reference to the poles of a powerful magnet, and the direction was definite for each substance tried. Gases and liquids were enclosed in glass tubes; whilst solids were chosen of such forms as were found to be most suitable for the purpose. By these investigations, we are enabled to classify all bodies, in reference to magnetism—iron, nickel, manganese, cobalt, cerium, chromium, platina, palladium, titanium, and osmium—having directly magnetic properties; whilst most others seemed to indicate an opposition to the magnetic force; or rather, under certain circumstances, range themselves in a direction at right angles to the lines of polar force in a powerful magnet—the metal bismuth being the most prominent in this respect. Such bodies have, from this fact, been termed *dia-magnetics.*

If some substances in the form of powder are placed between the poles of an electro-magnet, it will be found that the powder will rise up into a conical form, evidencing a peculiar effect of the magnetic force in relation to the forces of gravitation and cohesion. Another singular experiment, having the same result in a different form, may also be tried. A circular copper disc is mounted on an axle, and fitted with a winch handle: of course, it will readily revolve thereon in the usual manner. If, however, the rim of the disc be placed vertically between the poles of a powerful electro-magnet, the moment a current of electricity is passed, and the iron becomes magnetised, great resistance is offered to the revolution of the wheel. Now, generally speaking, we exclude the possibility of any magnetic effects being inducible on copper; but this experiment at once shows that the magnetic force can act on that metal in the method indicated; and herein we have another illustration of the universality of its action.

The subject of Dia-Magnetism is at present in its infancy. The results already obtained go towards proving that magnetism has a direct connection with the forces of gravity, cohesion, electricity, and light; and that every kind of matter is susceptible of its influence. These facts alone make the subject of deep interest, and extend materially our views of the possibility of the various kinds of forces being but modifications of one prime agent.

ADDENDA ON TELEGRAPHY.

Amongst a host of other objects which the Exhibition of 1862 brought prominently out to public notice, the numerous inventions connected with Electro-Telegraphy rank high in importance. We have made the following selections, as being of the most practical and highly improved kind. In our previous pages, we have frequently alluded to the difficulties of submarine telegraphy, the imperfect insulation of the wire, weight of the cable, &c. The failure of the Atlantic Telegraph has caused a vast number of inventions to be brought out; but, in most respects, that of Mr. Allan, whose electro-magnetic engine we have already described, is the most feasible. Its value was acknowledged by the jurors in their award of the prize medal; and, as the jury was composed of the most eminent men in connection with telegraphic affairs, we have no hesitation in endorsing their decision, by giving an extended description of Mr. Allan's cable, instruments, &c. We have to acknowledge his kind assistance in the matter.

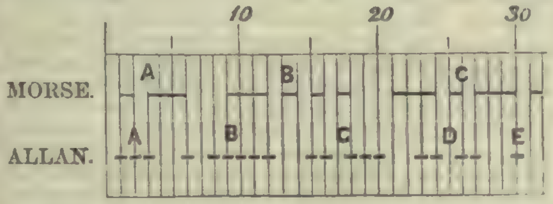
First, then, as to Mr. Allan's signal code. He rejects that of Morse, and adheres to the dot symbol alone for signalling and receiving. At the signalling extremity, a ribbon of paper has the dots separately punched by a machine; and in this prepared message, when passed into the apparatus for transmission, and the automatic action once commenced, each single punch-hole, as it passes over the tooth of a small rotating spur-wheel, permits of electrical contact being made within the sending-machine, and of thereby inducing a perfectly synchronous movement at the receiving extremity of the line wire, and of causing a puncture in the ribbon passing through the automatic apparatus there; so that, at the same instant of time, what is hole at one extremity is puncture or "emboss" at the other. Reverting, then, to the code of signals, and to the method by which the message is punched or marked on the paper ribbon. The apparatus employed is called a "Composing Machine." It consists of an oblong mahogany case, 11 inches by 8 inches, by 7 inches deep, wherein are mounted a set of keys, 30 in number, resembling those of a *pianoforte.* The letters of the Roman alphabet are printed on the touch-part of 26 of these, leaving four for purposes incidental to the working of the machine. Within the box, and movable by the key-levers, are eight punches. A ribbon of paper is made to pass through the composing machine. Now, any person who can read a message, has simply to spell out its words upon the keys by depressing each letter of the words, and its symbol in the code is punched out at a single stroke. This operation, which is perfectly simple, resembles the act of playing on the piano. The message, on being punched, is passed into the telegraphic instrument, which, from its automatic character, continues to work on, till the whole passes through; and the corresponding automatonism of the receiving apparatus is brought into play at the same instant. Further, any one may have his own "composing" or punching "machine," and adopt his own code of signals, by the very simple device of transposing the Roman characters on the touch-part of the keys. Secrecy is secured by this means; and the message on being punched, it may be, in a government or business establishment, if dispatched to the telegraph office, can be at once sent through to the confidential receiver of the same, who is in possession of the cipher to read the message, whilst the telegraph office-clerks know nothing whatever of its import. Further, this "composing machine," taken with the system of telegraphy of which it forms a part, possesses considerable interest to the newspaper press, as a probable means of cheapening what is a heavy cost in their annual expenses—namely, the telegraph despatches. One single punched ribbon may be carried continuously and simultaneously over any number of sending machines, and the same political news or parliamentary speech may be sent to half-a-dozen distant places from the same centre—say from London—at the same time; and all this can be done by so many boys as there are receiving places. Again, to receive messages depending upon either visual or audible signals, the clerk must always be in attendance; and when the distance is great, over land or water, so as to embrace many degrees of longitude, that attendance must be unremitting night and day. The clerk, in such a case, is a part of the instrument, and the complement of it; he can no more withdraw himself an instant than he can safely remove from its connections the telegraphic portion of the message system. By this automatic scheme, the attendant need not be always present. He may even go to bed; and when he awakes he may find the communications sent in the meantime in the message basket. Further, one attendant at each end of the line wire is all that is now needed; and the sender need be no other than a person of average intelligence, of little experience, and who can, as has been already said, read well. A boy or girl of twelve or fourteen years may do the sending work; and a moderate education and experience are all that is needed to receive, interpret, extend in writing, and distribute correspondence. A uniform charge for messages within a wide circuit belongs to the economy of this system, upon the basis of the plan adopted for our post-office. The Telegraph Company, according to Mr. Allan's scheme, should issue blank and file books; and any person possessing one such book, has only to write his message on a blank leaf, tear it out, envelope, and drop it into the office-box, when it has instant attention given to it. All this appears quite plain and possible, but the distinguishing features of the mechanism, conjointly with the electrical influence by which it is produced, is not so obvious. According to Allan's plan of signalling, the punctures or "embossings," on the paper at the receiving points, are made by the method of reverse currents, or the positive and negative electric currents are both made effective for marking; and the receiving instrument itself, without any expense of power, makes the distinguishing spaces between the letters; whereas, in other instruments of this kind, small spiral springs are introduced, for the quick and certain recovery of the deflected needle to the neutral position, in order to make spaces. This latter plan is also followed by Digney, a French maker of good repute; but it is objectionable for various reasons; and one of these is the superfluous demand that is made on the electric force to overcome a mechanical resistance, and the possible fluctuations and depressions of battery force, which, from the resistance of the spring, might destroy the signalling power. In the instances of the telegraphic instruments of other makers, reverse currents are employed instead of springs; but, with them, one of the currents is devoted to making the spaces, whereas Allan utilises both, as has been already stated, for marking. By this means he diminishes the number of currents sent through the line wire by upwards of 30 per cent.; and, on the other hand, the gain in point of time, by adopting altogether the "dot" system of marking, is about 50 per cent. This particular will be at once appreciated by the intelligent telegraphist at its proper importance, because, by the arrangement in question, greater signalling power is attained with relatively less expense of electrical force; and besides this, and with especial reference to the application of this plan to long-range submarine telegraphy, greater speed of transmission is also attained. But further, the effective workings of such instruments depend, amongst other things, upon the nice adjustment and suitable condition of the metallic surfaces, which are required to act by making and breaking electrical contact with each other. First, the sending or reversing break is here made to preserve clean contact by a rubbing action, which effectually wipes off any abraded matter which the spark carries over from one terminal point, and deposits upon the other and opposite point. In Allan's "relays," or pole changers, as these instruments may be called, this contingency is very ingeniously provided against. The relays are "sparkless;" and the small disruptive discharge of electricity which takes place on breaking contact is not produced in the relay at all, but in the recording instrument, where the mutual attrition of the metallic surfaces constantly preserves the parts clean. The importance that attaches to this particular will be apparent, when it is remembered that foul contact-points in the relay would soon reduce the action of the battery, which should work it, to inefficiency. By Allan's plan the power of the battery is preserved, and the machinery of the whole line kept open for the transmission of correspondence. Moreover, the absence of the spark in the relay admits of a great increase in the power of the local battery, and therefore of more efficient action in working; whereas the sparkling relay of other makers compels them to use only a very moderate power, so as to injure the operations of the instrument as little and as slowly as possible. This inconvenience, therefore, carries with it a limit upon the energy with which a telegraph line can be worked, without the risk of delaying its action for cleaning the relay at very short intervals of time.

The above gives a general description of Mr. Allan's signal arrangements: we shall now refer to his improvements in the construction of cables, especially those intended for deep-sea working. Near shore, Mr. Allan uses cables of considerable comparative thickness, so as to avoid the danger which always arises from the abrasion by rocks, and other sources of injury. The following observations, for which we are indebted to a valuable periodical, the *Electrician*, will afford the reader an insight into the improvements claimed for Mr. Allan's cable.

"Mr. Allan claims for his principle of deep-sea telegraph cable, that it combines the maximum of conducting power, insulation, strength, flexibility, and durability, with the minimum of weight, bulk, cost, and risk in submergence. He adopts the solid copper wire as giving the greatest amount of conducting power, with the least amount of inductive surface. The strand of copper wire used for ordinary forms of cable, presents considerably more surface than would be obtained with the same amount of conductivity in a solid copper wire; but it is found safer to sacrifice a small amount of speed, owing to the increased surface, than to run the risk of a fracture in the solid copper conductor. Having obtained the best soft solid copper wire, he surrounds it with small steel wires of the best quality, laid on with a slight spiral; and this forms the inextensible core or conductor, and also the strength of the cable. This core, or backbone of the cable, is then insulated with separate layers of gutta-percha, or india-rubber, or any other combination of the two; but it is Mr. Allan's opinion that none of the failures in deep-sea cables ought to injure the reputation of gutta-percha as an insulator; and his confidence in its suitability for submarine telegraphy remains unshaken, provided it be applied to the conductor with the necessary amount of care, and not submitted to any crushing or stretching process before it reaches its ocean bed. The insulated core is then clothed with a slight covering of hemp, or any other cheap material, saturated with marine paint; and this completes the deep-sea cable.

"The true mechanical test of a submarine cable is to ascertain the number of fathoms of its own length it will sustain in water without elongating to any serious extent. If the conductor, or metallic portion of the cable, be small, then the cable may sustain an enormous length of its own weight in water, and still not be at all suited for a long distance, because of the insufficiency of conducting power. In this respect Mr. Allan's cables were excellent examples, with a much larger conductor than most of the other light cables sent in for testing. Mr. Allan's bore a weight nearly equal to 7,500 fathoms without elongating one per cent.; and this may be taken as the weakest link in the chain, for joins in the steel wire abounded. This cable was also tested round a 12-inch wheel, to see if the core would cut through the gutta-percha; and although this ordeal was at least ten times more severe than it could be subjected to in submergence, not the slightest deviation from the centre could be detected."—The following is the report after the experiments were conducted (*Government Report*, page 28). "The results shown in the above table for Mr. Allan's cables are remarkable. In these cables the strength is given by steel wires laid spirally round the copper conductor, thus using the strength-giving material to form part of the conductor; the area of the conductor is therefore increased; and there is no danger of the conductor knuckling through the gutta-percha from the resiliency of the latter. This addition to the conducting area increases the induction of the cable in the full ratio of the increased area, but it only increases the conducting power of the cable in the proportion which the conductivity of steel bears to that of copper, which is about one-seventh. To obtain the same capacity for the transmission of messages in a cable of this kind, as in a cable in which copper forms the sole conductor, the dimensions of the conductor must be increased to give the same ratio of conduction to induction. The insulating material, of course, requires protection in these as in other cables." The latter portion of this report we consider scarcely correct. We have now before us a specimen, in which the compound conductor has no greater surface than the ordinary copper strand of the same conducting power. We intended giving an illustration of this principle of cable, but it is so few in parts, that we can readily convey it to our readers, by simply saying that it is composed of a No. 8 soft copper wire, surrounded with 25 No. 25 best steel wires; this is insulated with four separate coatings of best gutta-percha, and then finished in a skin of hemp, merely to protect it during submergence; the conducting power of the core is equal to 520 lbs. of copper, and it is insulated with 550 lbs. of gutta-percha per nautical mile; in diameter, it measures five-eighths of an inch; weight per naut. in ship is 13 cwt., with a specific gravity of 1·7; and it is calculated to bear 7,500 fathoms of itself in water, without elongating one per cent. "Mr. Allan considers this cable suitable for a distance of 2,000 nautical miles, and a depth of 3,000 fathoms, the shore ends of course to be heavily protected. A cable of this description has the great advantage of being very simple to manufacture; in fact, it could be entirely finished by the manufacturer of telegraph cores. There are many instances of the gutta-percha core receiving injury during the process of iron wire covering, which have only been detected after the cable has been submerged."

The following cut illustrates Mr. Allan's method of recording messages, for use either on land or submarine telegraphs. As previously mentioned, the dot system, which he prefers, saves considerable time in transmitting the message.



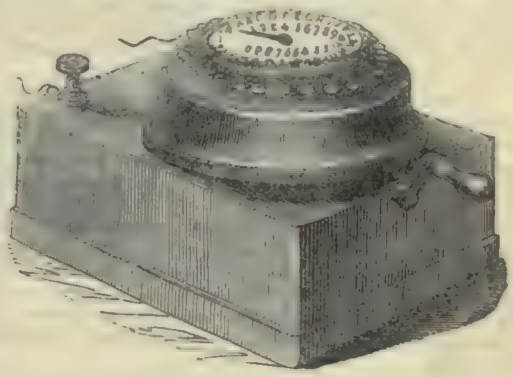
In the cut, Morse's system is compared with that of Mr. Allan's; and it will be seen that the latter has the advantage, in respect to space occupied on the receiving-tape, and that the code of signals is entirely different. The length of the dash is done away with, and the space between them economised. In Allan's arrangement, 126 currents produce the alphabet; against 164 required in the instrument employed in the system of Morse. The proportion of time is as 196 to 290 for the whole alphabet; and as 33 to 49 for a word; or generally about fifty per cent. is saved.

Tyer's Train Telegraph.—The numerous accidents which have taken place, owing to trains overtaking each other on the same line of rail, have given rise to numerous inventions, intended to prevent the recurrence of such casualties. Amongst them, we may notice Tyer's patent train telegraph. In this arrangement, a dial-face is placed at each station, on which needles are worked by electro-magnetism. A bell and gong are also provided, for calling the attendant's attention. The dial-face is divided into two parts—one for the up, and another for the down line; and on the right and the left of the face, the words "Train on Line," and "Line Clear," are engraved. According to the system adopted in this plan, each signal station communicates with the signal station on each side of it, so as to announce both the approach and departure of each train. The receiver of a signal cannot alter it; and a signal once given remains fixed, until the next signal is sent. The line of railway is divided into sections by the signal stations; and no train is permitted to pass one of the stations until the signal has been received that the next station in advance is quite clear. The mechanical arrangements are extremely simple, and the system itself is equally so. Its universal adoption would doubtless go far to prevent the possibility of collision by trains overtaking each other during a long journey. On short station-lines, such a plan would seem to be indispensable.

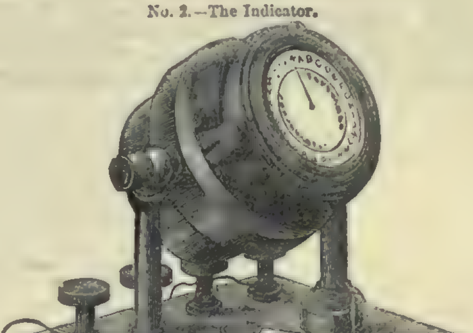
Wheatstone's Private Telegraph.—Much of the credit of all our telegraphic arrangements in this country is due to Professor Wheatstone, who, for many years, has been indefatigable in his exertions to bring the system into a state of perfection. The first attempts were confined to connecting our large cities together by means of telegraphic wires. Another step was that of extending the telegraph, by means of submarine cables, to foreign countries. Eventually, large warehouses were furnished with telegraphic apparatus, by which much time was saved by the telegraph doing the work of messengers. District telegraphs were another development of the system; and, at last, the Universal Private Telegraph Company has stepped in to give private individuals the opportunity of using the electric current for the expression of their wishes in any direction, and under their sole control. We can well remember hearing it said, somewhat derisively, some years ago, by a learned but crotchety professor, "that some day, electric wires would be as common in London as gas and water-pipes." This prophecy has been exceeded in its fulfilment; for the number of electric wires in many streets of the metropolis, far exceeds that of the pipes of both classes we have named.

It is, of course, requisite that the instruments employed in private houses should be so simple, both in their working and indications, as not to be liable to get out of order, or to require much practical knowledge in

No. 1.—The Communicator.



No. 2.—The Indicator.



reading them. These two desiderata have been accomplished by Mr. Wheatstone. The instrument consists of two parts—the communicator and indicator—on each of which the letters of the alphabet, and numerals are engraved, in the form of a disc. By means of a needle, actuated by electro-magnetic machinery, the words of the message sent by the communicator are spelt, letter by letter, on the indicator; the former instrument being in possession of the sender, and the latter with the receiver; the current is conveyed by wires, suspended in the air—in one bundle or rope, which may be made to enclose almost any number, from their small sectional area. Round the discs of both instruments, as many keys are placed as there are letters; and being pressed down, as each letter required is arrived at, in the rotation of the needle, they indicate the letter which has been telegraphed. The electric power is obtained by a modification of the magneto-electric machine—that is, by magnetic induction; and thus, the expense and nuisance of a voltaic battery are obviated. The preceding engravings will give a general idea of the instrument.

Special instructions are given as to the arrangement of the apparatus before sending a message; and the earth is used for the return current, as in the ordinary method of telegraphy.

The instruments, and use of the wires, are charged for by an annual rental. And thus, any two individuals, having agreed to employ the apparatus, and having had it suitably fixed, may carry on a correspondence, either in letter or cipher, entirely between themselves, and without the possibility of their secrecy being invaded by curious telegraph clerks, or interested parties. This is, of course, ensured by the use of separate and isolated sets of wires for each set of telegraph instruments.

Such inventions as these cannot fail to be of great benefit, in a social, commercial, and political point of view. In great cities, it is of extreme importance that police, military, and fire-engine stations, should have instantaneous means of communication; and these are at once afforded by the private telegraph system.

BALLOON TELEGRAPHS.—During the long wars of France, Napoleon conceived the happy idea of employing balloons for the purpose of surveying the enemy's lines; and the same plan was adopted by the Federals during the unfortunate internecine struggle between the American States in 1862. A most important addition, however, was made in the application of the electric telegraph. The balloon was connected by means of wires with the earth, and thus a continued communication was kept up between the observers and their attendants on *terra firma.* By this ingenious plan most valuable information was obtained, and the course of the campaign materially influenced.

SIEMENS' ELECTRIC RESISTANCE THERMOMETER.—This peculiar arrangement, primarily intended to test the temperature of large coils of submarine telegraph wires, in cases where spontaneous heating was feared, is an adaptation of the laws of resistance in conducting-wires, the resistance being measured by means of an ordinary galvanometer. It is equally applicable to the discovery of heating in masses of hemp, &c., which have frequently caused disastrous conflagrations. We are indebted to the *London Review* for a description of its arrangement.

The apparatus consists of a differential galvanometer and of a bath of water (or oil), the temperature of which can be changed at will by opening one or the other of two cocks, the one bringing a supply of cold, and the other a supply of hot liquid, an overflow pipe being provided to prevent accumulation. A battery of from four to eight cells is also provided, besides a number of electric coils, consisting each of a certain length of thin insulated platinum wire inclosed in a sealed metal tube.

These coils having been carefully adjusted, in the first instance, so as to offer equal resistance at one temperature, are connected to insulated copper leading wires of comparatively large sectional area (No. 16, B. W. G.), the ends of which are brought to the binding screws of the apparatus, to be inserted, when required, into a circuit including the battery and the galvanometer. These "thermometer coils" are deposited at the places where the temperature is to be observed, excepting one which has to be reserved for comparison with the others. This last-mentioned coil is, through its leading wires, so connected as to form an electric circuit with the battery and the second coil of the differential galvanometer, and is immersed in the bath before mentioned. It is evident, that if the temperature of the bath should be the same as that of the place where the thermometer coil under examination is deposited, the two electric currents proceeding from the battery will meet with equal resistance in the two circuits, and, in passing two spirals of the differential galvanometer in opposite directions, will produce no visible effect upon the needle. If, however, the temperatures of thermometer and balancing coil should be unequal, the needle will be deflected by the preponderance of current in the cooler circuit, showing, by the direction of its deflection, whether cold or hot water should be added to the bath to establish equilibrium of currents. When this equilibrium is obtained, the temperature of the bath is observed by means of an ordinary mercury thermometer, which temperature must be identical with the temperature at the distant place.

In dividing the "thermometer coils" into two portions, the apparatus is rendered applicable for observing wider ranges of temperature than can be directly attained by the mercury thermometer, and in this modified form it may be used for pyrometrical purposes. In measuring ordinary temperatures, the employment of equal and undivided coils is, however, not only the most simple arrangement, but it has the advantage in its favour, that the accuracy of the observation is not dependent upon the rate of variation if resistance be uniform, or even accurately determined. The heat produced in the coils by the electric currents employed, affecting the two coils equally, is also completely compensated in using equal coils.

SECTION V.

ACOUSTICS, AND ITS APPLICATIONS.

CHAPTER I.

THE PRODUCTION OF SOUND.

Although we can scarcely consider the phenomena which are usually ranged under the term "Acoustics," as resulting from a purely undulatory force—the analogy which exists between the production of sound, and light and heat, is so great, as to permit of our including its laws and applications under that head, if we do so only by way of analogy.

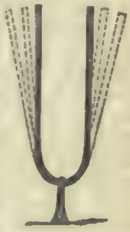
We have previously observed, that the vibrations of the atmosphere are really typical of those of the supposititious ether to whose undulations we assign the production of light; and our readers who have perused our previous remarks, will therefore be prepared to enter on a careful examination of the various conditions to which sound is subject.

In the experiments and remarks we suggested in connection with the subjects of Heat and Light, we had occasion to discuss the effects of reflection, radiation, and conduction on those agents; and, to a large extent, we shall find sound obedient to the same laws. Whenever motion is conveyed to a body, it partakes of the force imparted to it; and the result is, that heat, light, electricity, magnetism, and, almost universally, sound, is individually produced. If we take, for instance, the common process of striking a lucifer-match, we find sound first perceptible to the senses; then heat and light are observed; and, lastly, electricity may be discovered as having been set free, if the electroscope be employed to detect its presence.* Our present subject will therefore form a kind of corollary on all that have preceded it; and as such we shall treat it, including, however, many applications specially incident thereto.

The production of sound is so familiar to all our readers, that we need scarcely draw their attention to it. We cannot, however, fail to notice, that there exists a vast diversity in the sounds we hear. Thus, if a piece of wood or stone be struck, we simply notice a dull, heavy sound, entirely devoid of musical intonation, providing the bodies be struck in large irregular masses. If, however, they have certain definite shapes, and their lengths and thicknesses increase and diminish in definite ratios, then we hear graduated sounds. These may be produced by percussion—as in the case of the pianoforte, the strings of which afford "music" on being struck by the hammer or by simple vibration; as we observe in the cornet, the flute, and other wind instruments.

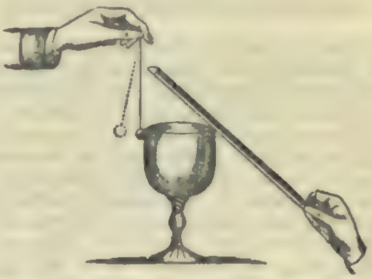
Now, in any case where sound is produced, such results simply from the vibration of the particles of the body which gives it; and the common tuning-fork, perhaps, affords us the best illustration of this fact. If the fork be struck against any hard body, then its prong at once vibrates, and, in so doing, it causes the air next to it to vibrate also. We hence have a successive series of waves afforded, just as we observe the same effect produced on casting a stone into still water. Now, just as a succession of circles passes from the spot at which the stone arrived on the surface of the water, so the same result occurs when a sounding body is put into motion. This is illustrated, so far as sound is concerned, in the annexed engraving, which shows, by the dotted lines, the vibrations which the metal of the tuning-fork undergoes after percussion. The body, however, must be elastic to produce sound: thus a piece of clay scarcely affords sonorous waves, because it has but a very slight amount of elasticity. If, however, a glass vessel of any kind, which is elastic, be struck, it at once produces and propagates in the air a series of waves, or vibrations; and these reaching the ear, so far act on that organ as to make it sensible to the sounds produced.

Fig. 1.



That an elastic body really vibrates when it is put into sufficient motion to produce waves of sound, is most readily proved: and the following engraving shows a very neat method of proving this fact. For this purpose, place a thin glass tumbler on any firm support, and hang a small wooden ball, by means of a thread, from any support, or by the hand, so that the ball may just touch the rim of the glass; then draw a violin bow against the rim of the glass. The vessel will thus be set into vibration; and the ball, resting against the rim, will be repelled, and oscillate for some considerable time. The mode of carrying out this interesting experiment is illustrated in Fig. 2; in which the straight line represents the cord holding the ball as suspended from any support, and the dotted line shows its vibration. The success of the experiment will depend on the glass rim being quite clean; and the bow should be well rubbed with resin, to afford as much friction as possible. Confining our attention for the present to the vibration of solid bodies, we may suggest a very instructive and pleasing mode of illustrating the production of musical sounds by means of glasses of various sizes. If eight finger-glasses, or tumblers, are placed on a hollow square box, and they be chosen so that they may have a relative size (of which we shall speak more fully hereafter), a series of musical sounds may be readily produced, which accord with an octave, or eight successive notes of any musical instrument. The sounds are given off on the edges of the glasses being rubbed by the finger, which has

Fig. 2.

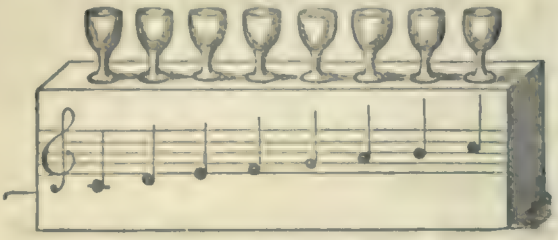


---

* See *ante*, p. 176; Fig. 16.

previously been wetted by a little lemon-juice, to give it a degree of roughness. The finger should be gently but firmly rubbed round the rim of each glass; and the arrangement of which we speak is illustrated in the following engraving—the octave succession of notes being also indicated. The effect produced by the action of the finger, is exactly similar to that afforded by the bow in our last illustration. The glasses are caused to vibrate, and the production of sound is the natural result.

Fig. 3.



We might add, to a great extent, various illustrations of the production of sound of a musical kind, by means of vibrations of the atmosphere and solid bodies. The Æolian harp is an instance in which the air, moving through the intervals between wires of different thicknesses, produces such results. Even the wires extended on the poles observed by the sides of our railways, for telegraphic purposes, often afford, by their vibration, what we may venture to call a wild kind of music. The striking of a gong, and similar instruments, on the other hand, afford instances in which sound is produced by the vibration of solid bodies, subsequently propagated through the air. Wind instruments of all kinds produce these effects on the ear, by a combination of the vibrations of their solid parts with those of the surrounding atmosphere. Having thus spoken generally of the production of sound, we shall now refer to its conduction through various media.

THE CONDUCTION OF SOUND.

We have already remarked, that whenever vibrations are produced, affording sound, the waves of sound are propagated by the surrounding bodies. But this depends on the elasticity of those bodies; as many substances—to use a common phrase—stop sound; that is, they prevent its passage, being incapable of continuing the vibrations which have arrived at them. This is taken advantage of in the erection of astronomical instruments, which, from the vibrations of adjacent bodies, would become so unsteady as to be perfectly useless. But if a telescope, of high magnifying power, be mounted on a clay and leaden foundation, the vibrations of surrounding bodies are stopped, and cease. The same materials, with many others, equally oppose the propagation of soniferous waves; and may, therefore, to some extent, be termed non-conductors of sound. The atmosphere permits the passage of sound at the rate of about 1,140 feet per second; that is, the sonorous vibrations of any body will not be perceived by the ear in less than a second of time, if 1,140 feet of air interpose. We find, however, that water, and many solids, convey sound much more rapidly than air; and if we make the rate of conduction in the air the standard of comparison, the following will show the relative powers of various substances:—

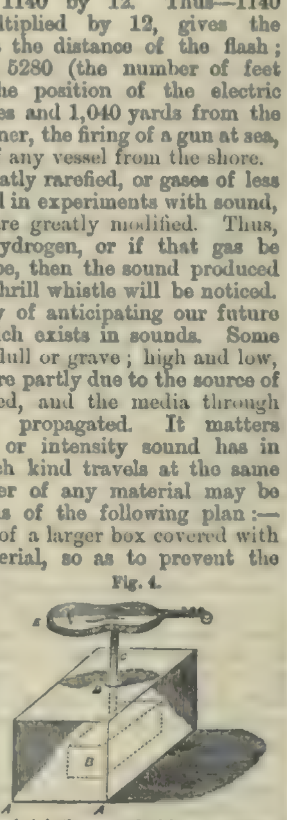
Air	1
Water	4
Tin	7½
Silver	9
Copper	12
Iron	17
Glass	
Various kinds of woods, 11 to	

Most of our readers must have noticed, in daily experience, how differently bodies conduct sound. Thus, if a long row of iron railings be struck at one extremity, the sound produced is heard at the other end long before it would be conveyed by the atmosphere.

The temperature and density of any medium, have the effect of modifying its conducting power; and this is most readily observed in the atmosphere. The rate, however, which we have mentioned, is pretty nearly uniform for all ordinary atmospheric changes; and, for this reason, the conduction of sound may be employed as a means of measuring distances. This depends on the fact that light travels infinitely faster than sound; requiring, as it does, no more than one second of time for traversing a distance of 192,000 miles. To illustrate this mode of ascertaining distances, we will suppose a flash of lightning to be seen, and that twelve seconds elapsed before the sound of thunder was heard. Presuming 1,140 feet per second to represent the rate at which the atmosphere conveys sonorous waves, we shall ascertain the distance of the place at which the flash occurred, by multiplying 1140 by 12. Thus—1140 (the rate of sound) multiplied by 12, gives the number of feet (13680) as the distance of the flash; and this sum, divided by 5280 (the number of feet in a mile), shows that the position of the electric discharge must be two miles and 1,040 yards from the observer. In a similar manner, the firing of a gun at sea, may indicate the distance of any vessel from the shore.

If the atmosphere be greatly rarefied, or gases of less specific gravity are employed in experiments with sound, then the resulting effects are greatly modified. Thus, if a person breathe pure hydrogen, or if that gas be blown through an organ-tube, then the sound produced will lose its volume, and a shrill whistle will be noticed. We may here state, by way of anticipating our future remarks, the difference which exists in sounds. Some are sharp or acute; others dull or grave; high and low, &c.: and these differences are partly due to the source of vibration, the body vibrated, and the media through which the vibrations are propagated. It matters not, however, what pitch or intensity sound has in respect to its speed, as each kind travels at the same rate. The conducting power of any material may be readily illustrated by means of the following plan:—Place a musical box inside of a larger box covered with baize, or any woollen material, so as to prevent the passage of sound from its inside. A hole should be bored in the top. Into this insert a wooden rod, so that it may rest on the musical box. If a violin, or empty box of any kind, be then placed on the outer end of the wooden rod, the sounds produced by the box will be distinctly heard. On removing the violin from the rod, the sound apparently ceases. This is owing to the wood conveying sonorous vibrations from the musical box, and the subsequent diffusion of them through the air by means of the violin. The mode of carrying out this interesting experiment, is illustrated in the above engraving.

Fig. 4.



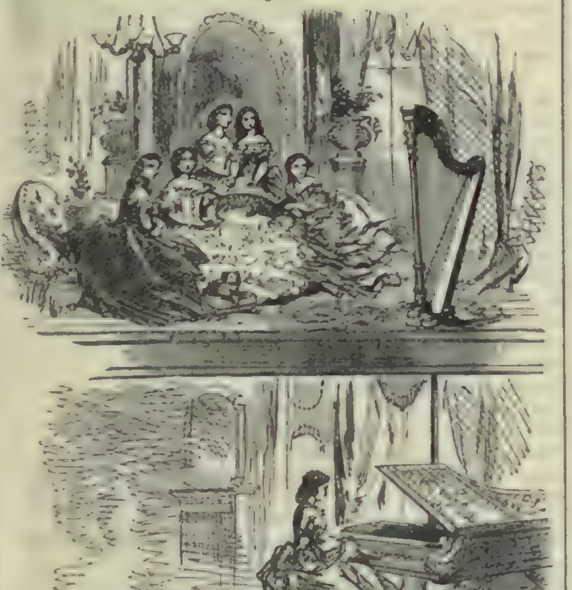
A A is the outer deal box, enclosing B, the musical box; C is a deal rod, through the hole D, resting on the musical box; E is a violin for diffusing sound.

This experiment also illustrates the use of sounding-boards, as seen in the piano, harp, violin, &c.; for it is not only essential that sound be conducted by a sufficient material, but also that an adequate diffuser be also present.

The stethoscope is constructed so as to convey the sounds of the beating of the heart, &c., to the ear of the person employing it: and a very common plan of ascertaining the regular supply of steam to each end of the cylinder of a steam-engine, is that of placing a wooden rod against the cylinder—biting it with the teeth, and closing the ears. The vibrations are thus conveyed to the ear by means of the conducting-rod. If a musical box be placed at a considerable distance from the ear, so that its tones can scarcely be heard, and afterwards a deal rod be placed with one end on the box and the other between the teeth, the sounds previously inaudible will be readily perceived, through the conducting power of the wood. In a similar manner, a poker, if hung by means of a piece of string held in the teeth, will produce a powerful sound when struck by a hammer or other body.

A very ingenious application of these principles was made, some years ago, by Professor Wheatstone, of King's College, London. He conceived the idea of conveying musical sounds from any instrument into a distant apartment; so that a "supply" of music might readily be laid on in each room of a house, if rods were attached to any instrument, and fitted with diffusers, such as we have illustrated in the last engraving. The plan was practically carried out at the London Polytechnic. In the basement of the building, a pianoforte, cornet, and violin were played; and from each a deal rod was carried, to a height of 40 feet, into the upper lecture theatre. On each deal rod a harp was placed; and by these means the sound produced by each instrument was at once diffused. The effect was singular and interesting, for each instrument was distinctly heard by itself, or in concert with the rest; the music, however, all proceeding from the sound-diffusing harps. In a similar manner the sound of human voices was also conveyed; the singers being placed with their mouths close to the sounding-board of the piano in the basement, and the harp answering as the diffuser in the lecture theatre. The following engraving shows how the same plan may be carried out in any two apartments in the same house.

Fig. 5.



The pianoforte and the performer are to be placed in a lower apartment, and the audience and diffusing-harp in the upper one. A deal rod rests on the sounding-board of the piano, near C treble; and the harp rests on its upper extremity. So long as this arrangement is maintained the performance is distinctly heard; but if the harp in the upper apartment be removed from the deal rod, the sound instantly ceases. A violin or empty deal box answers just as well as the harp for diffusing the sound.

If a musical box or bell be placed in the receiver of an air-pump, their sounds will be audible until the air be exhausted; but then, owing to the absence of any medium by means of which their vibrations may be conducted, the sounds are entirely lost; but if the air be allowed again to pass into the receiver, the sound becomes immediately perceptible.

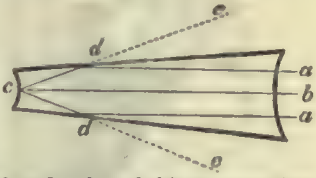
With respect to the greatest distance at which sounds can be heard in air, much depends on the state of the atmosphere. Bells of churches on shore, have been heard many miles out at sea; and the report of cannon has been noticed at astonishing distances. Sound is also well conducted by rocks; and the noise of the pickaxe of the miner may be heard by another person at a long distance off, owing to the vibrations being conveyed by the solid rock.

THE REFLECTION OF SOUND.

THE analogies between heat and sound are very evident, for they can each be conducted, and also reflected, by proper means; and having spoken of the conduction of sound, we shall now proceed to show by what means it may be reflected: and thereby explain the cause of echoes, and the construction and use of some acoustic instruments. Two concave reflectors, made of tin or zinc, will be required for some of the experiments we shall mention. They may be of a similar shape and size to those illustrated in a previous page.*

It may facilitate our progress, if, in future, we employ the term "ray" to the emanations, or waves of sound, proceeding from any source. This will also enable our readers to connect the laws of the reflection of heat and light with those of sound, and also to become acquainted with the analogy existing between them. If a ray of sound impinge on a plane reflector, such as an even wall or a sheet of glass, it will be reflected therefrom in a similar manner to one of heat or light; and the angle formed by the incident ray will be equal to that of the reflected ray. By pursuing this law, a variety of applications of it may be made in the construction of such instruments as the speaking, hearing-trumpet, &c. The annexed engraving illustrates the mode in which the voice of a man may thus be sent to a great distance by means of the former instrument. The external part of the figure represents the speaking-trumpet, usually employed on board ships: *a a* are two rays of sound, which have been reflected from *d* after proceeding from the mouth, *c*. Now, had not the reflecting surface of the trumpet been present at *d*, then the sound would have radiated off towards *e*, and only that ray proceeding in the direction *c b* would have reached the ear of a person at a distance. But by means of this tube, all rays passing from the mouth, *c*, otherwise than in a line parallel to *c b*, impinge on the sides of the tube, and are thence reflected therefrom in lines which are parallel to *c b*; and so a larger number reach the ear by the use of this arrangement.

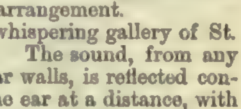
Fig. 6.



On the same principle, the whispering gallery of St. Paul's Cathedral is constructed. The sound, from any source, impinging on the circular walls, is reflected continuously, and at last reaches the ear at a distance, with a very slight diminution of effect. Echoes are similarly caused by the successive reflection of any sound from the walls or rocks, placed in such positions with each other, that any ray impinging on them may be readily reflected. Just in proportion to the length of such reflecting surfaces, and the number of incidences and reflections the sound makes, so the number of echoes occurs.

The principle of the successive reflection of sound is illustrated by the annexed engraving, which represents the half of a whispering gallery. We will suppose a sound to proceed from *a* to *c*; it may then be again reflected from *c* to *d*, or to A. Similarly, a ray of sound, proceeding from *b*, may be heard at *c b*, and reflected again to *d* or A. If the whole circle be formed, then the reflections, whether short or long, will be produced over the entire circular

Fig. 7.



---

* See *ante*, p. 27; Fig. 6—Section, "Heat."

wall; and an ear, placed in any portion of it, will hear them distinctly. If a concave reflector be so placed as to receive the rays of sound from a source at its focus, and another reflector be so arranged at a considerable distance from the first, but so that their foci shall be in one straight line—then all the sounds proceeding from the first reflector will be received on the face of the second, and be again reflected to its focus. If the ear be placed at that spot, all the sounds proceeding from the distant reflector will be distinctly heard, and yet none will be audible at any place intermediate between the two foci. Again, even if much noise be made on all sides of the reflectors, still the sounds at the focus will be readily distinguished, although they may have passed through a considerable distance of intermediate air. A very similar result is produced when heat is reflected, as has been shown under that section.*

On the principle of reflection, speaking-tubes are constructed, which simply consist of pipes having an even internal surface. The sound is reflected from side to side until it reaches the other extremity of the tube. These arrangements are largely employed in the warehouses, &c., of our cities, and are a great saving of time and trouble. An amusing effect may be produced by a modification of the speaking-tube. Two tubes may be inserted in a head of wood, or plaster—one communicating with the mouth, and the other with the ear of the figure, in the manner illustrated in the following engraving. A tube is carried into an adjacent room, and, of course, a person must there listen and reply to any inquiries whispered in the ear of the figure. The reply is received by listening at the mouth of the bust. This resembles what has been termed the "invisible lady," which, however, was first introduced to the public as an acoustic toy, in the following form.

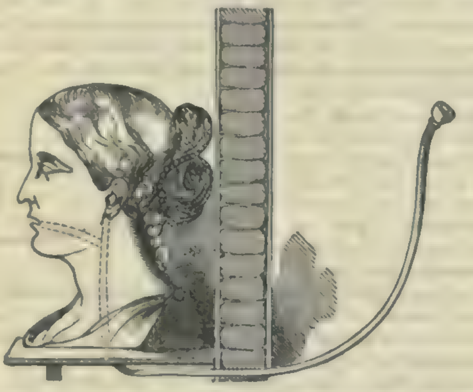

Fig. 9.

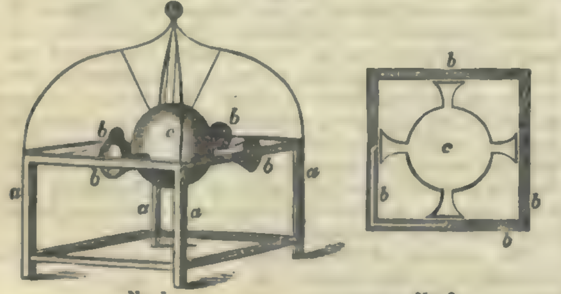


No. 1. No. 2.

No. 1, Fig. 9, represents the apparatus in its general appearance. It consists of a wooden frame, *a a*, supported on four pillars, from one of which a tube passes (as in our last illustration) to an adjacent room; *c* is a copper ball from which the tube proceeds; and *b b b b* are four openings in the side of the ball. These are shown in section, in No. 2. The mode of using the arrangement is precisely similar to that we have just mentioned in connection with the preceding illustration.

MUSICAL SOUNDS.

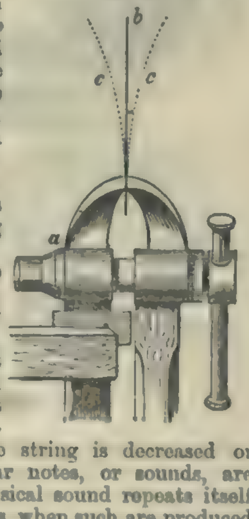
We shall now call attention to some of the laws observed in connection with the production of musical sounds; having already explained the general results obtained by the vibration of the air, and the conduction and reflection of those vibrations by means of suitable media and surfaces.

Of all the pleasures derived by our senses, those of music are the most refining and elevating. They appeal alike to the mind and the sentiments; at times, soothing the troubled spirit, and yet often rousing into action the military ardour of the soldier. It is, indeed, surprising to observe the extensive influence which musical sounds exert, whether they are produced by instruments, or by the voice of man or birds. The ancients were so impressed with this, that, amongst all their leading allegories and mythological fables, many relating to the power of music are included. The well-known tale of Orpheus, who was said to have charmed the very stones; and the influence ascribed to Apollo, the god of Music, over the gods and men—are instances, out of many others, of the kind.

We shall divide this portion of our subject into two parts. The first will deal with musical sounds as produced by instruments: and this will be followed by an account of the physiology of animal voice; for which we are indebted to Dr. Bushnan. It has already been remarked, that all sounds are caused by vibrations, but that such differ according to the body from which they proceed. Besides, the sounds so produced vary from each other in tone, and other particulars, according to certain definite laws, which we will now inquire into.

If a piece of steel be tightly held at one extremity, and then struck, it will, of course, vibrate, and, in so doing, will produce sound. If the length of the steel beyond the part at which it is held be decreased, then such sounds will become sharper. On the other hand, if the length be increased, then the sounds produced are duller, and deeper in tone. A very convenient way of trying this experiment is represented in the annexed engraving; in which *a* is an ordinary vice; *b* a piece of steel ribbon; and *c c* are dotted lines, showing the vibrations produced on the steel. The steel extremity, beyond the top of the vice, can be lengthened or shortened, by passing it, more or less, through its sides or cheeks, as may be required for altering the sound.

Fig. 10.



In trying this experiment, the reader may, by a little care, produce not only an apparently extensive range of sounds, but, in so doing, will notice, that at certain intervals the same kind of sound is reproduced; but either sharper or lower, according as the length of the string is decreased or increased. Now, these similar notes, or sounds, are termed octaves; that is, a musical sound repeats itself at every eighth set of vibrations, when such are produced according to certain rules. But intermediate to the notes forming the extremities of the octave, there are others which, to some extent, harmonise with them: such are termed thirds and fifths, owing to their relative position with that of the first or last octave note. This may readily be tried on a pianoforte, by placing the fingers on two successive C's, and then striking the following E and G. If the three notes be then struck together, the effect of their harmony will be at once apparent.

Another mode of trying the effect of increasing or lengthening a vibrating cord, is that of stretching tightly a piece of catgut between any two points. If this be vibrated it will produce sound, as usual. If it be halved in its vibrating length, by placing the finger on it and pressing it down, midway between its two extremities, then a shriller note will be produced, which will be an octave higher than that afforded by the long cord. If, again, a piece of steel be pressed against a rapidly revolving tooth-wheel, a certain sound will be produced; but if the tooth-wheel be made to revolve twice as fast, then the previous sound will be raised an octave.

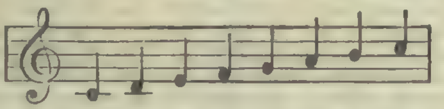
---

* *See ante*, p. 27; Fig. 6.

From these experiments we learn, that the tone of any sound—that is, its shrillness or dullness—depends on the number of vibrations produced in any similar period of time; and that these, again, depend on the length of the vibrating body—the number of vibrations being inversely as the length of the vibrating body. This will be more easily understood if our readers will notice the length of the different strings in a harp, or pianoforte. It will be found, that those which produce shrill sounds, are invariably the shortest; and the deeper the sound, the longer the string which produces the vibration. Violin players are thus enabled to obtain any variety of the sounds of other musical instruments, by means of the rapid movement of their fingers over the strings; for they are enabled to shorten their lengths, so far as the production of sound is concerned.

We shall confine our illustration of these principles to the eight notes in the treble clef forming an octave—from C below the lines, to C on the third space, as represented below. To each of the notes we have appended their names, for the assistance of those of our readers who do not understand music. When, however, an instrument, especially a pianoforte or harp, can be had access to, such will materially aid in making our remarks understood.

Fig. 11.



English names ... C D E F G A B C
Italian do. .....do re mi fa sol la si do

Now, the sounds of each of these letters, in Fig. 11, are produced by a definite number of vibrations, and the length of each string. Thus, that affording C vibrates 240 times per second; whilst the upper, or octave C, will vibrate 480 times per second. The length of the string producing the low C, may be 45 inches; whilst that producing the upper C, will be but 22½ inches. Each of the other notes will proceed from an intermediate length of string and number of vibrations. The following table gives the value of each of these—commencing with the lower C. Some consider that 256 vibrations equal C. We have chosen the lower number, for the purpose of avoiding fractions; but the reader can easily calculate a table on that standard, by using the table, or ratio, which follows this.

Name of note.	Length of cord in inches.	Number of vibrations per second.
C	45	240
D	40	270
E	36	300
F	33¾	320
G	30	360
A	27	400
B	24	450
C	22½	480

The law of the relation existing between the number of vibrations, the length of the cord, and the nature of the sounds produced, is thus at once made evident. The ratio existing between each of these is shown in the following table—commencing with low C, as before, it being the standard.

Name of note	C	D	E	F	G	A	B	C
Ratio of the length of the cord	1	$\frac{8}{9}$	$\frac{4}{5}$	$\frac{3}{4}$	$\frac{2}{3}$	$\frac{3}{5}$	$\frac{8}{15}$	$\frac{1}{2}$
Ratio of vibrations .	1	$\frac{9}{8}$	$\frac{5}{4}$	$\frac{4}{3}$	$\frac{3}{2}$	$\frac{5}{3}$	$\frac{15}{8}$	2

From which we perceive, as before stated, that the length of the cord is inversely as the number of vibrations, and *vice versâ*. We have already observed that harmonies are afforded when certain sounds are produced together. This occurs when C, and G (below), which are five notes apart, C, and E (above), which are three notes apart, and C, E, and G, are struck together—forming, as they do, a chord in which thirds and fifths are combined. The effects of such combinations are naturally pleasing to the ear: but this is not a pure matter of taste only; for if some pieces of paper are allowed to fall on strings thus vibrating, they will arrange themselves in such positions as will accord with those of the length of the octave, the third, and fifth, pointed out in our last table. We shall refer to this again when speaking of acoustic figures.

We have confined these remarks to stringed instruments only; but they are equally applicable to those in which wind is alone employed. Thus, in the organ, the length of the pipes corresponds to the length of the string in the pianoforte, because they enclose a similar length of air; and it is the vibration of this which causes the sound of different notes. In the flute, cornopean, &c., the length of the column of air is regulated by the skill of the performer; hence the difficulty experienced in acquiring the art of blowing those instruments properly. Many instruments, of entirely different kind of construction, such as the harmonium, concertina, the pan-pipes, bells, &c., all owe the production of their various notes to the laws we have here explained.

The diffusion of sound, from an instrument producing it, is effected by means of a readily vibrating body. Of such kind is the sounding-board of the piano, harp, violin, &c. We have already mentioned various facts relating to this subject, and must therefore refer our readers to our previous remarks.* Great variety exists in the power, sweetness, and other qualities of instruments. Thus the flute and the cornopean, although each producing their sounds directly by the vibration of the air, convey entirely different effects to the ear. The same may be said of the violin and harp, amongst stringed instruments. These results chiefly arise from the nature and quality of the material employed, and the skill exhibited in their construction. A fastidious, or rather educated musical ear, can detect great differences in this respect; and even to persons with no special musical taste, it is by no means difficult to distinguish the tone of the same kind of instruments made by different manufacturers. It is, however, no part of our plan to enter into such details; our object being solely to illustrate the principles of which we have been speaking.

Despite the perfection of many of the musical instruments of our day, we still cannot arrive at the production of that richness, body, and flexibility of tone which is found in the human voice; and we shall now avail ourselves of Dr. Bushnan's remarks in illustration of that portion of our subject; in which he also explains the organs on which the sound-producing powers of animals and birds depend.

THE PRODUCTION OF ANIMAL SOUNDS.

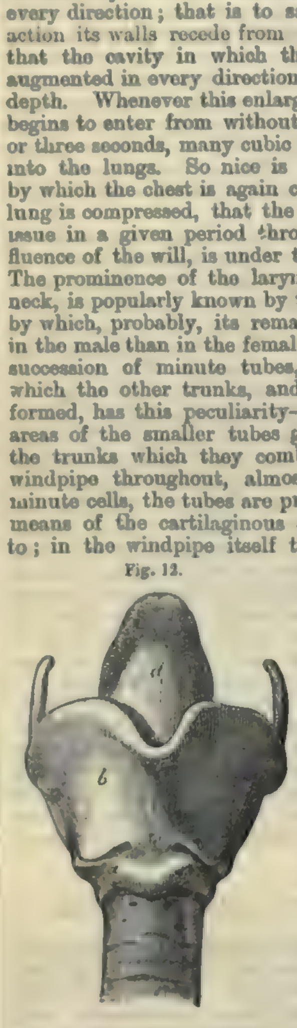
Organs of Voice and Speech in Man.—The organs concerned in voice and speech may be described as the chest and lungs, the windpipe, the larynx, the posterior cavity of the mouth, the nostrils, which communicate with that posterior cavity, the palate, the tongue, the teeth, and the lips. The sounds which constitute voice, belong to the order of musical sounds, independently altogether of the singing voice. All that is rightly termed voice, takes place in the larynx, which is properly the instrument of voice. But even independently of the modifications by which voice is changed into articulate speech, the voice is variously affected by the other parts which have been enumerated: by the chest, as regulating the force of the air; by the windpipe, as susceptible of several degrees of length and tension; by the posterior cavity of the mouth, as offering an expanded vault; by the nostril, as affording a double passage of exit for the breath; and by the various conditions of the tongue, the palate, the teeth, the lips, according to the position in which they happen to be at the moment.

---

* See *ante*, p. 275.

The chest and lungs together constitute, in reference to the voice, a musical bellows, capable of supplying air with more or less force to the organs of voice. The peculiarity of these bellows is, that by them the air must be renewed at short intervals, entering from without by the same passage by which it is expelled when the voice is exercised. It can, however, supply air without interruption, in a continued stream, for about fifteen seconds. The lung consists of two large bags of air, and does not materially differ from the wind-box of an organ, or rather from the bag of a bagpipe. No air can enter the lung, or escape from it, except through the windpipe. The walls of the chest are everywhere in contact with the outer surface of the lung, and close in, around the point at which the windpipe rises upwards to the larynx. The chest is capable of expansion in every direction; that is to say, by means of musqular action its walls recede from the surface of the lung, so that the cavity in which this air-bag is contained, is augmented in every direction—in length, in breadth, in depth. Whenever this enlargement commences, the air begins to enter from without. By this process, in two or three seconds, many cubic inches of air can be drawn into the lungs. So nice is the action of the muscles, by which the chest is again contracted in size, and the lung is compressed, that the stream of air which shall issue in a given period through the larynx, by the influence of the will, is under the most complete control. The prominence of the larynx on the fore part of the neck, is popularly known by the name of Adam's apple; by which, probably, its remarkably greater prominence in the male than in the female, is referred to. The long succession of minute tubes, by the gradual union of which the other trunks, and, finally, the windpipe, are formed, has this peculiarity—that the aggregate of the areas of the smaller tubes greatly exceeds the area of the trunks which they combine to form. From the windpipe throughout, almost to their origin in the minute cells, the tubes are provided with tense walls, by means of the cartilaginous appendages before referred to; in the windpipe itself these cartilages assuming a more definite form. They are in complete rings of cartilage, being deficient posteriorly; that is, each ring of the windpipe traverses about two-thirds of its circumference, leaving the remaining one-third, on its posterior aspect, destitute of this support. The number of rings in the windpipe is from fifteen to twenty; in other respects the tube is chiefly membranous, yet provided with muscular fibres capable of diminishing its calibre, by drawing together the extremities of the rings. It has been proved, by sufficient experiments, that when the larynx is raised by the powerful muscles attached to it, the windpipe is drawn up from the chest in a corresponding extent, and that at the same time its diameter is diminished by about one-third.

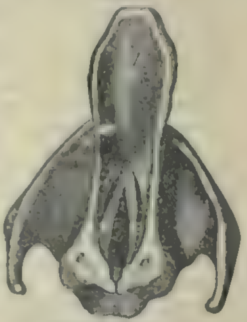
Fig. 12.



a, basement or cricoid cartilage, resting on the cylindrical windpipe; b, protecting cartilage or thyroid cartilage; d, valve-like cartilage or epiglottis.

The base, or lowest part of the larynx, rests on the upper part of the windpipe (Fig. 12); and this base consists of a ring, somewhat more developed than any of the rings of the windpipe, yet not so different from these but that it might be regarded as the summit of that tube. This ring differs from the rings of the windpipe in being complete all round; it is not, however, of a uniform breadth in the direction of from below upwards, being broader at the posterior part. It may be likened, then, to a ring, with a stone or a seal, the expansion behind corresponding to the stone or seal. On the upper edge of the expanded portion of this ring, at the base of the larynx, are set two slender bodies of a pyramidal form, which bear the most important part in the mechanism of the larynx as an organ of voice. These two bodies are exactly alike, and are placed almost close together, like two miniature obelisks set on end. The connection of their inferior extremities with the basement ring of the larynx, is by articulation—viz., by a true joint, like the shoulder-joint; that is to say, they are movable on the cartilaginous ring which supports them. From the one to the other, on their posterior aspect, muscular fibres extend, by the contraction of which, these two minute pyramids are made to approximate together. From the fore part of each, near their bases, an elastic substance proceeds forwards, converging, to interlace with its fellow at the anterior part of the larynx; that is to say, a minute, somewhat triangular, space is formed by two portions of elastic tissue, which cross the basement ring of the larynx from behind forwards, the base of this triangle being the space between the two pyramidal bodies just spoken of and its apex behind—a portion of the larynx to be presently alluded to. This triangular space between these two portions of tissue, or vocal ligaments, as they are called, is the aperture by which the breath enters and issues in respiration, and by which, when contracted to a narrow chink, the air is forced through in the exercise of voice. (See Fig. 13). These, then, are the most essential parts of the larynx; the two pyramidal bodies each resting on the posterior part of the basement ring, while the two ligaments proceed forwards, each from the base of one of these pyramids, to form a triangle, the apex of which is so directed as to be over the anterior part of the aperture of that basement ring. It is manifest, that when these two minute pyramids are drawn close together by the action of the muscular fibres, the base of the triangular opening is diminished, so that the posterior, or wider part of the opening, becomes obliterated; also, if the apex of this triangle be drawn forwards, that the sides formed by the two vocal ligaments will still further approximate. Such, then, are the two actions by which the triangular aperture is reduced to a minute chink—namely, by the points to which its base is attached being made to approximate, and its apex being drawn forwards.

Fig. 13.

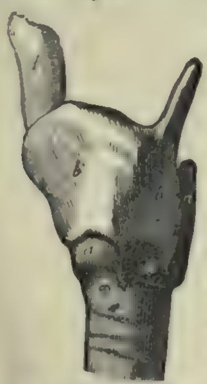


c c, Pyramidal or arytenoid cartilages; a, cricoid or basement cartilage; e e, the tongues or proper vocal cords, called also vocal ligaments; also arytenotheroid ligaments and inferior vocal ligaments; f f, the ventricles of the larynx; d, the epiglottis.

Other muscular fibres are so disposed as to antagonise the forces which close the aperture; two sets of fibres on each side extend from the basement ring inwards, to be attached to the pyramidal cartilages, by which they are drawn asunder, and the base of their rectangular aperture again restored to its former extent.

Several important, yet less essential parts of the larynx, remain to be described. The anterior narrow part of the basement ring supports that great prominence which constitutes Adam's apple. This is by far the largest portion of the larynx, but may be regarded merely as a defensive plate guarding the essential parts of the organ from injury. When the finger is placed upon its upper margin, and directed a little upwards, a hard, wire-like circle is felt; this is the convexity of the hyoid bone, or bone of the tongue, which has intimate connections, by ligaments and muscular fibres, with many adjacent parts, so that it is rendered, as it were, a centre of motion. Hence, when the hyoid bone is raised, many of the adjacent parts follow its movements. The hyoid bone is described as having the shape of the Greek upsilon, the convexity being directed forwards, and it may be felt immediately above the great cartilage of the larynx. This great cartilage, then, termed the thyroid cartilage (see Fig. 12), may be described as a quadrilateral sheet of cartilage, with appendages at its four angles, named its cornua, or horns. This quadrilateral sheet is bent along its perpendicular middle line, and this bending constitutes the angle which is felt in Adam's apple: the upper horns are attached to the hyoid bone; the under horns to the basement ring before spoken of. Thus the thyroid cartilage is wrapped round the essential parts of the larynx, covering them in front, leaving them exposed behind. The prominent angle in front corresponds to an interior angle on its posterior aspect; and to the middle part of this interior angle extends the apex of the triangle formed by the vocal ligaments, and there obtains an attachment.

Fig. 14.



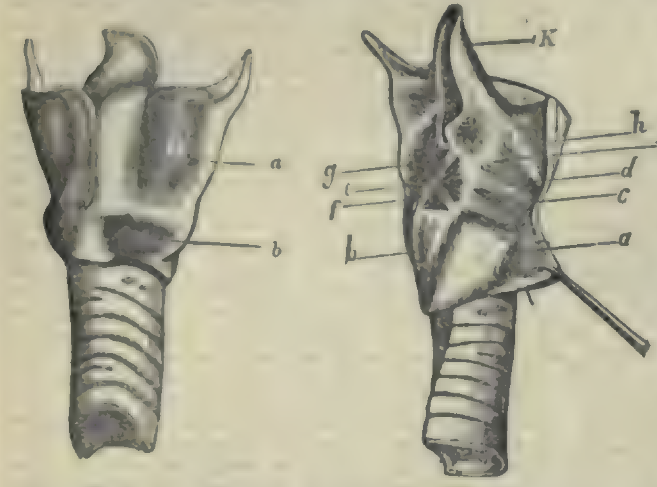
a, the cricoid; *b*. the thyroid; *d*, the epiglottis.

A movable valve, like a little tongue, its apex directed backwards, is attached to the same interior angle of the protecting cartilage, a little higher up, overhanging the cavity of the larynx. Between the same interior angle of the anterior protecting cartilage, and the two movable posterior cartilages before described, muscular fibres proceed, by the contraction of which those triangular movable cartilages are drawn forwards, so as to relax the elastic cords, already termed vocal ligaments. From the same interior angle of the protecting cartilage, an elastic substance proceeds, radiating in different directions, so as to close in the parts otherwise unoccupied, above the lateral portions of the basement ring of the larynx. This elastic substance, in particular, forms two cords, extending between the superior points of the movable triangular cartilages, and the sides of the tongue-like valve before spoken of. These cords constitute what have been termed, somewhat improperly, the superior vocal ligaments. (See Fig. 13). When the space beneath these so-called superior vocal ligaments and the true vocal cords, or vocal ligaments, is examined, a cavity is found on each side of considerable extent; and the two cavities are called the ventricles of the larynx. The mucous membrane, descending from the mouth and nostrils, covers and forms a lining to these parts in its passage downwards into the windpipe and lungs; so that the so-called superior ligaments of the larynx are often described as mere folds of the mucous membrane, extending between the posterior pyramidal cartilages and the protecting cartilage. It appears, however, from more minute investigation, that these folds of the mucous membrane do actually contain an elastic substance, not less capable, under certain circumstances, of vibratory action than the true vocal cords, or true vocal ligaments.

To recapitulate, then, the prominent points in the conformation of the larynx—the windpipe, called by anatomists the trachea, is surmounted by a complete cartilaginous ring, about an inch in diameter. This ring is the only outlet of the lungs by which air can issue from their numerous cavities, and is the only inlet by which air can penetrate from the atmosphere into the same cavities. This ring, being of a firm cartilaginous structure, is plainly incapable, under any ordinary circumstances, of dilatation and contraction. But the air is permitted neither to pass inwards, nor to come forth through the whole area of this cartilaginous ring, whether in respiration or in the exercise of voice. Its area is closed up on each side by impervious texture, so as to permit a passage to the air only by a chink, variable in its size, extending in the direction of its antero-posterior diameter. This chink is bounded, according to the common descriptions, by the vocal ligaments, one on each side; and at its posterior part by the cartilaginous processes of the base of the movable pyramidal cartilages to which these cords are connected. This chink, when most expanded lengthways, is about eleven lines in length; and of this space seven lines lie between the vocal ligaments, and four between the opposite cartilaginous bases of the pyramidal cartilages, above spoken of, to which anatomists give the name of arytenoid. (See Fig. 13). This chink, as above stated, is usually described as triangular, with its base between the two arytenoid cartilages, and its apex attached to the anterior angle of the protecting cartilage, above spoken of, to which anatomists give the name of thyroid. (See Fig. 14). More correctly, at its greatest dilatation, it has a lozenge shape, with the posterior angle truncated. Thus the chink commences narrow immediately behind the thyroid cartilage, expands between the vocal ligaments to their attachment at the base of the arytenoid cartilages, and then contracts in the space between the cartilaginous bases of these two bodies, not to a point, but to a truncated angle. The widest part of the chink, in its greatest state of dilatation, is about five lines and a-half—nearly half an inch. This greatest degree of dilatation takes place during inspiration; during expiration, the chink undergoes a slight contraction. But during the exercise of voice, the posterior part, bounded by cartilaginous margins, as being between the base of the arytenoid cartilages, is entirely obliterated. Thus it is correctly stated, that the chink, concerned in the exercise of voice between the true vocal ligaments, at its greatest dilatation, is of a triangular shape, being entirely bounded on the sides by the vocal ligaments, and its base corresponding to the points between their attachment to the arytenoid cartilages. As before stated, the arytenoid cartilages are attached to the upper surface of the posterior part of the basement cartilage of the larynx, or cricoid cartilage (see Fig. 14); and the vocal ligaments being attached to the bases of these arytenoid cartilages, it is manifest, that when these cartilages are drawn together, the vocal cords must approximate; that when these cartilages are drawn asunder, the vocal cords must recede from each other at their posterior part; that when the arytenoid cartilages are drawn backwards, the vocal cords must be put on the stretch; that when the thyroid cartilage, to the interior of which the apex of the triangle, formed with cords, is attached, is drawn forwards, they must also be put on the stretch. All these changes are known to occur by the action of particular sets of muscles. The thyroid cartilage, which forms "Adam's apple," is connected to the basement, or cricoid cartilage, by an elastic membrane, which of itself tends to keep the thyroid cartilage nearly in the same perpendicular line with the cricoid, so as, in some degree, to stretch the vocal ligaments. But there are two muscles extending between the cricoid cartilage and the thyroid, by which the thyroid cartilage is drawn forwards, so as distinctly to stretch the vocal ligaments. There are also two muscles extending between the posterior part of the cricoid cartilage, and the posterior surface of the arytenoid, by which the arytenoid cartilages are drawn back. These two pairs of muscles, when they act concurrently, must very much stretch the vocal ligaments. A set of muscular fibres, before spoken of, passing between the arytenoid cartilages on their posterior aspect, by their contraction causes the cartilages to approximate. Two other muscles, extending from the sides of the cricoid cartilage to the arytenoid, draw them asunder. Some other muscular fibres are found, connecting the cartilages of the larynx; but the account of these, owing to their less importance, may be omitted.

The small muscles of the larynx are represented in the following figure. The crico-thyroidei (*b*, No. 1; *a*, No. 2), and the crico-arytenoidei postici (*b*, No. 2), extend the vocal cords in the direction of their length, and, at the same time, narrow the glottis. The crico-arytenoidei laterales (*c*, No. 2), and the thyro-arytenoidei (*d*, No. 2), rather relax the vocal cords. The oblique and transverse fibres of the arytenoideus (*e*, and *f g*, No. 2) close the posterior half of the glottis. The epiglottis (*K*, No. 2) forms a valve, which can be brought over the glottis by fine muscular fibres attached at *b* and *i* (No. 2).

Fig. 15.



No. 1. No. 2.

Such, then, are the parts of the larynx which must be explained to render the phenomena of voice intelligible.

The larynx, like other organs of the body, is largely supplied with blood by the common blood-vessels. Two nerves, on each side, are devoted to the actions of the larynx. These nerves are from the eighth cerebral pair: the superior laryngeal nerve, is expended chiefly on the mucous lining of the larynx; the inferior laryngeal nerve, derived from the recurrent of the eighth pair, sends minute filaments to the several muscles concerned in the movements of the larynx.

Besides the movements of the component cartilages of the larynx on each other, attention must be paid to the motion of the whole larynx upwards and downwards. This motion takes place constantly in the act of deglutition, but also, on many occasions, when the voice is exercised, particularly in singing. When the whole larynx is raised, the windpipe is drawn proportionately upwards from the chest, and so put on the stretch. This movement has unquestionably some effect in extending the compass of the voice. It was before stated,* that the hyoid bone is connected to the protecting cartilage of the larynx, and that when this bone is drawn upwards, the larynx is drawn upwards along with it. The hyoid bone is drawn upwards by muscles attached in particular to the lower jaw, and also to the temporal bone of the skull. The hyoid bone is drawn downwards by muscles attached to the superior part of the breast-bone and to the shoulder-blade. From the upper part of the breast-bone a pair of muscles ascends, to be attached to the thyroid cartilage of the larynx, and a pair of muscles also extends between the thyroid cartilage and the hyoid bone. Thus, ample provision is made for the movement of the whole larynx in concert with the movements of the hyoid bone.

A few words must next be devoted to the cavities through which the air passes outwards, after issuing from the larynx. Behind the larynx, is the cavity of the pharynx, situated in front of the cervical vertebræ, and ascending to the inferior portion of the base of the skull. This cavity, not improperly termed the posterior cavity of the mouth, communicates with the nostril above, and on either side, by a narrow canal, called the "Eustachian tube," with the cavity of the drum of the ear. This posterior cavity of the mouth, is divided from the anterior cavity by the veil of the palate, a musculo-membranous movable curtain, which, by its motions, more or less completely divides the anterior from the posterior cavity of the mouth. The movable, tongue-like valve, before spoken of, termed by anatomists the epiglottis (see Fig. 15, *K*), overhangs the orifice of the larynx; the arches of the palate descend on either side, and are possessed of a muscular character. From the union of these above, the uvula hangs down. The tongue, free and movable in its anterior part, forms the floor of the whole passage between the root of the epiglottis and the incisor teeth of the lower jaw. The muscular mass forming the cheeks, contracts the cavity of the mouth on the sides; and the lips, by their mobility, variously modify the aperture by which the air issues.

Thus the air issuing from the larynx, may pass out either by the nostrils or the mouth. It passes out by the nostrils when the mouth is closed, or even when the veil of the palate descends. When the veil of the palate is raised, and the mouth is opened, a free passage is afforded, through what has been called the oral canal, outwards. The oral canal is manifestly capable of much greater modification, as to size, than the passage of the nostrils.

> "The tongue, the lips, articulate; the throat,
> With soft vibration, modulates the note."—DARWIN.

On the Human Voice.—In the investigation of the cause of the human voice, two points in particular deserve attention: first, the precise seat of the sounds; and secondly, the mode in which these sounds are produced.

As to the first question, it is now determined, beyond all doubt, that the sound of the voice is generated in the glottis, and neither above nor below that point. Before going further, it should be remarked, that this word glottis has not always been used in exactly the same sense. "By turns," says the eminent French physiologist, Adelon, "the superior aperture of the larynx, its inferior aperture, and the intermediate space between these two apertures, have borne the name of glottis; but, according to the etymology of the word, derived from γλωσσα—the tongue, the speech—no other part of the larynx should be called by that name but that where the vocal sound is formed; and we shall see that that part is the inferior aperture or chink."† In this sense alone, then, the word glottis is here employed—namely, to signify the aperture between the two vocal ligaments; that is, between the two inferior vocal cords, as they are sometimes called.

Among the proofs that this chink, or glottis, is the seat of voice, it may be mentioned, that if an aperture exist in the windpipe, the sound of the voice ceases. Such an aperture is frequently formed in man as a surgical operation, and an opening has often been made in the same situation in animals, for the purpose of experiment. When an opening exists above the glottis, the voice is not lost. Again, though the epiglottis, the superior vocal ligaments of the larynx, and the upper part of the arytenoid cartilages, be injured, the voice is not lost: moreover, in living animals, when the glottis is laid bare, it is seen that the inferior ligaments of the larynx which form the boundaries of the fissure termed the glottis, are thrown into vibration. It is known, too, that the division of the laryngeal nerves supplying the muscles, which regulate the states of the aperture, and make the vocal cords tense, destroys the power of producing vocal sounds. It is also found, that sounds can be produced in the dead human body, by forcing a current of air from the windpipe through the larynx, provided the vocal cords be in some degree tense, and the glottis narrow. The larynx has been cut from the body, and freed from all the parts in front of the glottis; thus, the epiglottis, the upper vocal ligaments, and the ventricles of the larynx between the superior and inferior, or vocal ligaments, the greater part of the arytenoid cartilages—namely, their upper part—may be removed; in short, if nothing remain but the inferior ligaments, or vocal cords, and these be so approximated that the glottis shall be narrow, clear tones will be produced by forcing air through it from the windpipe.

Such facts as these entitle us to regard the glottis and the vocal cords, which form its immediate boundaries, as the essential source of voice; while the windpipe simply conveys air; and the cavities above the glottis, comprehending the upper part of the larynx and the air passages through the mouth and nostrils, correspond to the tube of a musical instrument, by which the sound is modified, but not generated.

---

* *See ante*, p. 280.

† *Physiologie de L'Homme*, ii., 256.

It has been already remarked,[*] that the vocal ligaments are composed of elastic tissue; and it is owing to this elasticity that they are adapted to the office which they perform. While, then, it is quite certain that no proper vocal sounds can be produced, except in the glottis, it seems manifest that the adjacent and somewhat abundant tissue of the same kind, is susceptible of a vibration and resonance in unison, so as at least to modify the sounds of the voice.

In reference to the second question—what is the nature of the change produced in the glottis during the formation of voice?—no inconsiderable difficulty is met with. The points of debate which have arisen on this subject are, whether the vocal ligaments be a set of membranous cords obeying the laws of musical strings; if the aperture of the glottis be a reeded instrument, in which the vocal ligaments play the part of vibrating tongues; or even whether the real source of the sounds of the voice be not a molecular vibration of the air, produced by its passage through the narrow aperture of the glottis; and, lastly, whether the organ of the voice does not, in part, combine all these three sources of sound, so as to be at once, in some respects, a stringed instrument, a tongued instrument, and a simple wind instrument.

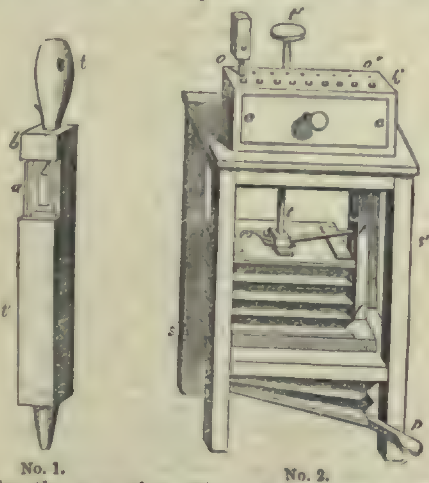
The ancients regarded the sounds of the voice as analogous to those of a flute. According to this view, the vibrations of the larynx are of little account, the actual sounds being produced by a molecular undulation of the air. That the organ of voice is, in some degree, analogous to this kind of musical instrument, is not to be absolutely denied; but it is certain that this is not the principal mode in which the sounds are produced.

One of the earliest ideas of modern times on the subject of the voice is, that the larynx is analogous to a horn; that is to say, to a wind instrument, in which the vocal cords act the same part as the lips of the performer on a horn. Not much more than a hundred years ago arose the idea that the larynx is a set of musical cords—namely, that the vibrations of these cords, on the same principle as a stringed instrument, produce the sound, which was then conveyed outwards by the air.

The prevailing opinion of the present day is, that the larynx is a wind instrument, but a reeded one.

This common view may be expressed as follows:—The expired air is thrown into the larynx through the windpipe, by the muscular action of the chest; and the proper muscles of the larynx being contracted, create a sufficient tension of the vocal cords to permit them to be thrown into vibration by the impulse of the air. The sound so produced is conveyed through the mouth and nasal passages, undergoing various modifications in its passage outwards.

Fig. 16.



No. 1. No. 2.

Let us consider, then, in the first place, what evidence there is that the organ of the voice is a reeded instrument, with a double membranous tongue.

In short, the action of the organ of voice may be best explained, in general terms, by comparing it with the pipe of an organ. Let us suppose *t'* (No. 1, Fig. 16) to be the wind-tube, into which the air is driven from below; *b*, the stopper, in which is placed the tongue; *a* and *t*, the body-tube; and let there be a pipe, *o* (No. 2), to the wind-box, *c c*, and the air be driven from the bellows, *f f p*, through *t*. The air throws the tongue, *a* (No. 1), into a state of vibration, and passes out in undulating movements from the body-tube. Such is a general illustration of the nature of voice.

An experiment may be made which illustrates the effect of an elastic organic tissue, like that of the vocal ligaments, in producing sound on the principle of a double tongue. The extremity of a tube is closed by two bands of moist elastic tissue—for example, arterial tissue—so applied as to cover the whole end of the tube, with the exception of a slight fissure between the bands. India-rubber, or leather, may be employed for this purpose. Both these substances produce a similar effect; but it appears that the middle arterial coat, being composed of the same tissue as the vocal ligaments, and having the same physical properties, forms the best kind of artificial larynx. When this tube is blown through at the free extremity, the tongues not only vibrate readily, but produce a range of musical tones. To obtain a pure quality of tone, it is necessary that the two membranous bands should be of equal weight and breadth, and subject to equal tension, otherwise they cannot vibrate equally in equal parts of time.

If the human larynx be dissected out, and the vocal cords be stretched, they will vibrate like a piece of artificial tissue, such as india-rubber or leather, in a current of air. In conducting these experiments, the same conditions must be secured as are required in the experiment with the tube, and the two membranous laminæ, before referred to. For example, the inner edges of the glottis—that is to say, of the vocal ligaments—must be turned outwards towards each other, so that they shall be in the same plane and parallel to each other, otherwise they will not produce any sound. Hence it may be inferred, that when the tension of the vocal ligaments takes place in the living animal, they turn upon their axis, till their planes, which, in the state of relaxtion, are inclined to the axis of the vocal tube, become perpendicular to it; and as the edges of the glottis approximate, its chink is nearly or entirely closed, and they acquire the true vibrating position. The production of the most simple tones of the voice requires the associated action of a most extensive range of organs; for it is calculated that, in the ordinary modulation of the voice, more than one hundred muscles are brought into action at the same time.

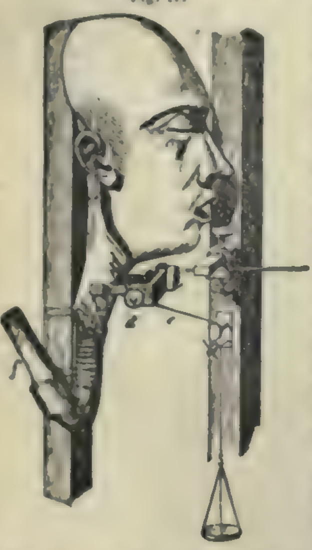
As the air rushes upwards from the windpipe, a portion of each edge of the glottis yields to its pressure, and is curved upwards, so as to form an angle with the axis of the vocal tube, and leave between the two edges a narrow aperture, through which the air escapes. The tension and elasticity of the vocal ligaments tend to restore them to the plane of their former position. The air having been rarefied below the glottis during their elevation, becomes dense from their depression, and the necessary force being again accumulated, they are re-elevated, and thus an oscillating movement, consisting of an opening and closing of the glottis, takes place; which, being communicated to the contiguous air, the sounds of the voice are produced.

The vibrating edge of the glottis varies in length, according to the pressure of the column of air in the windpipe, and the resistance of the vocal ligaments. When other circumstances are alike, the intensity of the voice is determined by the pressure of the column of air in the windpipe, and the range of movement described by the vibrating edges of the glottis. The pitch of the voice does not depend solely on the tension of the vocal ligaments, but jointly on the variations which they undergo in length and tension. Magendie observed, in the larynx of a dog, that a longer portion of the vocal ligaments vibrated while grave tones were produced, and that a diminution of length accompanied the succession of acute tones. Mayo has described the movements of the glottis in a man who had attempted to destroy himself by cutting his throat. The larynx in this case was cut through just above the vocal cords; and, owing to the oblique direction of the wound, an injury of the arytenoid cartilage, and of the vocal cord on one side, had occurred. When respiration was going on, the glottis was seen to be of a triangular form; but when the voice was exerted, the vocal cords passed into a parallel direction, and the glottis itself had a linear form. The posterior part of the aperture appeared to remain unclosed.

---

[*] See *ante*, p. 280.

Fig. 17.



The cut (Fig. 17) represents the prepared head of a corpse, after Müller. A thread *e*, which passes over a roller to a scale, is so applied to the larynx that the tension of the vocal cords can be increased by placing a greater weight on the scale. The action of the muscles is thereby imitated. The compressing apparatus seen on the wood-cut, brings the vocal cords nearer to each other, and thus produces the requisite diminution in the width of the vocal fissure. The tube *f* serves to convey the wind, which throws the tongue-apparatus into action. And thus, if we use the human head, or the head of the dog, the pig, or of any other animal, we can imitate the voice of man, the bark of the dog, the grunt of the pig, &c.

Membranous tongues, like those in the larynx, differ widely from a metal tongue, shutting up the aperture, and necessarily opening and closing as the air issues.

Objections have been taken to the view which represents the voice as the result of sounds produced by membranous tongues set in motion by air—1st, that the vibration of tongues consists in the periodical opening and shutting of the orifice through which the stream of air passes—this not being the case in the glottis; and, 2nd, that had it the structure of a reed, the edges of the vocal ligaments which open the chink would be alternately separated by the column of air in the larynx, and drawn together by their tension; while it has been found by experiment, that air transmitted through the glottis gives rise to sound, notwithstanding that its edges are from one-sixth to one-fourth of an inch asunder. In these objections, however, there is a mistake as to the essential principle of reeds; for those of the clarionet, bassoon, hautboy, &c., fail to close entirely the passages through which the breath escapes; and the case is not otherwise with the natural reed, which the lips of players on the flute and horn represent. In short, a sound can be produced by a tongue apart from the surrounding framework, indicating, beyond doubt, that so much importance should not be ascribed to the usual mode of forming reeded and tongued instruments, and to the circumstance of the air passing between the tongue and its frame. It has been shown, that the law by which the variation in the notes yielded by the tongue of a mouthpiece or reed is regulated, is the same when the tongue is made to vibrate by a current of air, as when it is thrown into vibrations by being struck or inflected. By the same law are regulated the vibrations of vibrating rods; the frequency of the vibrations of two rods of the same texture and thickness being in the inverse ratio of the squares of their length. The note afforded by a reed without a tube, is of the same pitch, whether it be the result of a current of air, or if produced by striking the tongue. The strength of the blast does not, for the most part, determine the pitch or sharpness of the note; but when the force of the blowing is increased, the strength of the tones is augmented. The size of the fissure between the tongue and the frame within which it vibrates, is of little consequence; when the opening is large there is a greater difficulty in obtaining the tone, but its pitch is not altered.

Some slight difficulties may still exist in the explanation of the theory of the voice as considered to be chiefly the result of a double vibrating tongue; but, altogether, as close a resemblance has been proved to exist, between that kind of artificial musical arrangement and the structure of the living larynx, as can reasonably be expected in such a case.

It has been hinted, that the vocal ligaments may possibly act not only as vibrating tongues in the production of voice, but also on the principle of musical strings. On this point a few words must be added. It may seem, at first sight, that the remark of so distinguished a philosopher as Biot, when he says, "What is there in the larynx that resembles a vibrating string? Where is the space for such a string of sufficient length to yield the lower notes of the voice? How could sounds, of the compass which the human voice represents, be produced by a string which the larynx would contain?"—would suffice altogether to set aside the idea of the vocal cords acting as musical strings. But Biot here seems to have fallen into error. Deep notes are still produced by a string greatly shortened, if it retain, after a sufficient amount of relaxation, the elasticity required for vibration. His attention does not seem to have been drawn sufficiently to the nature of organic membranes; strips of india-rubber, and elastic animal membranes, still retaining enough of elasticity for this purpose, after being much relaxed. There is, therefore, a perfect agreement between the vocal cords and vibrating strings, though their vibrations, whether as strings or as tongues, are produced not by the direct impulse of a solid body, but by the momentum of air. When the ordinary principles to which musical strings are subject are applied to the vocal ligaments, there is found to be a very close agreement, if allowance be made for the peculiarities of animal substances, as respects their elasticity and the like.

In their ordinary state, the vocal cords must be regarded as subject to a considerable tension, which, however, admits of being diminished, so as to add to the range of the lower notes. At the ordinary pitch of the voice, the glottis may be regarded as partially closed, and becoming more open as graver tones are produced; this opening of the glottis coinciding with the relaxation of the vocal cords, a double cause is afforded of the lowering of tone. When higher notes are uttered, the glottis closes, assuming more of a linear form; while, at the same time, the vocal ligaments, though elongated, are thrown into a much higher state of tension. In the words, then, of Mr. Bishop, "Since the vocal ligaments have been proved to extend and contract for acute and grave sounds respectively, and after death vibrate, in a great measure, like musical strings, we think it may be fairly inferred, that they likewise obey, to a certain extent, during life, the laws of the vibrations of such strings. * * * * It is, moreover, observable, that the extension and relaxation of the vocal cord, which, as we have seen, are analogous to those of a musical string, produce a corresponding shortening and elongation of its axis, if regarded as a tongue; and, lastly, since one tone only is produced at a time, the vibrations resulting from the double action which appears to exist in the vocal apparatus must be synchronous. * * * * It might possibly be objected to the idea of this twofold action, that the production of sound by the vocal cords is sufficiently accounted for by supposing them to vibrate merely as elastic tongues; but then it is found by experiment, that by artificially dividing their length into two ventral segments, there results the octave of the fundamental note, which proves that at all events they vibrate as cords. In conclusion, we must bear in mind the vast difference between natural and artificial mechanism; and however complicated a problem it may be to determine that constitution of the vocal apparatus, by which the thyro-arytenoid ligaments may simultaneously obey the laws of cords and tongues, yet, to a physiologist who is accustomed to meet with the most admirable contrivances and combinations in the animal frame, the difficulty of finding a strictly mathematical solution is, in such a case, no objection to its truth, when the facts, as far as they have been observed, are decidedly favourable to its reality."*

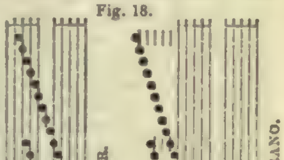
It was before hinted at, that the vibrations of the walls of the tubes through which the voice is conducted, may, in some degree, influence its sound. In rigid tubes, the vibrations depend on the nature of the impulse propagated in the air within, jointly with the length of the pipe. So long, then, as the length of the pipe remains the same, and no change takes place on the material of its walls, the pitch of the sound produced by the undulations of the air within, remains unaffected. The dimensions of the windpipe, such as its length and diameter, are invariable; and, were the height of the larynx, and the dimensions of the bifid tube (the nose and mouth), through which the air issues after the formation of voice, equally invariable, the vibrations of these parts would produce no change on the pitch of the voice, the quantities being constant for each tone produced in the glottis. It has been found, that by taking tubes composed of layers of paper, of constant length, but varied in thickness, graver sounds were produced as the parietes became thinner, and that the gravity of the sound was increased by moistening and relaxing the sides of the tubes. It was before noticed, that the windpipe is capable of being drawn upwards from the chest, to a small extent, while the larynx is elevated; and that this tube admits of being diminished in its diameter by about one-third part. Moreover, the pharynx, the mouth, and the nasal cavities are also susceptible of various modifications of diameter; so that the pipe, so to speak, near the middle of which the vocal sound is produced, is in a very different condition from a rigid tube. Hence, it has been concluded that provision is made for an invariable adaptation between the amount of tension, the vibrating length of the vocal ligaments, and the walls of the vocal tube, for the production of the ordinary tones of the voice. It appears, indeed, to have been proved that the vocal tube is so short, that were it rigid, it could not influence the pitch of the note which the glottis originates. But its want of length is compensated for by the relaxation of its walls, so that it comes to vibrate synchronously, and so to give forth sounds equally grave with those of the glottis. Its effect, therefore, is to add to the force of the tone, which, without its aid, would have been found to possess less intensity.

After considering this subject in every possible light, the conclusion appears to be that to which Mr. Bishop has come; namely, that the evidence shows "the vocal apparatus to be influenced by the air expelled from the chest, in precisely the same way as if it were a stretched cord, a reed, or a vibrating tube. Why, then," he continues, "should we hesitate to adopt the obvious conclusion, that the vocal organs do, in fact, combine the properties of these various instruments, and are thus the perfect types of which these instruments are only imperfect imitations?"

Singing.—The notes of the human voice are capable of being produced in three separate kinds of sequence. In ordinary speaking, the successive notes have nearly all the same pitch. This kind of succession, then, is properly termed the monotonous. Some deviation from this monotony occasionally arises, as when certain syllables receive a higher intonation for the sake of accent, and when, in reading or reciting poetry, rhythm is added to the accent. In these cases, however, the deviation from monotony of pitch is too slight to require a separate head. In the expression of passion, accompanied by vehement exercise of the voice, there is heard a sudden transition from high to low notes, or the reverse. This, then, constitutes the second kind of sequence in the notes of the human voice. Musical notes constitute the third mode of sequence. In music, the sound has the requisite number of vibrations; and as the sounds succeed each other, they exhibit that relative proportion in the number of vibrations which jointly characterise the notes of the musical scale. Of the adaptation of one sound to succeed another, so as to preserve the musical character of the succession, the human ear is the only original standard.

Compass of the Voice.—In singers, the compass of the voice extends through two or three octaves. When the male and female voices are taken together, the entire scale of the human voice includes four octaves. The lowest note of the female voice is about an octave higher than the lowest of the male voice; the highest of the female voice is about an octave higher than the highest of the male. The first four notes of all voices are most commonly weak. There are two kinds of male voice, the bass and tenor; and two kinds of female voice, the contralto and soprano. The essential distinction between these voices does not consist in their difference of pitch. The bass voice commonly reaches lower than the tenor, and its strength lies in the low notes; while the tenor voice extends higher than the bass. The contralto voice has most commonly lower notes than the soprano, and is strongest in the lower notes of the female voice; while the soprano voice reaches higher in the scale. It is found, however, that bass singers can sometimes go very high, and the contralto not unfrequently sings the high notes like soprano singers. The difference between the bass and tenor voice, and between the contralto and soprano, is plainly, then, not one of pitch, but consists in the peculiar timbre or quality of the notes; for these several voices are distinguished from each other, even when sounding the same note. The qualities of the baritone and mezzo-soprano voices are less marked; the baritone being intermediate between the bass and tenor, the mezzo-soprano between the alto and soprano.

Fig. 18.



Scales of Notes of the different Voices, showing the range of each.

The difference of pitch between the male and female voice, is connected with the different length of the vocal ligaments in the two sexes. It appears that the lengths of the male and female vocal cords in repose, are nearly as 7 to 5, and in tension as 3 to 2; in boys at the age of fourteen, the length is to that of females, after puberty, as 6·25 to 7—so that the pitch of the voice is nearly the same. The difference in the quality of the female voice, as compared with that of the male, is owing to the considerable difference presented by the two sexes in the walls of the larynx; the male larynx being much more expanded, and forming a much more acute angle in front. It is not yet clearly understood what is the cause of the different qualities of voice, as exhibited in the tenor and bass, and the contralto and soprano. As Müller remarks—"We may form an idea of the cause of these differences of timbre, from recollecting that musical instruments, made of different materials, as metallic and gut-strings, metallic, wooden, and membranous tongues, metallic, wooden, and paper pipes, or flutes, may be tuned to the same note, but that each will give it with a peculiar quality or timbre."

---

* *Cyclopædia of Physiology:* article "Voice;" p. 1481.

In short, when the variations of the larynx in different individuals of both sexes, and at different ages, under the various circumstances more or less favourable to the development of the respiratory organs, are considered, as well as the remarkable fact that every human being is characterised by a speaking voice peculiar to himself, we shall be at no loss to understand why the singing voice should vary in different persons, not only in pitch, but also in quality.

The voice termed falsetto has much engaged the attention of physiologists. Most singers, particularly males, besides their natural voice falling under one or other of the before-mentioned characters, have the power of producing a double series of notes, of a different description. To the second series of notes the name of falsetto is applied. The notes of the natural voice—called also chest-notes—are fuller, and distinctly indicate a stronger vibration and resonance; while the falsetto voice has more of a humming character. It is only with the natural voice that the deep notes can be produced; while the highest notes of a male voice are falsetto. The notes accompanying a middle pitch may belong either to the natural or the falsetto voice. Thus the two registers, as they are termed, of the voice are not bounded in such a manner that the one ends where the other begins, as, through a certain compass, they run side by side. It is remarked that the bass voice becomes falsetto lower in the scale than the tenor. In the female voice there is less seldom presented a very marked distinction between the natural and falsetto registers.

In a human larynx, detached from the body, two distinct series of tones can be produced, when the tension of the vocal cords is very slight. One of these series corresponds to the tones of the ordinary voice, the other to the tones of the falsetto voice. With a certain degree of tension of the vocal cords, both these kinds of tones may be produced—sometimes the one kind, sometimes the other, being heard. With a different kind of tension of the cords, notes of the falsetto character are constantly produced, whether the current of air passing through the glottis be forcible or feeble. If the vocal ligaments be much relaxed, the sounds of the ordinary voice always result, whether the current be feeble or forcible. When a slight tension of the ligaments is kept up, the falsetto is most easily produced by blowing very gently; while, if the blowing be more energetic, the sound belongs to the ordinary voice. Thus, two different notes may be produced, under the same degree of tension of the ligaments, by a different force in the blowing; and the distance of these two notes from each other may be as much as an octave. "The real cause," says Müller, "of the difference between the falsetto and the notes of the natural voice is, that, for the former, the thin aperture only of the lips of the glottis vibrates; while, for the latter, the whole breadth of the cords is thrown into strong vibrations, which traverse a larger sphere." The peculiarities of the voice in different individuals, must be chiefly dependent on the particular form of their air-passages and of the lining membranes, and the consequent differences in their mode of resonance. That such causes are adequate to produce all the varieties of the voice in individuals, appears from the circumstance, that many persons, by altering the form of their vocal organs, can imitate the various tones of the voices of other individuals.

The nasal quality of the voice is determined by like causes. This nasal tone appears to be given to the voice in two ways: thus a nasal sound is produced, though the external openings of the nostrils be closed when the arches of the palate approach each other, and the larynx ascends higher than in the natural voice. When the nostrils are obstructed by mucus, a nasal sound is produced; this obstruction having the same effect as the voluntary closure of the anterior opening of the nostrils. In the second mode by which the nasal sound is produced, the nostrils are open, the larynx ascends considerably, the arches of the palate contract, the upper surface of the tongue ascends towards the palate, so that the air passes between the narrowed arches of the palate, and receives the resonance of the nasal cavities without that of the cavity of the mouth. The deficiency of tone in the voice of old people, arises from the ossification of the cartilages of the larynx, and the altered state of the vocal cords. It is unsteady, owing to the loss of nervous command over the muscles.

The strength of the voice depends partly on the extent to which the vocal cords are capable of vibration, and partly on the great capacity of the chest, and the fitness of the various parts, over which the air passes, for communicating resonance. The intensity or loudness of a given note cannot be rendered greater by the mere augmentation of the force of the current through the glottis. Such an increase of force in the current, will raise the pitch both of the natural and falsetto notes. It is therefore concluded that the variation in the intensity of a note, without the alteration of its pitch, must depend on some other cause than the mere change in the force of the current. Such a provision plainly lies in the power of modifying the tension of the vocal cords. To render a note more intense, without increasing its pitch, the vocal cords must be relaxed in proportion as the force of the current of the breath through the glottis has increased. When it is desired to render a note fainter, an opposite mode of action must be adopted.

The failure of perfectness in the notes of the human voice may arise from many causes. Variations in the temperature of the atmosphere, and in its states of humidity, have a powerful influence on the pitch of the voice. During a cold, moist state of the atmosphere prevalent in these islands, the voices of singers become lower by two or three notes; while they regain their usual pitch when the air becomes dry. Mr. Bishop mentions, that when Grassini came to this country, owing to the change of the air from that of Italy, her voice became one octave lower. After singing for two or three seasons, her natural voice returned, but it had lost its attractions with the loss of the low tones which had gained her so great applause. After long singing, dissonance of the voice is apt to arise; this is easily accounted for by the slight changes produced on the vocal cords in consequence of repeated tension, together with the fatigue of the muscles concerned, which, as in other cases of muscular contraction, at length cease accurately to obey the will, and hence afford unsteady movements.

Whistling.—Before leaving the subject of the human voice, whistling deserves a few words. The sound in whistling does not arise from the vibrations of the lips. Several experiments prove that the lips are not thrown into vibrations. They may be touched, covered, or may have a disc of cork with a central hole placed between them, and yet the same sounds will be produced. It has been supposed, then, that the air is thrown into sonorous vibration by friction against the borders of the opening. According to Müller, the cause of the vibration is the same friction of the air; but the vibration produced upon the borders of the opening, throws the whole column of air in the mouth into vibrations, and the vibrations of this column of air, by a reciprocal influence, determine the rapidity of the vibrations of the air at the orifice. The only difference, according to him, between whistling and the sounds of a pipe is, that in whistling, the whole column of air is in constant progressive motion through the tube and orifice; while, in a pipe, the air in the tube merely vibrates, and does not move as a current.

Speech.—Speech is peculiar to man. Because speech is not possessed by individuals deprived of the organs of voice or hearing, it is not, therefore, to be concluded that it originates in the mere possession of these organs. Inferior animals are fully provided with the organs both of hearing and of voice, and yet, in all essential respects, they are destitute of speech. Speech, therefore, must be considered under the light of a potentiality of man's intelligence, the condition of the exercise of which is the presence of the organs of hearing and of voice. That is to say, man is born susceptible, by the development of his nervous system, of the acquisition of speech, provided his organs of hearing and voice are perfect. But if man be born susceptible of speech, it may be asked, why does not the deaf-mute invent a language? He does invent a language, but it is a language of expression independently of speech; he fails to express his inward feelings by the use of speech, because the defect of hearing prevents him from discovering the sounds which his voice is capable of producing. His language, therefore, is confined to the other modes of expression by which an intercommunication, however imperfect, can be carried on between men. The deaf-mute might undoubtedly carry the use of natural signs of expression much further, were he not overwhelmed and overpowered by the multitude of ideas which his fellow-men around him possess, and are continually striving to make him understand. It may also be asked if, owing to this natural susceptibility of speech, every infant should not invent a language? Indeed, every infant does invent a language; but as, long before any progress is made in its language, the sounds which it continually hears are caught up, it is impossible to judge to what extent each individual is capable of carrying such an invention.

There is no more interesting speculation than to consider the several steps by which language must have arisen among men. It is easy to understand how, in the rudest community of mankind, conventional signs must have arisen of every description; nor is it difficult to perceive, that those sounds of speech which are most easily produced, would quickly form a large share of those conventional signs. But it forms no part of our present design to investigate the origin of languages; it is more to the purpose to consider, in a few words, how men came to understand the several acts concerned in speech. At a certain period, then, in the progress of mankind, it appears that languages of no inconsiderable extent had already been formed, and yet that no attention could have been paid to the individual sounds composing those languages. Men spoke, and in that speech employed words without the least reference to letters, and, perhaps, with none even to syllables. The curious inquiry, then, which arises is, in the first place, how men were led to reduce speech to letters; that is, to analyse words into their elementary sounds.

We may suppose that the difficulty of pronouncing certain sounds, such as the words of a foreign language, must have been the first circumstance which would lead men to reflect on the modes by which speech is produced. Man's natural curiosity would not fail to engage him more largely in this inquiry as soon as the subject was suggested. Little progress, however, could be made in this pursuit till some method of fixing the sounds by name, and of representing them to one's self, or to others, at periods more or less distant from their first recognition, was invented. It may be supposed that men had already acquired the art of depicting objects of sight, were it no more than rude representations made with a rod on the sands left by a receding sea. The idea, however, of representing a sound by such a symbol is plainly not of the same kind. To think of representing a sound by a symbol is manifestly a fresh step in discovery. It required, in short, an effort of invention to produce such a stretch of thought. But the moment the idea arose, all difficulty must have vanished. Nothing was easier than to observe the similar simple sounds, occurring in the compound sounds, which constitute speech. The mere observation of the form of the mouth, as certain simple sounds are uttered, would be sufficient to afford a foundation for this kind of knowledge. What the original symbols, corresponding to our modern alphabets were, is of little moment. The first alphabets, doubtless, consisted of the representatives of but a small number of sounds. It is easy, however, to perceive, that as soon as this kind of investigation was fairly commenced, it would make rapid progress, there being no great difficulty in discovering the collocation of the several parts of the mouth concerned in the production of most of the simple sounds. Thus, by an easy analysis, syllable-sounds would be reduced to letter-sounds, and each letter would quickly come to be marked by a particular symbol. The most remarkable effect of this great discovery, simple as it seems to us, would unquestionably be the rapid multiplication ot sound-symbols—that is to say, the vast extension of language. The greatness of the discovery hardly strikes us at the first sight. Some idea of the character of it is obtained from the fable of words spoken becoming frozen at the moment in their fixed forms, and not reaching the ear until the return of a more genial temperature. Letters, in short, are the pictures of sounds, by which any sound now pronounced is perpetuated, while the picture itself, or a copy of it, shall endure.

Speech, then, consists of combinations of sounds produced in the larynx, and variously modified in their transition through the oral or nasal passages outwards. No language exhausts all the sounds which can be produced in the passage of the voice outwards in this manner. Languages may be described as composed of those sounds which are most easily produced in the passage of the voice from the larynx outwards into the atmosphere. And languages differ from each other, chiefly, by presenting various predominant groups of such sounds. The chief distinction of the sounds of speech depends on the way they are transmitted through the oral canal before spoken of, or the nasal passage. Another important distinction between articulate sounds is, that some are only of momentary duration, taking place during a sudden change in the conformation of the mouth, and are not capable of prolongation by a continued effusion of the breath; while others can be prolonged as long as a particular disposition of the mouth and a constant expiration are maintained.

The same sound produced in the larynx is converted into any one of the vowel-sounds merely by a modification of the parts of the mouth through which it passes. The parts of the mouth concerned, have been termed the oral canal, and the oral opening. The oral canal, it is to be remembered, is the space between the tongue and the palate; the oral opening is the aperture formed by the lips. Some physiologists have described five degrees of size in each of these two parts—that is, five degrees of size in the oral canal, and five degrees of size in the oral opening. One sound, then, produced in the larynx is converted into *a*, *e*, *i*, *o*, *u*, according to the modifications in the size of these two parts. Thus, when the size of the oral canal is in the third degree, and the size of the oral opening is in the fifth or highest degree, the act of voice is converted into the sound of the English *a* in *far*. When the size of the oral canal is in the second degree, and that of the oral opening in the fourth degree, the sound of the English *a* in *name* is produced. When the size of the oral canal is in the first or lowest degree, and that of the oral opening in the third degree, the sound of the English *e* in *theme* is produced. When the size of the oral canal is in the fourth degree, and that of the oral opening in the second degree, the sound of the English *o* is produced. When the size of the oral canal is in the fifth or highest degree, and that of the oral opening in the first or lowest degree, the sound of *u* like *oo* in *cool* is produced. Of the general truth of this statement, any person may satisfy himself by remarking, when he utters the broad *a*, how much he opens his mouth, simply breathing forth the voice with open mouth. When, on the contrary, he, with the same breath, attempts to pronounce *e*, he finds the mouth close considerably, and the tongue rise towards the roof of the mouth, so as to contract the oral canal. In pronouncing *o*, he will observe how the lips are thrown into the form of the letter, the tongue at the same time raised from the bottom of the mouth. The form of the vowel o, in most languages, points to one source of origin of those representations of sounds which we call alphabets.

Some consonants, like vowels, can be pronounced with an uninterrupted sound, which continues as long as the expiration can be prolonged, the disposition of the parts within the mouth remaining throughout as at the commencement of the sound. Of these, the aspirate *h* is pronounced with the whole oral canal open; no interruption is offered to the passage of the breath; its sound is the simple result of the resonance of the walls of the cavity during expiration. Others of the same class, such as *m*, *n*, and *ng*, are produced by continuous expiration through the nasal canal, the aperture of the mouth being closed either by the lips or by the tongue being pressed against the palate. The mouth is closed by the lips while *m* is pronounced, the sound being produced by the simple passage of the air through the nasal cavity. When *n* is pronounced, the mouth is closed by the extremity of the tongue being pressed against the fore part of the palate. *Ng* is regarded as a simple sound in the words *sing* and *bang*. It is produced also by the passage of sound through the nostril, while the posterior part of the tongue is pressed against the palate. Other consonants, again, of the same class, are continuous sounds developed by the valve-like application of different parts of the mouth to each other, such as *f*, *s*, *r*, *l*. *F* is pronounced by the application of the lower lip to the teeth. In pronouncing *s*, the teeth are brought into contact with each other, while the point of the tongue touches the lower teeth; in the sound of *r*, the tongue vibrates against the palate; in the sound of *l*, the point of the tongue is applied close to the palate, and the air escapes between the tongue and the cheeks. The English *th* is a modification of *s*.

The mute consonants, with explosive sounds, come next to be spoken of. The organs of speech, by which these sounds are formed, undergo a sudden change of position during their production. The sound commences with the closing of the mouth, and terminates when it opens—that is to say, these consonants cannot be prolonged at pleasure; *b*, *g*, *d*, of which *p*, *k*, *t* are modifications, coming under this head. In sounding *b*, the lips are brought together, and close the mouth, while they separate again at the moment the air is expired. In sounding *d*, the tongue is applied to the anterior part of the palate, or to the upper teeth, so as to close the mouth, which opens with the escape of the breath. In sounding *g*—that is, the hard *g*, as in *gold*—the momentary closure of the passage through the mounh takes place, more posteriorly, by the application of the back part of the tongue to the palate. In sounding *p*, *t*, and *k*, the requisite modifications of *b*, *d*, and *g* are produced, by a stronger aspiration during the opening of the mouth, which was previously closed. All the sounds hitherto mentioned are capable of being pronounced in whispered speech. The English *y* and *z* cannot be uttered without an accompanying vocal sound. Thus, when an attempt is made to sound the English *y* in a whisper, the German *ch* is produced in its stead. All the vowels are capable of being produced equally in whispered speech, and with a vocal tone. Many consonants also, as *f*, *s*, *r*, *l*, *m*, *n*, *ng*, can be pronounced either with mute sounds or with vocal intonations. The continuous consonant *h* can only be pronounced in whispered voice; and it is quite impossible to combine the sounds of the explosive consonants, *b*, *d*, *g*, and their modifications, *p*, *t*, *k*, with an intonation of the voice.

Besides the ordinary sounds of consonants which enter into the formation of languages, other sounds are capable of being produced in the mouth and throat. The smacking sounds produced by the separation of the teeth from the tongue or palate, are reported by travellers to occur in the language of the Hottentots, and in those of other African tribes.

The several sounds and tones of language can even be imitated by artificial contrivances. When the sound of the voice is made to pass into a cylindrical tube, before which the hand is held, and then withdrawn, the sound of *b* is produced; and if the tube be a pipe with a membranous tongue, the sound of *v* is produced. Various speaking machines, by attention to such principles, have been produced: the most perfect of these is that contrived by Faber. The automaton, invented by Faber, has a singing voice, extending over twelve notes. The difference in the height of the notes is made by varying the width of the glottis without tension of the cords. In this respect, it is hardly an exact model of the organ of the human voice.

The singular faculty possessed by ventriloquists has engaged much of the attention of physiologists. Many different views as to the nature of this kind of speech have been at various times brought forward.

One of the oldest and most common ideas on this subject is, that ventriloquism consists in speech produced during inspiration. It is unquestionably possible, though not without difficulty, to articulate during inspiration; and the sounds so produced have some resemblance to the tones uttered by a ventriloquist.

A more recent view of the nature of ventriloquism is, that it is a mere imitation, produced in the larynx, of the various modifications which the voice ordinarily suffers from distance, by the interposition of a partition, as if the individual were enclosed in a narrow space—in a trunk, a cask, or the like. This view has been supported with much ingenuity by Magendie.

The distinguished German physiologist, Muller, has adopted an idea on this subject which coincides better with the original name of this artifice. He says that the notes of ventriloquism are produced by inspiring very deeply, so as to protrude the abdominal contents by the deep descent of the diaphragm; and the diaphragm being retained in this position, by speaking through a very narrow glottis, expiration is performed very slowly by the lateral walls of the chest alone. He affirms, that the quality which the voice has, in speaking through an expiration thus performed, is that peculiar to ventriloquism, and that sounds may be thus uttered which resemble the voice of a person calling from a distance.

A very large share of the artifice practised by the ventriloquist, particularly in the imitation of voices coming from particular directions, lies in the deception of other senses besides the hearing. The directions in which sounds reach the ear are never very easily distinguished; and when the attention is drawn to a different point, the imagination is very apt to regard the sounds produced as coming from that quarter.

Of the imperfections of speech, stammering is that which has been chiefly investigated; and it lies in a momentary inability to pronounce a consonant or vowel, or to connect it with the preceding sounds. This impediment may occur either in the commencement or in the middle of a word. When the impediment arises in the middle of a word, the commencement of the word is often several times repeated. Hence stammering is apt to be defined as the successive repetition of one sound. The repetition of the commencement of the word, however, is not the essential defect which constitutes stammering; it merely marks repeated attempts to overcome the difficulty. Neither is it correct to say that the difficulty in stammering lies chiefly in pronouncing the consonants, for the impediment most frequently occurs in the case of vowels. The best account which has been given of the nature of stammering is, that it depends on the momentary closure of the glottis, so that the passage of the air necessary to the pronunciation of the particular sound is arrested. In persons severely affected with this impediment, there are manifest indications of the struggle at the glottis, occasioned by the impediment to expiration, in congestion of blood in the head and in the veins of the neck. The real cause of stammering, therefore, must be described as an unusual movement in the larynx, associated with the articulate movements. In short, stammering is a temporary spasmodic affection of the glottis. For the prevention of stammering, the proper plan is to endeavour to bring the associated movements of the larynx with the organs of speech more under the command of the will. To sing words is one method of obtaining this effect; since in singing, more attention is directed to the action of the larynx than in ordinary speaking. Moreover, it is observed, that persons who stammer, pronounce better in singing than in mere speaking. The raising of the point of the tongue towards the palate has some effect in counteracting this habit; and this elevation of the tongue seems to have been the object of the plan practised by the ancients, of placing bodies, such as pebbles, under the tongue. Müller recommends, for the cure of stammering, that the patient should practise himself in reading sentences in which all the letters which cannot be pronounced without a vowel sound—namely, the explosive consonants, *b*, *d*, *g*, *p*, *t*, and *k*—are omitted, and only those consonants included which are susceptible of an accompanying intonation of the voice. He also directs that all those letters should be very much prolonged. He says that, by this means, a mode of pronunciation will be attained, in which the articulation is constantly combined with vocalization, and the glottis, consequently, never closed.

As already mentioned, dumbness is dependent, not on the defect of the organs of speech, but on the absence of hearing. By assiduous efforts, deaf-mutes learn the movements of articulation by means of their sight. The speech which they acquire is most commonly harsh, owing to the want of the sense of hearing to regulate their articulation. There was no discovery hailed with greater interest than that of teaching the dumb to speak; and undoubtedly, harsh though the sounds be—and yet they are not always disagreeably harsh—there can hardly be a greater triumph of human art. It will hardly be believed that some innovators on the education of the deaf and dumb, seek to abolish the practice of teaching them to articulate, on the ground that their harsh speech is unfitted for the uses of society, and that they can communicate with their fellows sufficiently by other means, as by speaking on the fingers and by writing. This is a most unwarrantable view of the case of these unhappy persons, particularly when they belong, as by far the major part of them must do, to the labouring classes of society. We have only to consider how many persons there are in the condition of a labourer who cannot write, or read writing, to be satisfied that this innovation on the education of the deaf and dumb, should be at once put down in every institution in which it has gained a footing. There is every reason to believe, that in proportion as a knowledge of the mode in which the sounds of the human voice in speech are produced, becomes better understood, the artificial articulation of the deaf and dumb will become gradually less harsh and disagreeable.

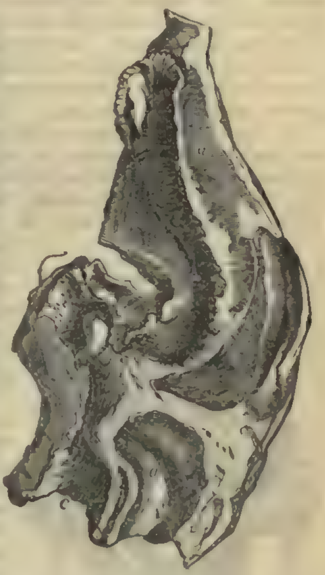
Comparative Physiology of Voice.—Organs of voice occur among inferior animals, in the mammalian tribes, birds, and reptiles. In mammals, the organs of voice bear a close resemblance to those of man. In birds, considerable modifications occur in these organs. In reptiles, the apparatus of voice is of greater simplicity.

Voice of Mammals.—Among mammals, some are mute; and yet these are not always deficient in those parts of the larynx which are most essential to voice.

Among the orders which compose the class mammalia, the cetaceans, consisting chiefly of the whale tribe, are often described as mute. These animals, however, are not mute altogether, but possess only a single lowing note, or, at the utmost, they have the power of simply bellowing. There are two distinct sections of cetaceans. The first includes what have been termed the herbivorous cetaceans, such as the sea-cow, *the representative of the popular mermaid*, and the dugong. The second order includes the common cetaceans, popularly known as blowers. The act of blowing, from which they derive their name, consists in the expulsion of water by the nostrils; that is, along with their prey they receive a large quantity of water into the mouth, and, while the mouth remains closed, they blow out this superfluous water by a hole in the upper part of the head.

This expulsion of water is produced by means of a peculiar arrangement of the veil of the palate. The water accumulates in a sac situated at the external orifice of the cavity of the nose, whence, by the compression of powerful muscles, it is violently expelled through a narrow aperture pierced on the summit of the head. By this contrivance these animals throw forth those jets of water which are seen by mariners at a great distance. The larynx has a pyramidal form (see Fig. 19), and penetrates into the posterior portion of the nostrils to receive air, and conducts it to the lungs, without the animal being obliged to raise its head and mouth above water for the purpose. As there are no projecting laminæ in the glottis, they can hardly be said to have the proper organs of voice; and thus the noise they make may be described as a simple vehemence of expiration.

Fig. 19.



SECTION OF TONGUE, PHARYNX, AND LARYNX OF PORPOISE.—*Museum of College of Surgeons of London.*

a, pyramidal position of larynx; *c*, pharynx; *d*, laryngeal cavities laid open.

The larynx, however, in these animals is highly developed in other respects.

Among the animals commonly described as mute, is the giraffe or cameleopard, termed by naturalists *Cameleo-pardalis giraffa.* In the giraffe the vocal ligaments appear to be absent.

The armadillo (*Dasypus*) is another of the mammalians described as mute. The only peculiarity of the larynx which has been observed is, that the epiglottis, or valve-like cartilage of the larynx, is bi-lobed. The armadillo, it will be remembered, is remarkable among mammals for the scaly, hard, bony shell, composed of pavement-like compartments, which cover the head, the body, and even the tail. These animals belong to the order termed Edentata. They live in burrows, which they excavate. To the Edentata also belong the ant-eaters (*Myrmecophagæ*), which are regarded as mute. In the same order is found the sloth (*Bradypus tridactylus*). In this animal, however, vocal ligaments are found, and the windpipe is convoluted. The voice is a plaintive melody, consisting of an ascending and descending scale of the hexachord.

LARYNX OF CAMEL LAID OPEN.—*Bishop.*

a, epiglottis; *b*, superior vocal cords; *c*, inferior; *d*, arytenoid cartilages; *e*, vertical ridge; *h*, tubercle; *f*, trachea.

Among the Rodentia, or gnawers, the common porcupine of Europe is mute. In this animal it has been ascertained that there are no vocal ligaments.

Such, then, are a few examples of the animals in the class Mammalia which are mute, or nearly so.

In the order Ruminantia, we find animals possessed of a sonorous voice, exemplified particularly in the ox. In the ox, the larynx is well developed; there are no superior vocal ligaments, but the inferior or true vocal ligaments are strong, and nearly an inch in length; the windpipe consists of fifty-two cartilaginous rings; that is, nearly three times as many as their number in man. The voice is sonorous, intense—pitched in C=256 vibrations in a second.*

The sheep belongs to the same order of quadrupeds. The larynx differs from that of the ox only in dimensions. The voice is guttural—pitched in F=341 vibrations in a second.—To the same order belongs the camel (*Camelus Bactrianus*). In the camel, the larynx is well developed; the superior vocal ligaments are present, and the inferior vocal ligaments are strong. The voice is grave, but seldom exercised. (See Fig. 20).

In the Pachydermata, or thick-skinned animals, there are many species possessed of a sonorous voice. Among these are the horse, the ass, the hog, the rhinoceros, and the elephant. In the horse, the larynx is highly developed (see Fig. 21), and the windpipe has as many cartilaginous rings as that of the ox. The superior vocal ligaments are not prominent. Above the junction of the proper vocal ligaments, between that and the epiglottis, there is an oval cavity; and on the posterior surface of the epiglottis there is a groove, furnished at its base with a semi-lunar membrane. To this membrane much effect has been ascribed in the production of the peculiar neighing of the horse. It is doubtful, however, if this peculiar sound be so much dependent on this membrane as has been believed.

In the ass the larynx is also well developed. In the windpipe the rings are spiral. The bray of the ass—which seems greatly to depend upon the presence of two large sacs placed between the vocal ligaments and the internal surface of the thyroid—is well known; it has a range of about five tones.

In the mule, the larynx resembles that of the ass. The voice is a species of bray, more resembling that of the ass than the neighing of the horse. The tapir (*Tapir Americanus*) has some peculiarities in its larynx. It has, however, superior vocal ligaments, which are short and distinct, and inferior vocal ligaments, which are strong. The voice is a species of whistle.

a, thyroid cartilage; b, cricoid; c, crico-thyroid ligament; d, trachea.
B. POSTERIOR VIEW OF THE SAME.
e, cricoid; c, laryngo-tracheal ligament; d, trachea.

The hog (*Sus scrofa*) has also some peculiarities in its larynx: its voice, as is well known, is a grunting, discordant sound.

The rhinoceros is remarkable for having the superior vocal cords very prominent.

In elephants the larynx is largely developed. The superior vocal ligaments are indistinct; the inferior or proper vocal ligaments are strong. The windpipe exhibits thirty rings, which are often partially subdivided, as in the case of the bronchial ramifications. The voice, aided by the trunk, is intense, and of a grave pitch.

Under the head of Marsupial animals, we find the kangaroo and the opossum.

In the kangaroo (*Macropus major*), several peculiarities occur in the larynx. In particular, the vocal cords are membranous, and fold upon themselves, so that they cannot be stretched by the arytenoids. The voice, when in pain, consists of a piteous moan. In the opossum (*Didelphis opossum*), the vocal ligaments are very short; hence the voice is acute. The opossum purrs like a cat. (See Fig. 22).

In the order Carnivora, we find examples of animals with intense voice.

In the lion (*Felis leo*), the larynx is well developed; the vocal ligaments, both superior and inferior, are present; the superior being prominent. The ventricles of the larynx are deep, forming a sac between the upper and under vocal ligaments. The windpipe is possessed of fifty cartilaginous rings. The voice is grave—highly intense; the roar terrific.

The tiger (*Felis tigris*) has a larynx resembling that of the lion, the superior vocal ligaments being very prominent. The voice of the tiger is more acute than that of the lion. It purrs like the cat. The leopard and the cat belong to the same genus; *Felis leopardus* and *Felis catus*. These two animals, like the rest of the feline tribe, have the superior vocal ligaments well developed. It is supposed that by these superior vocal ligaments the purring sound is produced. The voice in both animals is a mewing; and they have by night a melancholy cry. (See Fig. 23).

In the order Quadrumana, to which the apes and monkeys belong, the essential form of the organ of voice does not vary much, but peculiarities occur in the resounding walls. Thus, in the ourang-outang, a sac exists between the thyroid cartilage and hyoid bone; and in the mandril, pavian, and macacos, membranous sacs are observed below the hyoid bone. In the Mycetes, or howling apes of the New World, the apparatus for the resonance of the voice is greatest. In these the hyoid bone, and the thyroid cartilage, are expanded in such a manner as to contain large cavities, which open into the ventricles of the larynx; and besides this, there appear to be sacs common to the larynx and pharynx. Further, the epiglottis, in these apes, has a very large and peculiar form. In the Sapajous (Ateles and Cebus), a curved tube is formed by the increased size and altered forms of the epiglottis, and some adjacent structures. The voice of these animals has a whistling character.

In the chimpanzee the true vocal ligaments are prominent. The windpipe has sixteen rings. The voice is more acute than in women; its quality inferior, owing probably to the sacculated larynx. (See Fig. 24). In the ourang-outang the inferior vocal ligaments are prominent, but not so long as in the families of the human race. The ventricles are valvular, so that the inflation of the peculiar sacs is under the control of the animal.

In the Gibbons, the ventricles are deep, and communicate with a sac. The voice is acute; the cry "bow wow."

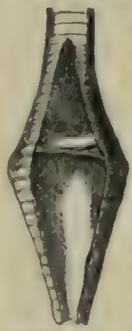
---

* See *ante*, p. 279.

In the monkeys of the old continent, there are also laryngeal sacs. These sacs modify the quality of the voice, giving to it, even when acute, a peculiar hoarseness. In the *Simia appella* and *Simia capucina*, there are some peculiarities in the structure of the channel for the passage of air. The voice, in quality, is like that of a flute; hence these are called whistling apes; and, from the peculiar expression of this whistle, which is a plaintive melody, they are termed weeping apes.

Voice of Birds.—The great peculiarity in the organs of voice, among birds, is the inferior larynx; that is, birds, in addition to the larynx corresponding to that possessed by mammals, have one peculiar to themselves, at the inferior extremity of the windpipe. Even the superior larynx of birds differs considerably from the larynx in mammals. The superior larynx, like that of mammals, is placed just below the hyoid bone. It is partly cartilaginous and partly osseous. In the superior larynx of birds there are cartilages corresponding to the thyroid and the cricoid, the two arytenoid, and the epiglottis. The cricoid is much less developed than in mammals; it forms but a small portion of a ring, occupying the posterior part of the larynx, and supporting, as in mammals, the two arytenoid cartilages. The thyroid cartilage, consequently, rests on the first ring of the windpipe. To the posterior margins of the thyroid cartilage are connected two quadrilateral bones, by which the extent of the protection afforded by the wings of the thyroid cartilage is much increased. The arytenoid cartilages are long, and taper upwards and downwards; they form, by their inner margins, the chink of the glottis. They are generally ossified; their external margins are bounded by the thyroid cartilage. The epiglottis, in most birds, is rudimentary, and generally is osseous. The chink of the glottis in birds is triangular, the apex being directed upwards. It is bounded in front by the thyroid cartilage; on each side by the arytenoid cartilages; and behind by the cricoid cartilages; but it has no salient membranous laminæ, such as the vocal ligaments in man and mammals have. It is capable of expansion and contraction under the action of several muscles. The inferior larynx is, as we have seen, peculiar to birds. (See Fig. 25). It varies very much in form and structure. This larynx, the vocal instrument of birds, is a tube, at the opening of which is a membranous tongue. This tongue is a doubling of the interior lining of the bronchus, its free margin being directed upwards; and birds have, for the most part, a smaller or greater number of muscles, capable of shortening this tongue, or of lengthening it in the direction of its height, and of rendering it tense or lax in a transverse direction.

Fig. 25.



SECTION OF INFERIOR LARYNX OF BIRDS.

In general, the inferior larynx of birds is produced by a membrane which makes a projection on each side of the inferior orifice of the windpipe; this orifice is divided into two apertures, sometimes by an osseous bar passing from before backwards, sometimes merely by the angle of union between the two bronchial divisions of the windpipe. The bronchi are not composed, like the windpipe, of complete rings, but merely of osseous or cartilaginous segments of rings, of a greater or smaller number of degrees in extent, each having a proper curvature in the state of rest, which curvature may vary, to a certain amount, by the action of voluntary muscles.

It hence follows, that the portions of the walls of the two bronchial divisions of the windpipe, adjacent to (that is, looking towards) each other, are, for a greater or smaller extent, membranous, being there destitute of any osseous or cartilaginous structure; and it is to this usually large portion of the wall of each bronchus that Cuvier gives the name, tympaniform membrane. Thus two tympaniform membranes descend, looking towards each other from the angle at which the windpipe divides, forming the interior wall of each of its subdivisions, and being extended transversely between the anterior and posterior extremities of the upper osseous segments of the same subdivisions; these osseous segments extending only along the posterior, the external, and anterior part of their wall, so as to leave the inner part of each bronchus simply of a membranous structure.

The first osseous segment of each bronchus has much the same curvature as the windpipe itself; but the second and third are portions of larger circles, and are less convex exteriorly than the first, so that the latter project on the inner side of the tube.

On this interior projecting part, the lining membrane forms a fold; and it is this fold, half shutting one of the inferior apertures of the windpipe, which offers to the air issuing forth, a tongue capable of vibrating and of producing sound.

The inferior larynx of singing and some other birds, in which the voice is far from musical, is very complicated. The last rings of the windpipe unite into a structure two or three lines in length, nearly cylindrical above, and expanded below, where it has two obtuse points—one anterior, another posterior—joined by the bony bar passing from before backwards, already spoken of more than once. This bar is so placed that the windpipe opens below by two oval holes, making with each other an obtuse angle; and each of these holes communicates with one of the bronchi.

The three first osseous segments of each bronchus are more near to each other, and flatter, than those which succeed them. From the first to the third there is a gradual elongation behind, so that the posterior extremity of the last makes a sort of projection, owing to the sudden diminution of the fourth segment. The arc which these segments form hardly exceeds 60°; and in each bronchus, the cord of this arc, so to speak, is the tympaniform membrane. The first segment of each bronchus curves its anterior extremity towards the inner surface of the tube, where it articulates with a small oval cartilage which is fixed to the tympaniform membrane; while it forms within, a prominence which is the vibrating lamina of the larynx on that side. Thus the transverse section of each bronchus is below—nearly circular; the section higher up becomes the segment of a circle, which diminishes in one direction while it enlarges in another; and the passage of the air, upwards into the windpipe, takes place by two oval holes, each furnished at its anterior border with a salient lamina. This apparatus is supplied with ten muscles, five on each side.

Of these, one descends from the interior of the windpipe to the anterior extremity of the third segment of the bronchus; and, by its contraction, draws that point upwards, thereby making the vibrating lamina project further inwards, and, at the same time, rendering tense, lengthwise, all that part of the tympaniform membrane lying below the segment to which the muscle is attached. Another muscle, parallel to this, has nearly the same attachments, and a like office. A third muscle, much smaller, extends from the inferior and posterior part of the windpipe, and is inserted into the posterior extremity of the second bronchial segment. Its action is similar to that of the former. A fourth muscle passes obliquely from the windpipe to the posterior extremity of the second bronchial segment. It draws that segment upwards and outwards, so as to aid the action of the muscles already referred to, and of that which follows. The fifth muscle is no longer than the preceding, but is much thicker. Taking its origin from the last ring of the windpipe, it passes downwards and forwards, and is inserted into the anterior extremity of the first bronchial segment, and particularly into the minute cartilage already mentioned as being articulated with that point. Its chief action is to draw forward the small cartilage, and consequently to put forcibly on the stretch, in a transverse direction, the upper part of the tympaniform membrane.

Such a complex structure of the inferior larynx belongs, as was hinted at, not only to singing birds—such as the nightingale, the wren, the blackbird, the goldfinch, the lark, the linnet, the canary, and chaffinch—and to those with a monotonous cry, like the swallow, the sparrow, the starling; but also to some with a decidedly disagreeable cry, such as the jay, the magpie, the crow, the raven. Thus, not only is a complex organ necessary to the musical singing of birds, but also a fine general organisation and a singing instinct.

The windpipe in birds presents some very singular modifications. As the voice is produced in the inferior larynx of birds, situated at the lower part of the windpipe, this tube comes to form, together with the mouth, the tube or pipe placed in front of the organ of voice. In short, the windpipe of birds comes to occupy a place corresponding to the situation of the organs of speech in the human body. It is capable of being shortened, not only by the diminution of the spaces between the rings themselves, but also by the rings being received one within the other. In many birds, the windpipe is much longer than the neck, being thrown into convolutions. This structure is observed in the cock-of-the-wood, the stork, and crane. In the wild swan, the convolutions of the windpipe are lodged in a cavity of the breast bone. Nor is the windpipe always cylindrical, for in herons and cormorants it has a conical figure, becoming gradually wider and wider towards the mouth. In some species of ducks it presents a sudden dilatation; while in the goosander, and some members of the duck family, it undergoes gradual dilatations.

That the inferior larynx of birds is the true organ of voice has been proved by many experiments. For example, anatomists have divided the windpipe in singing birds, such as the blackbird, about the middle of its length, so that the air could no longer pass through the superior larynx, and yet the bird would continue to sing, though with feebler tones than before. Similar experiments have been made on magpies and on ducks. After such an experiment, the magpie is found to cry with as great intensity of tone, and with the same acuteness, as before the operation. Again, if air be blown into the bronchial divisions of a duck, after their separation, together with the inferior larynx from the body, a sound exactly similar to the natural cry of the bird is obtained. Even after the bronchi have been cut away, by blowing into the trachea the same sound is produced.

It is not, however, to be concluded that the superior larynx exerts no modifying influence on the voice in most birds. It is manifestly opened and closed rapidly in singing birds, so that it is impossible to doubt that it takes an active part in the production of melody. In the song of the canary and the linnet, its simultaneous movements with those of the mouth are readily observed. Its effect, however, on the pitch of the voice, is not supposed to exceed a semi-tone. Physiologists still doubt whether the sounds of the voice in birds are the result, as in man, of the vibrations of a reed or tongue; or, as in mere flute-pipes, of the vibrations of a column of air excited by friction against the lips of an opening. There is unquestionably a great difference in the mode in which voice is produced in different birds. It seems certain that the simple organ of voice in the duck, the goose, and the like, is a reed instrument. In these the vocal cords, or bands, which form the exterior margin of the opening of the larynx, can be seen to vibrate strongly; while the sound produced, closely resembles that arising from the vibrations of membranes. But it is by no means so clear that the piping and whistling sounds of singing birds are produced in the same manner; and it is not impossible that these may be effected in the same mode as whistling by the mouth in man.

Several reasons, however, may be urged in favour of the opinion, that the sounds uttered by singing birds are the effect of the vibrations of tongues, as well as the voice of the duck and the goose. For example, the vocal cords under muscular action can hardly escape being thrown into vibrations; and even though the friction of the air may be in part concerned in the production of the sounds, a compensation must arise between the vibrations of the air and those of the vocal ligaments. If this be correct, the organ of voice in birds would not be entirely analogous to a whistle or pipe; but would, in part, possess the constitution of a reed instrument. It is found that the length of the windpipe has but a very slight influence on the note produced by the larynx; and that fact corresponds with the slight effect on the pitch of the notes produced by placing a tube in front of the human larynx. It is also found, that sounds produced by blowing, by means of a tube inserted in a bronchus, through the lower larynx of some birds after its separation from the windpipe, are not perceptibly altered in pitch by holding a tube in front of the larynx: thus is confirmed the resemblance of the lower larynx in birds to the character of the larynx in man. It may be added, that the greater number of the notes of birds can be obtained from the inferior larynx by varying the force of the blast, which, at first sight, seems to point to a resemblance with the effect of blowing by varying force upon the notes of flute-pipes, of the same size as the windpipe of small singing birds. But it is to be remembered, that the same variations of notes, by varying the strength of the blast, may be produced in reed instruments with membranous tongues, and even in reeds with very delicate metallic tongues.

The influence of the windpipe on the notes, may be either the same as that of the notes of flute-pipes, or it may merely affect them in the manner of the tube of reed instruments. Contraction of the upper opening of the windpipe, at the superior larynx, may lower the note, as in pipes and reed instruments.

An influence may be exerted on the sounds produced in the lower larynx by the tympaniform membrane, which vibrates strongly at the time. Between the internal vocal cord, the semi-lunar membrane, and the tympaniform membrane, there is a relation of compensation, the latter being analogous to the membrane formed of a reed stalk.

The muscles which vary the tension of the walls of the vocal pipe are in continual action during the modulation of the voice, in order to adjust the tube of the windpipe to the pitch of the glottis; but the number of vibrations may be determined by the glottis, reinforced by the walls of the pipe, as in mammals.

The voice of birds, as of other animals, is also in a minor key. The range of notes is commonly within an octave, though some birds can greatly exceed it. In the parrots, which have a voice of great power, the inferior larynx is single. The two membranes of the larynx leave a narrow chink between them, through which the air is forced from the lungs. These membranes, vibrating in all their dimensions, produce that harsh and disagreeable quality of sound peculiar to them. They can also whistle, during which the glottis is probably silent, and the column of air vibrates as in a flute, when a vibratory movement is communicated by the air traversing the elastic walls of the tube. Besides the power of speech possessed by some birds, many can imitate almost every sound they hear: the blackbird has been known to imitate the sound of the nightingale, the crowing of the common cock, and the cackle of the hen. The jay is said to mock the notes of the greenfinch and the neighing of a horse so closely, that it was scarcely believed to be a bird by those who heard it; it can also imitate the calling of fowls to their food, and the barking of the house-dog.

The variety in the song of singing birds is a subject of the greatest interest. The songsters, properly so called, include the skylark, the woodlark, the thrush, the blackbird, and the nightingale. A slight notice of the notes of each of these follows.

The skylark is one of our most agreeable songsters. Its song is composed of several strains, each consisting of trilling and warbling notes variously modulated, occasionally interrupted by a powerful whistling. Sometimes the lark sings on the ground, perched on a clod, or crouched among the grass; but generally, in commencing its song, it starts off, rises perpendicularly or obliquely in the air, with a fluttering motion, and continues it till it has attained its highest elevation, which not unfrequently is such as to render the bird scarcely perceptible. Even then, as remarked by a distinguished naturalist, if the weather be calm, its warble can be heard coming faintly on the ear at intervals. The lark is also a bird of singular capacity; the young learn the notes of any other bird which hangs near them in confinement; and some full-grown birds are observed to possess a like facility. There is, however, a considerable difference among larks in the strength and melodiousness of the note. In confinement, some larks begin to sing as early as November, and go on singing until moulting time; others begin in March, and cease as early as August. In the wild state their period of singing is much shortened.

The woodlark is considerably less than the skylark; but, of all the larks, it is the sweetest songster. Its voice has all the melody of the flute, marked at times by a tender, and even somewhat melancholy strain. It sings sometimes in the air, sometimes on the top of a tree. When singing in the air, it is frequently seen flying in large, irregular circles. The woodlark sings late in the evening, so as sometimes to be mistaken for the nightingale. The female woodlark, like the female of larks in general, is not destitute of song; but all that it can reach is a few strophes, which are much interrupted.

The thrush has a clear and beautiful song. On the tops of the highest trees it welcomes the approach of spring, and sings throughout the whole summer, especially in the morning dawn, and the evening twilight. It is kept in a cage by bird-fanciers, whence often on a morning, even as early as February, it will delight a whole street by its pleasing song, outside the window, or even inside, provided the window be a little open. The thrush, in its wild state, is fond of bathing. In September and October they are often caught at the places where they water, before sunrise and after sunset, and even so late that they cannot be seen, but are only heard. At the time of bathing they have a peculiar call-note. When a thrush finds water, or when it is flying towards a known watering-place, it pipes loudly—*sik, sik, sik, sik, siki, tsak, tsak!* and immediately all the thrushes in the neighbourhood reply, and come on.

The blackbird has a song rich in melody, containing some deep notes, like those of the nightingale, yet varied with some which are unpleasantly harsh. When at liberty, it sings from March to July, particularly at night. In the cage it sings throughout the whole year, except at moulting time. Its note is pure, distinct, and clear. It has a good memory, and will learn several airs or melodies without confusing them. It is even able to imitate words.

The nightingale, by the fineness of its voice, surpasses every other bird. The variety and peculiarity of its tones express its varying emotions. When the male is alone, its most significant note is the pipe-note *witt.* But if the harsh syllable, *krr*, be added, it forms the call of the male to the female. To express anger or fear, the note *witt* is repeated with great loudness and rapidity before the termination *krr* is added. When happy and contented, the nightingale utters a deep *tack.* Under the excitement of anger, jealousy, or alarm, the nightingale utters an unpleasant shrieking tone, which resembles the cry of the jay. When they sport and chase each other, which they frequently do in pairing-time, they utter a very short chirping sound. Such notes belong to both sexes; but the power and the brilliancy of its song distinguishes the male. Its vocal organ is of striking power; the muscles of its throat are more robust than those of any other singing bird. Besides the strength of its voice, the nightingale is remarkable for the force, the agreeable transitions, and the beautiful harmony of its song. Commencing softly, it warbles for a moment a succession of low melancholy notes, which gradually increase in strength, and at last die away upon the ear. A variety of sharp notes follows, and then are uttered numerous hurried sharp notes, intermingled with some detached ascending notes, with which it generally closes its strain. In the song of a fine nightingale, without reference to slighter variations, there are at least four-and-twenty different strains.

Among the sparrow and finch tribes there are many much-prized singing birds.

The bullfinch has naturally a harsh, creaking tone; but young birds learn all kinds of songs, airs, and melodies. If it be desired that a bullfinch should sing perfectly, it ought never to be taught more than one melody, in addition to the fanfare, which is always added by way of surplus.

The chaffinch has a variety of notes expressive of its wants and desires. There is one delicate note, expressed *treef, treef*, by which it appears to remark a change of temperature. The call-note, which it uses chiefly on its migration, is a repeated *yack, yack.* A spontaneous sound appears to be *fink, fink*, which it reiterates, and from which perhaps the root of its name is derived. More remarkable than these notes is its clear and trilling song; as approaching more to distinct articulation, it is termed a quaver. Each bird has one, two, three, and often as many as four different songs, each of which lasts a couple of seconds, and consists of several strophes.*

The linnet has a very remarkable, loud, and flute-like song, consisting of many connected strophes; which is the more beautiful the oftener it utters some high-sounding notes, which are termed its crowing, from the resemblance to the crowing of a cock. From its natural flute-like voice, this bird surpasses all others in its capacity for imitating melodies in a beautiful and pure style. A young linnet, taught by a nightingale, has an exceedingly pleasing song.

The goldfinch has a shrill, agreeable song, heard during all seasons, except at the period of moulting. It contains many warbling and twittering notes, on which it dwells more or less; and the oftener the syllable *fink* is repeated, the more it is admired. Some birds utter these notes only once or twice in their song; while others give them forth four or five times in succession. The goldfinch does not acquire the song of other birds with so much ease as the linnet and the canary.

The canary is distinguished by correctness of ear; by the remarkable skill it possesses of imitating all tones; and by an excellent memory. While canaries imitate the notes of other birds, they mix them with their own, so as greatly to improve the song. In different countries, canaries exhibit a different character of melody. Those birds which intermix in their melodies several strophes of the song of the nightingale, are called Tyrolese canaries. The English canaries, on the contrary, imitate the song of the lark.

Even birds of prey often exhibit no small extent of voice. The kestrel has a bell-like, ringing voice—*kli, kli, kli*, which he often repeats in rapid succession. The white owl utters a plaintive cry, which, by the superstitious, has been regarded as a sign of death. The raven has a hoarse croak, resembling the syllable *crock* or *cruck;* but it also utters a note not unlike the sound of a sudden gulp, or the syllable *cluck*, which it seems to utter when in a sportive mood. The rooks have a considerable variety of sounds. Their chief cry resembles the syllable *khraa*, more or less harsh or soft, according to occasion. There is great diversity in the voice of individuals; the notes of some being much louder and clearer than those of others. Their cries, separately, are monotonous and disagreeable; yet, when at some distance, and uttered by a large flock, they become by no means unpleasant. Mr. M'Gillivray describes the sounds proceeding from a rookery at night, as consisting of a variety of soft, clear, modulated notes, very unlike their usual cry. He regarded these sounds as expressive of affection, and was persuaded that the mothers were fondling and coaxing the newly-hatched young.

The jackdaw is extremely clamorous, with a loud and clear note, resembling the syllable *kae* or *caw*, variously modulated. The noise produced by a large flock, though in no degree musical, is far from being disagreeable. The jay can even learn to speak—uttering, however, nothing but solitary words. They may be taught also the fanfare of a trumpet, and other melodies of single bars, as well as little airs, and the notes of many birds. The magpie imitates all striking sounds, and can be taught to speak more easily than any other of the crow tribe. The cry of the cuckoo is universally welcomed as the harbinger of spring. Its principal sound is nothing but *hu-hu* or *coo-coo*, repeated at short intervals: when attention is given, however, it is found that these two loud and mellow notes are preceded by a kind of churring or chuckling sound, which consists of a low and guttural inflexion of the voice, during which the throat seems distended.

---

* Those who desire a particular account of the different songs of the chaffinch, may consult *Chamber Birds*, by Bechstein; translated from the German by Mr. Shuckard: London, 1848.

The parrot tribe are most remarkable for their power of imitating human speech. The cockatoo shrieks its own name, *cockatoo;* and calls loudly, in a trumpet-like tone, *derdeny*. It acquires the cries of all animals; particularly those of the domestic cock and hen. It rarely, however, acquires the power of articulating words. There are numerous species of cockatoo parrots having much the same character of voice. Among the commonest of the parrot tribe in Europe, is the ash-coloured parrot. This parrot readily learns to speak, and to pipe. It has not the unpleasant wild shriek of some of the parrot tribe. It takes no small delight in imitating the voice of children; hence children are its best instructors. If its education be begun early, it will sometimes acquire entire verses, and even axioms.

The grey woodpecker has a note which resembles a loud shout of laughter, whence some of its popular names are derived; this note is never varied, except by its more clamorous repetition during the spring and early summer months, and by the peculiar cry, *plui, plui, plui*, which has been supposed to indicate the approach of rain. The wryneck, in spring, frequently and loudly utters *gigigigi*, which is the call whereby it attracts its mate. The nuthatch utters a loud call, which may be heard at a considerable distance, resembling *grew, deck, deck*. The ring-dove, or cushat, has a loud and particularly pleasing cooing, during which it makes very grotesque motions, which may be backwards and forwards, or from side to side, moving the head in every direction. The turtle-dove has a peculiar cry, and bows its head while it is uttered.

Voice of Reptiles.—The sounds uttered by reptiles and amphibious animals have their source in the larynx, like the voice of mammals. In frogs, as well as in the crocodile, there are vocal cords. In the crocodile, the larynx, though more simple than in mammals, still retains something of the same character. There is one large, long-shaped cartilage, to which are attached two movable cartilages. The mucous membrane, descending from these movable cartilages into a deep pouch beneath, leaves a free fold on each side, which, when the movable cartilages approximate, becomes a vocal cord. In the gecko and the chameleon the vocal cords are more developed than in the crocodile; nevertheless they are formed on the same plan. The lizard has an acute, chirping voice, which has been supposed to depend on a peculiar membranous fold attached to the larynx; but it really seems to depend on a vibration of the margins of the glottis. In the turtle tribe there are no vocal cords, nor is their larynx adapted to a perfect intonation of the breath.

In the true serpents there are no vocal cords; the hissing sound, which constitutes their imperfect voice, is a mere forcible breathing. In the male frog, membranous sacs at the side of the neck become distended in the utterance of the voice, and serve to increase its intensity. In the *Rana pipa*, in which the larynx, as in all other frogs, receives the bronchi directly, without the intervention of a windpipe, there is a large cartilaginous box, within which are two solid reed-like bodies, nearly as long as the larynx itself. The anterior extremities of those bodies are fixed; their posterior extremity is free, and projects on each side towards the opening of the bronchus. The vocal sound is produced by the vibrations of reed-shaped tongues, which act like a tuning-fork; while in other animals of the same class, the parts which produce the sound are membranous. If a small piece of cartilage, a few lines in length, be fixed by one end, and a current of air be thrown from a small tube upon its edge at the other extremity, a humming sound will be heard. In the *Rana pipa*, also, the movable cartilages are convex externally, and concave internally; so that when the entrance to the larynx is closed, they form a dome over the windpipe, which has been compared to a kettle-drum. In the *Rana temporaria*, *R. esculenta*, and *R. hyla*, the larynx opens into two sacs on either side of the lower jaw; and these, during the cry of the animal, are filled with air. (See Fig. 26).

Sounds Produced by Fishes.—A very few fishes are known to utter sounds, such as the trigla, cottus, pogonias.

The trigla utters a grunting sound when it is taken out of the water. It has been supposed that the peculiar muscle of the air-bladder, in these animals, has a share in causing the sound. The cottus, however, from which a sound is heard to proceed when pressure is made upon its body, has no air-bladder. The pogonias, on account of the sounds which it produces, has been named the tambour. These fishes produce continued sounds under the water. The air-bladder is very large, and is covered by strong muscles; further, it has appendages, which, according to Cuvier, pass between the ribs, and become imbedded in the muscles.

Sounds produced by Insects.—Most insects are mute; others produce sounds merely by friction; others, again, by the passage of air through their spiracles. The sounds produced by friction come under the head of stridulation; those produced by air from the spiracles, purring or humming. In the orthoptera, and some of the coleoptera, there are parts adapted to produce stridulation.

In the cricket, the muscular apparatus may be described as consisting of a serrated string like a file, which, in the movement of the wings, is drawn rapidly over a firm, transparent, and nearly triangular disc, or sounding-plate, surrounded by a string; and by this act the sound is produced. The pitch of the sound of the house-cricket is very acute, being equivalent to about 4,096 vibrations in a second.

The cicadæ, termed sometimes the "*chanteuses*," or singers, are so called because the males produce, in the hottest part of the day, a kind of monotonous and noisy music:—

"Et cantu querulæ rumpent arbusta cicadæ."—VIRG.

The music of the grasshopper has from early times attracted attention. Archias sung of it; and his verse has been thus translated from the Greek:—

"Erst on the fir's green blooming branch, O grasshopper! 'twas thine
To sit—or on the shady spray of the dusky, tufted pine;
And from thy hollow, well-winged sides, to sound the blythesome strain,
Sweeter than music of the lyre to the simple shepherd swain."

Those, too, who loved these "living lyres in the olive groves, sounding all the summer long," have celebrated the locust:—

"Soother of loves, encourager of sleep,
O locust! mystic muse, shrill wing'd;"—

And the cicada:—

"Cicada! thou, who, tipsy with the dews
Of weeping skies, on the tall poplar tree
Perch'd swayingly, thyself dost still amuse,
And the hush'd grove, with thy sweet minstrelsy."

Melanger, alluding to the buzzing of insects, says, "Excute facundas pedibus titubantibus alas":—

"Striking thine own speaking wings with thy feet;"

but their real organs of sound are placed on the side of the base of the abdomen, internal, and covered by a cartilaginous plate, like a shutter, which is an appendage of the under side of the meta-thorax or posterior thorax. The cavity which incloses these instruments is divided into two partitions by a scaly and triangular edge. Seen from the under side of the body, each cell exhibits, anteriorly, a white and folded membrane, and, in the hollow part, a stretched-out, slender membrane, called the mirror. If this part of the body be opened from above on each side, there is seen another folded membrane, which is moved by a very powerful muscle, composed of a great number of straight and parallel fibres, extending from the scaly ridge; this membrane is called the *timbale*. The muscles, by contracting and relaxing with quickness, act upon the *timbales*, stretching them out or bringing them into their natural state, whereby the sounds are produced, and which, even after the death of the animal, may be repeated by moving the parts over each other in the manner they act whilst alive. The cicadæ occur chiefly in warmer countries of the world. One species, the *Cicada Anglica*, the only English species, is found in the New Forest.

It is a common belief that the buzzing of insects is produced by the oscillations of their wings during flight. This idea has been often called in question. John Hunter found that insects emitted sounds after their wings were cut off. More recently, it has been stated that the sounds produced by many insects are the effect of a rapid transmission of air through the thoracic air-holes as they dash through space. Mr. Bishop has observed a peculiar mechanism for this purpose in the blue-bottle fly, and humble bee. Figures 27 and 28, show one of the large thoracic spiracles in each of these insects —the *Musca vomitoria* and the *Bombus terrestris*.

(*Bombus terrestris*).

Having thus availed ourselves of Dr. Bushnan's elaborate paper on animal sounds, we shall now proceed to speak of other laws than those we have named; and also shall refer to various matters connected with daily life, in which the principles we have investigated are put into practical operation, or are more or less involved.

PRACTICAL ACOUSTICS.

UNDER the head of Practical Acoustics, we shall consider those applications of the science which relate to the construction of buildings specially devoted to concerts and public meetings; including, at the same time, some remarks on churches, and places of worship generally. Other matters incidental to the subject will fall under review.

Speaking from personal experience, we do not hesitate to affirm, that there are few buildings properly constructed on the principles of acoustics. In some places of small size, a great deal more exertion is required on the part of a public speaker, than in those capable of containing a very large audience; but which, by their shape, are more fitted for the purposes for which they have been erected. It is, however, a matter of congratulation to all whose profession or position requires of them to address an audience, that architects are, at the present time, inclined to sacrifice their own views, with respect to the appearance and ornamentation of an edifice, to considerations of utility. It is a custom, in China, to nail a baker by his ear to the doorway of his shop, if he have been found guilty of selling an adulterated article; similarly, it might conduce to the comfort of both speaker and audience, were each architect compelled to practise public speaking in a building of his own construction, until such were fit for the purpose for which it had been designed.

Sound is a radial force; that is, it proceeds from a point, in straight lines in all directions, like the radii or spokes of a wheel. Whatever object intercepts these rays of sound, either reflects or absorbs them. If such rays are emitted in the centre of a circular, or at the foci of an elliptic or parabolic shaped hall or other place, then they are reflected in exactly the same manner as rays of heat and light; and if such reflections take place from any of the curved forms we have named, then they are always inclined again to their source, and each reflection harmonises with another. In a building so constructed, we have the principles of acoustic science attended to. In the majority of modern edifices, however, we do not find such principles consulted. An eligible piece of ground has been purchased for a sum of money, and the cost of a building on it is regulated by the number of persons which can be crammed into it. Each corner must be utilised; peculiar modes of ingress, egress, and ventilation are adopted; and the only question generally solved, is that of remuneration. This evil, although great, may have a palliative in the fact, that places of public amusement are notoriously a bad speculation. But in the case of churches, &c., which, generally speaking, are utterly independent of speculative considerations, it is to be expected that some deference would be paid to the rights of those who contribute to the expenses, and to the manner in which the objects of their erection are carried out.

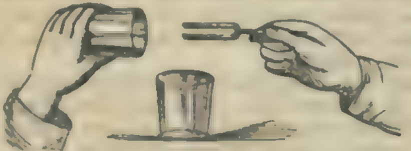
In most modern churches we find a cruciform structure. The body of the building is of great length; and, at some part, recesses are formed, which tend to produce an elegant appearance at the exterior. Now, as sound radiates from its source, it follows the laws of all radial forces—namely, that its intensity decreases as the square of the distance. Hence, persons sitting at the extremity of many of our churches, are utterly unable to hear sufficient of the discourse to understand its purport, because the person addressing them is compelled to modulate his voice, so that he may be heard distinctly by the mass of his audience near to him, and that he may avoid that undue straining of the voice which would degenerate into "screaming," were he to attempt to make himself heard in all parts. In many instances, our churches have a length equal to three times their breadth; and as it is necessary that an audience should be ranged in curves, having successive and gradually increased distance from the centre or focus, to be in accordance with the principles of acoustics—it follows, that all buildings of the class we have referred to, will render the words of the speaker inaudible to many, or he must exert himself to a most painful and harmful degree, and to the annoyance of those near to him.

There are other circumstances, independent of form, which also affect the acoustic properties of public edifices. For instance, in churches we find massive stone pillars arranged in each long aisle, from which the voice of the speaker is reflected in all directions. The stone walls, with their innumerable angles, have exactly the same effect; and, what is still worse, the glass of the windows has so great a reflective power, as to produce numerous echoes, which, on their part, again induce an annihilation of sound by the interference of its waves.

In our remarks on the interference of light,* we pointed out, that when two waves of that force were in certain phases, they combined and destroyed each other; and what happens to waves of light, equally does so to waves of sound, as a simple experiment will prove.

Place a glass cylinder on a table, and having struck a tuning-fork, hold it over the rim of the vessel, when that will at once vibrate, and produce a sound identical with that of the fork. Then bring another glass vessel, held horizontally near the first, in the manner represented in the following figure, when the sound will instantly cease.

Fig. 29.



This result of the destruction of sound arises solely from the interference of two waves, which neutralise each other. In a similar manner, the same effect is produced in a building when two or more waves of sound act on each other after reflection, or by a reflected wave interfering with one transmitted directly from the speaker. For this reason, there are many places in our public buildings in which it is impossible to distinguish the different words spoken. They are intermingled with each other, and so mutually destroy their intended effect.

The roofs of buildings have also a prejudicial effect; and this arises from the unequal reflective powers which they have. In many instances, we may notice deep recesses, which, whilst they add to the elegance of the room, materially injure its qualities in an acoustic point of view. Indeed, in every case, the walls and roof of a building should be as level as possible, provided their curves are constructed on proper principles. The reflection is thus made equal and regular; and the production of half, or irregular undulations, which are the cause of the interference of sound, is thus avoided.

It is a singular fact, that every room, hall, church, &c., has a peculiar "note" of its own; that is, if a speaker would be well heard therein, he must so pitch his voice as to suit the peculiarity of the edifice. To persons in the habit of addressing audiences in different places, in rapid succession—say, night after night—this is often a source of great annoyance. It thus frequently happens, that a really proficient rhetorician utterly fails to impress an audience in some places, whilst he may exceed their most sanguine expectations in others; and this is sure to occur if the speaker be addressing an audience in a hall in which he had never before spoken. It is true, that a singular circumstance eventually tends to remedy this evil; which is, that a speaker can always tell whether his listeners hear him, after he has spoken for a short time. If he have calmness and self-possession, he may gradually raise or lower his tone, to suit the circumstances in which he finds himself placed. This, however, requires a skill and discretion which few persons possess. Again, it often happens that the speaker himself is incapable, from physical defect, to remedy the evil to which we refer.

A common fault of public speakers, which no application of acoustic principles can obviate, is that of too rapid an utterance. Such persons produce the waves of sound so quickly, that each interferes with, and destroys the effect of the preceding one, and a confused jumble of sound results. We cannot here discuss those rules to which strict attention must be paid by those who wish to please their hearers; but may express an opinion, that however zealous and desirous of promoting the benefit of his fellow-creatures a man may be, he forgets half his duty if he convey not his ideas and opinions in an intelligible manner. It is a matter of congratulation to find, that public authorities, in religious and educational circles, are now actively turning their attention to this subject, and insisting that a good delivery shall be an essential condition to preferment.

In a concert, the arrangement of vocal and instrumental performers is of the greatest moment. In a previous page,† we pointed out the fact that each note was produced by a definite amount of vibrations. Now, in the concert-room, the bass, tenor, contralto, and soprano voices, singing in concert, are throwing off rays of sound, each of which is produced by a different number of vibrations; and the effect of the harmony results in all these producing a unison of effect on the ear. It is, therefore, the business of a skilful conductor so to arrange the voices or instruments as that the harmony shall be, as near as possible, perfect; and his success will entirely depend on attention to those principles of which we have just been speaking. Neglect in this respect will destroy the efficiency of the best choir; whilst attention thereto will frequently improve the effect of a choir of otherwise moderate pretensions. It is a remarkable fact, that almost the only public edifices in our country which have been properly constructed for speaking and musical purposes, are our theatres; and it is more than likely that such results from the fact, that they rarely present, or need any external embellishment, or that their owners depend for their existence or profit on their audiences being able to hear *all* that is said or sung in the place. Much of the charm of dramatic representation depends on the elocution of the actor; and as this would be wasted if delivered in an unsuitable building, the internal construction is considered as of the utmost importance. We forbear to extend comparisons which strike the mind on considering this fact, with respect to the relative importance of the objects for which our other buildings are erected. On this point we are sure that our readers will agree; and "a word to the wise" will doubtless be sufficient.

Having thus spoken of some of the acoustic defects which prevail in public edifices, we may suggest certain practical conclusions for the attention of those who have to do with such matters; and may divide them into two heads—namely, that of architectural construction, and of internal arrangement. A perfectly constructed building will be one in which the audience form a number of circumferences round a common centre, which is the speaker; or when they are so arranged as to assume an elliptic or parabolic form—the speaker in this case being the focus, and the walls, in either instance, the periphery of the circle, or other curve. The reason of this will be better understood if our readers peruse our remarks on the laws of the reflection of light from spherical and other curved reflectors;‡ which, as we have already observed, are equally to be applied in the case of sound. But, for the purpose of their special application to the subject we have in hand, we shall offer an illustration showing the directions of the waves of sound produced by the human voice, or otherwise, in a building constructed after acoustic principles, and compare such with the oblong edifices so common in this country.

In the following figure, we shall suppose that the solid external curved line represents the semi-circumference of a circular hall, and the cross-like figure illustrates the construction of a church, or other building, after the usual modern plan of building. In the circular building, the speaker being placed at *S*, it follows that every person placed on the curve *a a*, will be equally distant from *S*; and, as sound obeys the law of radial forces, it follows that each individual seated in that curve, hears equally well. The same holds good with the external curves, *b b* and *c c*, with the exception, that the intensity of the sound diminishes as the distance from the speaker increases; but still every person on the same curve has the same amount of sound arriving at his ears. This is a necessary consequence of the geometrical law—that the circumference of a circle is equi-distant in every part from its centre.

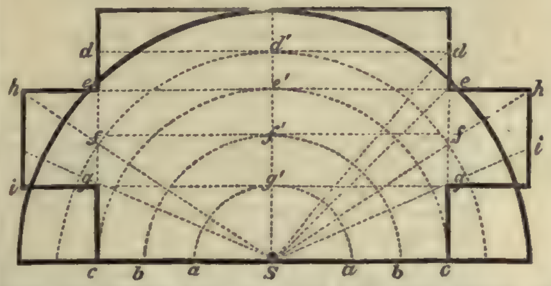
Fig. 30.



But this law is not applicable to the case of the oblong building; for we will suppose two persons placed, one at *g'* and another at *g*. The first one is nearer the speaker, and at the circumference of the first curve of sound *a a*, whose radius is *S*, *g'*; whereas, the other person at *g* is at the extremity of the third curve, *c c*, although level with him at *g'*; but because the curve *c c* is three times the distance from *S*, the speaker, than is *a a*—it follows, according to the law of radial forces, that he at *g* hears sound of only one-ninth the intensity of the listener at *g'*. The same reasoning holds good with the successive positions of *d*, *e*, and *f*, the parallel lines of which touch the curves at *d'*, *e'*, and *f'*. Many of our readers will have noticed how much more difficult it is to hear a speaker when they are placed at the sides instead of the middle of a building, although both positions may be in a similar parallel line with the speaker; yet perhaps few would expect that so great a difference existed between the chances of hearing at each place. But we will now transfer our attention to persons situated in the recesses on either side, and placed at *h* and *i*. Those on *h* are on the same parallel with others situated at *e'*; but being on a curve, the circumference of which is double the distance from *S*, they will only hear one-fourth as well. The same reasoning holds good with respect to persons situated at *i*, &c. Now, all the rays of sound impinging on the walls *c h*, on each side, are either lost or reflected back: and the same occurs with all the glass surfaces of the oblong building, which can be easily traced by our readers. The effect of this is twofold; for an echo is produced, and the interference and destruction of sound also ensues.

It will be therefore readily perceived, that considerable loss of acoustic effect is experienced in all buildings of the oblong form; and that the remedy which presents itself, is that of constructing new edifices in obedience to the principles we have been indicating. We have confined our attention solely to circular erections; but those of the elliptic or parabolic form may easily be studied in the manner already mentioned.

The faults of the internal arrangement of halls, &c., may often be remedied by the most simple means. They chiefly arise from the echoes produced by the reflection of sound from plane surfaces in oblong or square buildings, and especially from glass windows, which, having a very level surface, act as good reflectors. If the seats of a building are arranged in concentric circles, rising one above the other, the echo from the wall is at once destroyed, because the audience is arranged between them and the speaker; and this plan conduces highly to the comfort of both parties. The echo produced by windows, or other plane surfaces, is at once destroyed by covering them with cloth; indeed, ordinary cotton blinds will, generally speaking, answer the purpose perfectly well. If the walls of a hall are papered, instead of being left bare, or painted, the echo is almost destroyed. Those who have not had the opportunity of speaking in a building in which echoes abound, can have no idea of the painful effect experienced by the public speaker. Each word is reverberated to his ear, as its successor passes from his mouth; and the effect is most confusing to the mind if an extemporaneous address is being delivered by him.

Sounding-boards are a contrivance by means of which the voice of the speaker can be reflected towards the audience; and here again we perceive an analogy existing between sound and light. By means of a reflector, we can send the rays of light from their source in any direction we please; and the sounding-board answers the same purpose. In some buildings, the wall before which a speaker may stand, is made of a curved shape; and if the roof be contrived so that a regular geometrical figure be formed, such becomes an excellent reflector, and adds much to the acoustic character of the place. Besides acting as a reflector, it also serves as a diffuser of sound,* and, as such, tends to spread the vibrations in all directions. The acoustic effects of a solid reflector, and a sounding-board which is made hollow, are very different: for, in the former case, the sonorous waves are merely sent forward from the reflecting surface; but, in the latter, the body itself partakes of the vibrations, and so assists in their general diffusion. That such arrangements themselves vibrate, is easily proved by throwing a little sand on a drum-head, or placing on a piano a sheet of glass, over which some sand has been strewn. If any instrument be played near the drum, the sand will speedily arrange itself in various forms. The same will occur with the glass on the piano, if that instrument be performed on; and what are termed *acoustic figures* are produced. Another mode of obtaining the same appearances, is that of placing fine sand on a piece of thin sheet glass, and drawing over one of its edges the bow of a violin; the glass will vibrate, and the sand will assume star-like and other figures, owing to its partaking of the vibration. To so great an extent can these effects be produced, that a solid body, such as a thin glass cylinder, may be fractured by producing near it more powerful sounds in unison with the note which it affords on being struck.

THE EAR.

We shall now give a short description of the human ear, as the organ by means of which sounds are perceived. Its external part is of such a form as to receive the vibrations of the air, as they proceed from any sounding body. From the outer part there is a tortuous passage, by which the sounds arrive at the tympanum or drum. This is a thin membrane; and it is stretched over bones in a similar manner to that of the parchment covering of the musical instrument of the same name. The vibrations which have arrived thus far, set the drum in motion: and here we may mention a peculiar provision that is made, by which the intensity of sound is modified. When describing the eye,† we mentioned that the iris could be either opened or closed, so as to admit or restrain the rays of light, and prevent injury to the organ of sight. Now, similarly, the drum of the ear may either be tightened or extended, so as to increase or diminish the force of communicated vibrations; and by this beautiful arrangement, the ear itself is preserved from the injurious effect of too powerful a sound, or is enabled to catch the slightest whisper. From the drum of the ear, a channel, called the *Eustachian tube*, passes towards the mouth. This tube serves as an exit, by means of the air it contains, for the vibrations which have been communicated by the drum. It is, in fact, analogous in its office to the holes in the sounding-board of the piano, the harp, violin, &c.; and deafness always ensues when, by any means, this tube is closed, which occurs from cold, the deposition of wax, &c.

A cavity, called the vestibule of the ear, also covered with a membrane, is provided with nerves; and these, like the optic nerve,‡ connect the external vibrations of matter with the sensorium of the brain; and thus the sense of hearing is produced. The entrance of the ear is protected from the intrusion of insects and foreign matter, by means of hairs, and a peculiar wax-like secretion. This, in excess, often becomes hardened, and is thus the cause of difficulty of hearing, which some persons suffer from. It is, however, readily removed by syringing the ear with warm water. The following cut will give an idea of the different parts of the human ear.

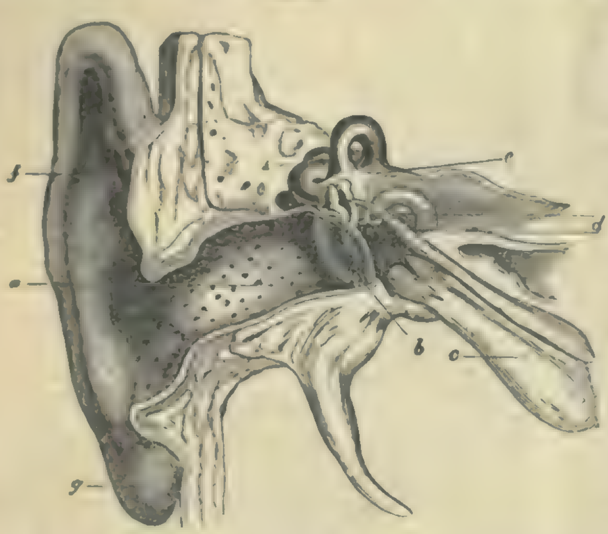
Fig. 31.



a, is the canal by which sounds reach the drum, *b*; *c* is the Eustachian tube; *d* and *e* represent the connections of the auditory nerves with the brain; *f* and *g* are the upper and lower portions of the external fleshy part of the ear.

The organs of hearing in the lower animals are all constructed on similar principles to those of the human being, modified, however, so as to meet the special circumstances of the individual.

Amongst the mammalia, we find the ear, generally speaking, defended externally by a large flap, which serves to protect it from being injured by insects or the twigs of trees, as the animal passes through a thicket: this may be best noticed in the elephant and the dog. All animals of prey are possessed of great powers of hearing, on which they partly depend for success in the search for food. Amphibious animals can readily adapt their organs of hearing to the medium in which they may for the moment dwell. Without such a provision, these animals would sustain much inconvenience, and suffer extreme pain, when beneath the surface of water. This is chiefly owing to the great conducting power of that liquid, by which sounds act more strongly on the tympanum than when conveyed by air; and if the organ were not protected, under such circumstances, its sensitiveness would speedily be destroyed. The ears of birds are not easily distinguished externally, owing to the outer orifice being covered with feathers. As we descend in the scale of nature, we find that these organs become of simpler construction; and, passing by fishes, we at last find their development to be but rudimentary in the tribe of insects. On this subject, we refer our readers to the excellent remarks of Dr. Bushnan, which will be found at page 36 in the second volume, in the section of Comparative Physiology.

CONCLUDING REMARKS ON THE UNDULATORY FORCES.

We have now completed our exposition of the laws of those forces which, although, so far as we at present know, have not that extensive application possessed by gravitation and cohesion, are yet only second to them in that respect. As we proceed, the student will observe how large is their range; and more particularly, in the next section, will he notice their importance in the general economy of nature. Their consideration, in fact, forms a fitting and necessary introduction to the study of chemistry, on the limits of which we have often had to tread. All the operations in the laboratory of nature, as in that of the chemist, depend on the exertion of one or more of the forces we have so extendedly treated on; and it will therefore be desirable that our readers shall have become well acquainted with the principles already expounded, before they attempt to make farther progress.

In the sections on Applied Mechanics and Meteorology, we shall have frequently to refer to what has already been enunciated. This affords an additional reason for the remarks we here make, and points out to the student the necessity of a close investigation of each of the preceding sections, as a preparation for such as are to follow.

SECTION VI.

CHEMISTRY AND ITS APPLICATIONS.

INTRODUCTION.

In our previous pages, we have endeavoured to explain and illustrate those laws which are found to be connected with every form and kind of matter. The relations in which the undulatory forces stand are universal, for they do not depend for their action on specific natures, but are rather affections of all bodies which have an existence. Second only to, and yet concomitant with, the forces of gravitation and cohesion, they are constantly to be found either in a sensible or latent state; and, as second causes, they produce all the phenomena which we can witness in natural occurrences.

We have now to narrow the scope of our ideas. In one sense, we have to descend to particulars; but, at the same time, our opportunities of generalisation will be greatly enlarged. Instead of viewing the entire range of the animal, vegetable, and mineral kingdom, we shall investigate the nature and properties of the materials of which they are composed. We shall have to inquire into the specific character of the different substances which afford all the variety of appearance and quality observed around us, and to trace, as far as possible, the affinities or attractions which each body has for another—availing ourselves of such characteristics to produce what often appear to us as new products.

It is impossible to overrate the value of Chemistry, either as a branch of natural and experimental philosophy, or in its applications to social and commercial purposes. But a few centuries ago, alchemy—a congeries of imposture and deceit—was its only representative. The search after the so-called philosopher's stone, which was to turn all the "base" metals into gold, was the only type of chemical science; and, as in every instance in which philosophy is followed simply for its pecuniary reward, that and every other recompense eluded the grasp of its devotees.

In every department of human knowledge, the inductive system has been productive of advantage. It checks an exuberance of imagination; restrains and guides the reasoning powers; and, in fact, makes the intellect of man of real use to its possessor. The science of Chemistry stands prominently forth as a proof of the truth of this opinion.

In former days, no theory was considered too crude to be received, and none so ridiculous as to want believers. Let it only have the sanction of high-sounding names, and its success over the *soi-disant* philosopher was certain. If water were raised by a pump, the presumed reason was, that "nature abhorred a vacuum." The process of digestion was considered as the work of an evil but active spirit. Imaginary powers were assigned to sequences and events; and to sum up all we can say on the matter, we may state generally, that the causes suggested to account for any effect, were only limited in their character and absurdity by the narrow intellect of their inventors. The evil result of this course was not confined to the authors of it; it spread over the whole of society; and, as the natural consequence of superstition, it was considered profanity to dispute the dicta of those who assumed to be authorities in such matters. We need scarcely state, that the applications of Chemistry—such as it was—were of the slightest character. When, however, systematic experiment and rigid induction became the guiding-stars of philosophical research—Chemistry, which is, *par excellence*, an experimental science, speedily made most rapid progress; and in the hands of Boyle, Priestley, and Lavoisier, it approached towards a higher and more useful position. It has been no part of our plan, hitherto, to enter into historical details; we shall not, therefore, here commence that course; but would simply remark, that in our own day, there is scarcely a branch of manufacture, commerce, agriculture, or, indeed, any occupation, which has not benefited by the application of the truth of Chemistry; and much of our position as a first-rate power in the world at large, is due to the stimulus and aid which our manufactures have derived from chemical discoveries.

In the following pages, we shall first attempt to give our readers an exposition of the general laws of chemical attraction, and other fundamental principles. We shall then proceed to investigate the chemical history of elementary and compound bodies; and, subsequently, speak of analysis, and the varied applications of chemical facts to the purposes of manufacture, agriculture, and the like.

Before entering on this extensive range of inquiry, we must remark, that some considerable knowledge of the subjects which have been treated on in the previous pages will be necessary, if the student desire to make rapid progress in his chemical studies. All the operations of nature, and those conducted in our laboratories, depend on the exercise of one or more of the agents of Heat, Light, or Electricity; hence, ignorance of their laws would entail great embarrassment on those who enter into an experimental examination of chemical phenomena. Independently of this, we need scarcely observe, that a repetition of what we have already stated, would much encroach on the limits we have necessarily to assign to each subject, and cause considerable confusion. Chemistry calls for but a moderate knowledge of mathematical science; in fact, scarcely any but the common rules of arithmetic are involved in its calculations. We have endeavoured to smooth, as far as possible, the various difficulties which may lie in the path of the student; and, to this end, have given him extended directions for the construction and use of apparatus, with a view both to economy and efficiency. On this head, we would particularly warn all our readers against incurring unnecessary expense, by purchasing a large quantity of apparatus, at the commencement of their chemical course. To the young student, in any branch of knowledge, nothing is so useful as moderate but surmountable obstacles to his progress. These, whilst checking undue ardour, give him time for reflection and thought. The attempt to overcome them, induces readiness of resources, and calls out powers which he otherwise would hardly know that he possessed. The experiments suggested are such as may be easily conducted; and have been introduced so as to give the reader a means of verifying the statements with which they are connected. They are equally suitable for private study, as for exhibition at the lecture-table.

CHAPTER I.

CHEMICAL ATTRACTION, OR AFFINITY.

We have had frequent occasion, in our previous pages, to refer to attraction of various kinds. The attraction of gravitation we found to subsist between masses; that of cohesion between the particles of bodies, operating at insensible distances; whilst the attractions exhibited by free electricity and magnetism, were special or individual in their character. But, in chemical attraction, we find an entirely different class of phenomena to occur when compared with those we have described. Hitherto, it has not been of much consequence as to the qualities or specific character of the substances we have experimented with; it will now be our business to investigate those points as closely as possible.

By chemical attraction, we mean that power by virtue of which two or more dissimilar bodies are brought together, united, and ultimately produce another body totally different, in most respects, to those from which it was derived. One of the simplest instances of this kind which we can adduce, is that of common salt. It is composed of two substances only; one of which, chlorine, is a poisonous gas, that acts with great and destructive effect on animal tissues: the other constituent is a metal called sodium, which spontaneously takes fire on being brought into contact with water, or paper moistened with that liquid.

We must here point out the difference which exists between a chemically constituted substance and a mere mechanical mixture. Common salt is a compound, in which the parts are held together by so powerful an attraction, that they cannot be divided by any but strictly chemical means. If, however, we dissolve sugar in water, we do not consider the product to be a chemical compound, but simply a solution or mixture, because we can readily take the water away from the sugar by the application of heat, and the sugar will be again present, unaltered in any of its characters. Indeed, during the whole process of solution, no change, except a mechanical one, occurs. If, however, we expose sodium to chlorine, a very different result is afforded us: then chemical action ensues; a combination of the two substances is effected, and a new compound is the result.

Now, it is by the union of different substances, effected by chemical attraction, that the whole of the materials composing the animal, vegetable, and mineral kingdoms is composed. The combinations are held together by varying amounts of force; and the causes which modify the attraction which each body has for those united with it, are modified by several circumstances to which we must now direct attention.

Amongst all the agents with which we are acquainted, that of heat is the most powerful in producing mechanical and chemical changes; and to it the chemist is chiefly indebted for the means by which he is enabled to separate existing compounds, and to form others. The mechanical effects of heat we have already inquired into in our first section, and we shall now more particularly investigate its action on the chemical composition of a body.

So far as we can judge, the mechanical properties of caloric always precede the development of its chemical agency; and this will be no matter of surprise if we bear in mind, that the slightest change from ordinary temperature is sufficient to produce expansion, &c. Now, chemical action is rarely promoted by caloric, except when present in great excess, beyond its ordinary sensible indications. We may find a very familiar instance of these facts in the ignition of gunpowder. On applying heat to that substance, the sulphur is first converted into a liquid state; then the nitre; a red-heat is next produced; and at that moment a chemical action is generated between the charcoal and one of the constituents of the saltpetre—an explosion immediately ensuing.

Heat has not only the power of producing such rapid chemical combinations, but it also assists, in many instances, to produce those conditions most favourable to such results, by altering the molecular construction of bodies. Thus, in making solutions, heat is constantly employed to render bodies more soluble; and, in many instances, heat produces this result to an astonishing extent. By such means, a much larger amount of the substance is dissolved than can be held in solution when the liquid again becomes cool; and the solid substance, on cooling, separates in the form of a powder, or, more generally, it assumes regular forms, and crystallisation ensues. In almost every instance in which we desire to separate bodies from each other, the liquid state is essential for that purpose; and when solvents cannot conveniently be employed, heat is applied until the body has been brought to the fluid condition. The same plan is adopted when the union of two solid bodies is required. Hence the use of a class of substances called fluxes—such as carbonate of soda, borax, and the like. Take, for instance, a piece of common granite, which is composed of several substances. It may be powdered, and then submitted to the action of every known liquid; but the chemical attraction of each of its constituents is such as to defy those means for their separation. If, however, after powdering, it be mixed with some carbonate of soda, and exposed to an intense heat, it is fused, and combines with the flux. It may, when cool, be readily dissolved in acids, &c.; and then its constituents can be at once separated from each other by the usual methods.

If, again, it be desired to cause the union of solid bodies, heat readily assists us. Thus, in making an alloy, or mixture of two or more metals, such could never be effected whilst they are in the solid state, because the distance of their particles is too great from each other. But by the aid of intense heat, the particles of each are made mobile; and although the distances between the atoms of a body are increased, still the readiness with which they are detached from each other, enables them more readily to combine with those of another body; and thus the state of fusion is favourable to chemical action, as well as to mechanical mixture. The processes of evaporation by the application of heat to liquids, is in common use by the chemist; and he thus is enabled to obtain, in a solid form, salts, &c., from a liquid, although they are present to but a slight extent. Thus, in a gallon of ordinary river water, only two to ten grains of solid matter may be dissolved. By evaporating the liquid, such are brought together, and are so fit for the experiments on them.

We have previously referred to the effects of heat in producing rapid combination in mixtures of solids: we may now add a few words on the explosion of gases, &c., by the aid of caloric. There are some substances in which the chemical attraction is so slight, as to be readily destroyed even when they are heated to but a trifling extent: amongst these, are fulminating mercury and silver, and certain compounds of nitrogen with iodine and chlorine. Now such afford instances in which heat is antagonistic to chemical attraction; and many others of a similar kind might be easily adduced. In such cases, gases are always formed, when the substance is either a solid or liquid, before the explosion; and it is owing to the rapid expansion of these gases, that the noise usually heard is produced. We shall generally find that the presence of one body, nitrogen, is mostly to be detected in such instances.

As we proceed, many other applications of heat will be noticed, which will be more properly dealt with as they occur.

The agency of light, in producing chemical changes, is more restricted than that of heat, and has been already enlarged on under the head of Photography. The recent discoveries of Messrs. Bunsen and Kirchoff, which have been also described, have opened a new connection between the relation of light and chemical phenomena.

Electricity has great influence on the attraction or affinity which one body has for another. It will be unnecessary for us to enter into that question, however, as it has been fully discussed under the head of Voltaic Electricity and Electro-Metallurgy; and the same remarks apply equally to magnetism. Such being the relation which the undulatory forces have to chemical attraction, we may now more fully inquire into its different phases and laws, and so prepare our readers to consider the numerous instances to which we shall have to draw their attention as we proceed. It may be explained, that certain terms are used to express the changes produced by chemical action. By *decomposition*, we mean the separation of existing compounds; and by *composition*, the union of bodies to form new compounds is expressed. When the chemist attempts to ascertain the constituent parts of body, the process is termed *analysis;* but the act of producing new combinations, is termed *synthesis.*

It has been stated that different substances have various powers of affinity for each other; and we shall now suggest some experiments illustrating this fact. We must, however, point out, that there are two classes of affinity; or, more properly, a double act of affinity takes place under some circumstances. Thus, if a piece of polished iron be exposed to the action of air, its oxygen unites with the metal to form oxide, or rust; and here we have only an action of simple affinity. If, however, we add together solutions of common salt and nitrate of silver, then a double affinity operates, for the silver unites with the chlorine of the common salt; whilst the nitric acid combines with the soda; and so two new substances—the chloride of silver, and the nitrate of soda—are produced. The following are instances in which the chemical affinity existing between two or more substances, attended with the removal or separation of another by decomposition, is involved.

Experiment 1.—Add a few drops of a solution of nitrate of silver to one of common salt. The silver, uniting with the chlorine, as already mentioned, will fall down as a white powder; and a solution of nitrate of soda will form the liquid.

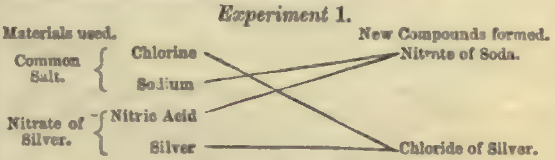
Experiment 2.—Pour off the clear solution into a clean glass vessel, and add to it a few drops of sulphuric acid. The nitric acid will be driven away from the soda, with which the sulphuric acid combines to form sulphate of soda.

Experiment 3.—Pour the solution of sulphate of soda, obtained in the last experiment, into a glass vessel, and add to it a little nitrate of baryta in solution. The sulphuric acid will now leave the soda, and combine with the baryta, forming sulphate of baryta; whilst the soda will combine with the nitric acid set free from the nitrate of baryta, and so form nitrate of soda.

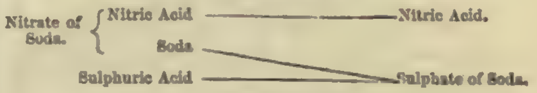
In these three experiments, we observe one substance, the soda, changing its state thrice. First, we found it in union with chlorine, forming common salt, which is left, owing to the superior affinity for it which nitric acid has. In the second experiment, we find that it left the nitric acid for the sulphuric acid, owing to the more powerful attraction which the latter exercised. But, in the third experiment, we noticed the paradoxical fact, that it united with nitric acid in preference to sulphuric acid. But this is easily explained. The baryta in the nitrate of that earth has a greater affinity for sulphuric acid than any other body, and so it decomposed the sulphate of soda—seizing the acid. Now, the soda being set free in the presence of the nitric acid, at once combined with it; and in this we have an instance of double decomposition, and a twofold exertion of chemical attraction.

Our readers will do wisely to master the principles involved in these experiments before proceeding further; and we have chosen the substances named that they may trace the progress of the soda in each of its combinations. To make the matter still clearer, we add diagrams representing the results, &c., of each experiment, in which the materials employed, and the new compounds formed, are mentioned.

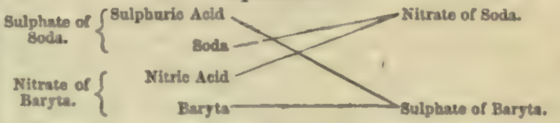
Experiment 1.



Experiment 2.



Experiment 3.



We thus perceive how much the affinities which one body has for another vary, and how the affinities of a third may destroy those exhibited in previous compounds when it is presented in proper circumstances.

In the above instances, we have confined our attention to changes easily understood. As we advance, however, into those which are produced when vitality assists the process, the conditions are so varied, and the states of bodies involved are so numerous, as to render the matter far more complex. Take, for instance, the ordinary process of digestion, and the conversion of bread and meat into blood and muscular fibre. Here we have a delicate and astonishing adjustment of affinities. The food contains charcoal, oxygen, hydrogen, and nitrogen, besides mineral substances. Part of the charcoal goes *separately* to form blood, fat, muscular fibre, nails, hair, skin, &c. With some of the oxygen it affords carbonic acid, which passes off from the lungs. The hydrogen, nitrogen, and oxygen are also employed to form various parts of the animal substance; and all these bodies, when in excess, are driven off in mutual combination as water, ammonia, or carbonic acid. Yet, complex though these changes may be, still the same law governs them as is found active in our experiments. Each body has a definite attraction for another; and the knowledge of this enables the chemist to trace, by the eye of science, the most obscure and difficult details.

There are some minor circumstances which powerfully assist in promoting the exercise of chemical affinity, to which we shall now allude; and they refer chiefly to peculiar conditions in which bodies may be placed with respect to their external surface, or relative mechanical conditions. As an instance of this, we have the peculiar action which the metal platina exercises on a mixture of oxygen and hydrogen gases; the action of light on a mixture of chlorine and hydrogen; the effect of minutely divided substances, as spongy platina, powdered charcoal, metal in a minute state of division; as in the case of finely divided lead in pyrophorus, &c., &c. Such, and many other instances we might name, affect, vary, and modify many of the exercises of chemical affinity; and all such must be taken into account in chemical researches, if truth and accuracy of result are hoped for. It will be thus perceived, that a thorough chemist must exercise the greatest care and penetration in all cases that are brought before his notice; and the science, therefore, is not only valuable for its philosophical and commercial results, but equally so as a system or means of mental training.

In cases of extremely low temperature, chemical attraction is often entirely suspended. Thus, on Mont St. Bernard, the bodies of deceased travellers have been kept, entirely unchanged, for many years. We have already mentioned that voltaic batteries, and electro-metallurgical processes, require certain temperatures for their successful working.* In many instances, however, the chemist avails himself of extreme cold to maintain the existence of many substances; as is the case with chloride of nitrogen, peroxide of hydrogen, and other compounds. In these there is a continual tendency towards decomposition if a low temperature be not maintained; and hence the employment of the means named.

The rapidity with which chemical action ensues between bodies, depends on the intensity of attraction they have for each other. Thus, if nitric acid be poured on silver or copper, the action is most violent; whereas none is perceived on platina. If, again, the acid be diluted with water, the intensity of its action is diminished, for fewer particles of the metal and acid come in contact. In some cases, a sudden suspension of action takes place: thus, nitric acid will act violently on the metal iron, and then all chemical action will cease, the iron having assumed a passive state. At times, the attraction is so powerfully exerted as to produce a large amount of heat and light—as when sulphuric acid is poured on chlorate of potass and sugar; at other times, intense cold is produced—as when freezing mixtures are dissolved in water. Indeed, it would be impossible for us to sum up the great variety of instances in which the exercise of chemical attraction is manifested, or to enumerate the peculiar effect which it produces. These, however, we shall frequently notice in our future progress—our desire having been just to put the student in possession of leading facts, which may serve as a guide to further details.

ELEMENTARY BODIES, AND THEIR COMBINING PROPORTIONS OR EQUIVALENTS.

To prevent any complication of subjects, in our previous remarks we have avoided any mention of elementary substances, and the proportions in which they unite together. These matters must now form the subject of our investigations.

All substances which have hitherto resisted our utmost endeavours to procure others from them of a different character or quality to themselves, have been termed elementary; and the number has been largely increased during the present century. For this we are largely indebted to the researches of Sir Humphry Davy, who, by aid of the voltaic battery, was enabled to decompose the alkalies potass and soda, and some of the earths. Since his time, other discoveries have been made, especially in connection with metallic bodies.

In most chemical works these bodies are arranged in groups; but, unfortunately, this arrangement is either modified or altered by each authority on the subject. The difficulty of obtaining a settled plan in this respect, lies in the fact, that the constant accessions which are obtained to chemical science, invalidate many of the conclusions which had been previously made. The point, however, is not of extreme importance; for as each element has its own distinctive character, it follows that the compounds it forms never exactly resemble those of other elements, although a great analogy may exist between them. We take hydrogen as an instance of the kind; for, in many of its chemical relationships, it behaves precisely like a metal; and yet, considering its physical characters, it seems the farthest removed of any from that class of bodies. Again, ammonia, which is known to be a compound substance, presents, under certain circumstances, every indication of metallic character; and, indeed, the existence of ammonium is theoretically admitted at the present day: yet no analogy exists between it and the metals in the characters which, of all others, distinguish them from other substances. Our present position, in these respects, is, therefore, one of great doubt and perplexity; for, whilst we see distant glimmerings of new facts by their analogies, the rigid system of philosophy cannot allow us to jump at conclusions which seem true, but are incapable of present proof. In our future pages, we shall therefore use the license which this condition of doubt permits; and after dealing with general principles, shall proceed to give the natural history of each of the elements, and of the compounds producible from them.

To Dr. Dalton, of Manchester, we owe the discovery that bodies combine in relative proportions; or, in other words, that every substance, elementary or compound, has a numerical ratio, in which alone it will form compounds with others. This ratio has had applied to it the terms, "equivalent," "combining proportion," and "atomic weight;" but, in our future pages, we shall only use that of equivalent, as expressing the facts of the case most clearly. What is meant, is simply that each substance must be taken in definite quantities to form a definite compound with others. Thus, eight grains, ounces, or pounds, of oxygen, must be united with one part of hydrogen, to form nine parts of water. If an excess or deficiency in these quantities be employed, then only so much water will be produced as the proportion of eight of oxygen and one of hydrogen would afford, and the element in excess of this ratio would be left free. Again, ten parts of oxygen would not unite with one of hydrogen, because the ratio we have named is not maintained. Sixteen parts, however, of oxygen, and one of hydrogen, may unite, because in that we have the ratio existing. A compound very different to water, however, would be the result, which, of course, might be expected from the union of two bodies in proportion, different to those producing water.—We may take another illustration in the case of oil of vitriol, or, as it is chemically termed, sulphuric acid. This is composed of three parts of oxygen, and one part of sulphur, if it be entirely free from water. In its commercial state, when pure, it is always combined with one part of water. Now the equivalent of sulphuric acid is obtained by adding together that of its constituents, thus:—

Quantity of each material.	Equivalent of each.	Total.
1 part of sulphur	16	16
3 parts of oxygen	8	24
1 part of water, composed of oxygen, 8: 1 part of water, composed of hydrogen, 1 .	9	9
Equivalent of sulphuric acid =		49

Or, in other words, we may say, that one equivalent of sulphur, three of oxygen, and one of water, form one equivalent of sulphuric acid, which, with reference to other compounds, has an amount equal to 49.

We will now take an instance in which both sulphuric acid and water are united with a metal which, however, has first combined with oxygen, and so formed what is called an oxide; and for this purpose we will choose the green copperas, or sulphate of iron. Oxide of iron is that metal united, in this case, with one equivalent of oxygen; and as the equivalent of iron is 28, it follows that the equivalent of its oxide will be 36. Now this salt of iron is composed of one part of oxide, one of sulphuric acid, and seven of water; and its equivalent will be as follows:—

Quantity.	Equivalent.	Total.
1 of oxide of iron	36	36
1 of sulphuric acid, free from water	40	40
7 of water	9	63
Equivalent of sulphate of iron =		139

These three instances of water, sulphuric acid, and sulphate of iron, will illustrate the mode in which the equivalents of compounds are formed. The last shows how that of two compounds, united together, is obtained. If the student fully comprehend these facts, he will have got over all difficulties presented in the study of the numerical value of equivalents; and have made a good advance in the study of chemical science. In the case of organic compounds, precisely the same plan is adopted; but as they present theoretical difficulties, we shall not enter into their discussion for the present.

---

* *See ante, p.* 210.

It will be asked, however, how these equivalents are found, with respect to the elementary bodies; and although the practical part of the question is one requiring the greatest skill and experience, its explanation will not be difficult. If, as we have shown, every body has a definite combining proportion—it follows, whenever we examine it, we shall procure its constituents in their proper proportion of combination. For instance, if we decompose water by any means, we always obtain one part of hydrogen gas from nine of water, provided the operation has been completely performed: we therefore infer the presence of eight parts of oxygen. Or, if we prefer to take the oxygen, and weigh it, in combination, say with iron, we find that, if pure iron had been used to the extent of 28 grains, it would weigh, after the operation, 36 grains, from which we should infer that eight grains of oxygen had been added to it. But even during the process of finding the equivalent of oxygen, we gain that of the iron; for, supposing we used 50 grains of pure iron in decomposing nine grains of water, we should find that the iron only weighed 58 grains at the end of the experiment; and as we could, by means we need not describe, separate the iron which had, from that which had not been oxidised, we should discover, that out of the 58 grains, there would be 22 which had escaped oxidation. This number deducted from 58, would leave 36 as the equivalent of oxide of iron; and subtracting eight, the equivalent of oxygen, we should obtain 28 as the equivalent of iron. This mode of finding metallic equivalents is not that practically adopted in all cases; but we have availed ourselves of it because it exhibits the facts with which we are dealing. We can, however, illustrate the method of finding equivalents by another process, which is that of decomposition; and this is the plan almost always adopted; and one which our readers can roughly try for themselves, after the following manner. Of course they must not expect to obtain anything like accurate results; for it requires great care and readiness of manipulation to succeed in such delicate investigations.

Experiment 4.—Dissolve 110 grains of *pure* silver (ordinary coin will not do) in some dilute nitric acid; and when the whole is in solution, add common salt, also dissolved in water, until no more white powder falls down to the bottom of the vessel. When this has settled, pour away the water, and add fresh until the last washing does not in the least taste of salt, taking great care that not a particle of the white powder is lost. Then pour the whole of the powder on to a piece of white blotting-paper so as to filter it, taking the precaution of weighing the paper accurately beforehand. The whole is then to be carefully dried, and, whilst still warm, must be weighed. It will be found, that the powder, after deducting the weight of the paper, will weigh about 144 grains, of which 36 parts are chlorine, leaving 108 parts of pure silver as the remaining constituent of the powder. Thus, knowing the equivalent of chlorine, we infer that of silver to be 108.

These results are controlled by experiments with other combinations of the same body; and, by pursuing a similar course, the equivalents of any element may be ascertained. The numerous precautions which have to be observed, and the difficulty of obtaining the substances in a state of sufficient purity, together with other circumstances into which we shall not enter, render the attempts to obtain exact and reliable results one of the most difficult operations in experimental science. We hence find, that tables of equivalents, compiled by different experimenters, vary somewhat in the numbers given to each element.

Of course some standard is required to commence with, the multiples of which shall form the equivalents of all other bodies. Hydrogen has been chosen, and adopted, by nearly every English chemist; and if no other be named in chemical works, the reader may always assume such to be employed. Some have proposed oxygen as the unit, from the importance of its combinations; but such do not compensate for many of the advantages of the hydrogen scale. Hydrogen is the lightest body in nature, and has the lowest combining proportion. There is, however, one difficulty which presents itself; and it is, that although hydrogen and oxygen combine in the proportion of one to eight by *weight*, they do in that of two to one by measure. This, however, only affects the gases; but a late writer has proposed to double the equivalent of oxygen, so as to meet the difficulty. It is improbable that such a proposition will be generally adopted.

CHEMICAL MANIPULATION AND APPARATUS.

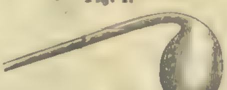
As we shall suggest a large number of experiments in future pages, with the intention that our readers may become practically acquainted with chemistry, it will be advisable that we should give some description of the apparatus which will be required, and the best mode of using and managing it. We shall, as far as possible, study the means of our readers; and therefore suggest the most economical and effective mode of carrying out the experiments. Many persons have an idea that the study of chemistry is a very expensive one. Such is not the case; for all the leading class experiments, teaching the elements of the science, may be performed with apparatus not costing more than ten shillings; and the chemicals are exceedingly cheap. If, however, the student enter into an extended course of original research, and the applications of chemistry to the arts and manufactures, and become, as many persons do, enamoured of the study, we should certainly decline to mention the extent of means required; for any amount of money may be so expended.

Much of the success which may be obtained in experimenting, depends on neatness, care, and cleanliness. A man may become an expert chemist, and yet may be but a poor philosopher; for it frequently happens, that whilst the experimenter may make the most valuable discoveries of *facts*, he has not the mental power of generalisation. On the other hand, a highly cultivated mind will avail itself of these facts, and so generate theories which shall embrace a multitude of effects. Some persons combine both these qualifications; yet such are rare accomplishments. But let none of our readers be discouraged by these statements. "*Suum Cuique*" is a motto which may be safely adopted in philosophy as in other matters; and during the last few years, the boundaries of science have been so extended, as to render subdivision of labour a question not of choice, but of absolute necessity. A schoolboy of our time, knows more of natural philosophy, so far as facts are concerned, than did all the philosophers of the days of Newton and his compeers; and the philosophers of our day are but the schoolboys of those who shall succeed them.

As we shall commence with the history of the gases, the various apparatus required for manipulating with them will first claim our attention.

Gases, such as oxygen, require the application of heat for their production; and, generally speaking, retorts, test-tubes, or flasks are employed for that purpose. The following engravings illustrate the appearance of each of these. Fig. 1 is a retort, in the bulb of which the materials to be heated are placed. They are made of various sizes. The student may provide himself with a few, varying from one ounce to a pint capacity. They require heating gently at first, to prevent the danger of cracking them. They should never be cleaned until quite cold, and are then to be placed stem downwards, so that the water employed for that purpose may drain off, and leave the inside quite dry.

Fig. 1.



A good substitute for a retort, when small quantities of materials are used, is a test-tube with a bent tube. A cork is first fitted in the neck; and a hole having been made in it, a glass tube, which has been previously bent into the required shape, is then introduced. The arrangement is represented in the annexed engraving (Fig. 2). When larger quantities have to be used, a Florence flask, fitted with a bent tube, may be employed. These are extremely useful for a great variety of chemical experiments. They are very cheap, and may be cleaned by pouring into them some strong sulphuric acid to remove the oil, and, subsequently, washing them out with hot soda and water. The student should provide himself with several of these, and various sizes of the test-tubes last described. They are both used for making solutions, and a variety of other purposes. A test-tube may be held over a lamp by means of a proper holder; but in the absence of this, a piece of brown paper held round it, will prevent the passage of heat to the fingers. Fig. 4 represents the mode of making hot solutions after this plan.

Fig. 2.

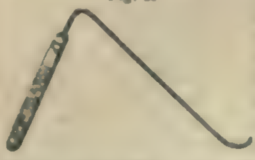


Fig. 3.

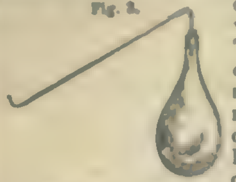

Fig. 4.

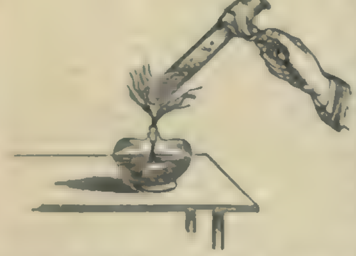
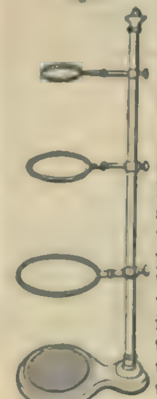


Retorts, flasks, &c., require a support to hold them over the flame of a lamp whilst being heated. The ordinary retort-stand answers this purpose; and one is easily made by fastening an iron rod in a wooden foot, and twisting round the rod rings of iron wire of various sizes. One of these stands is represented in the annexed engraving (Fig. 5).

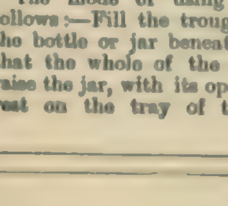
Fig. 5.



The application of heat is so frequently required in chemical experiments, that the student must supply himself with lamps for that purpose. Gas may be so employed; but the most generally useful instrument is the spirit-lamp, represented in Fig. 6. Spirits of wine, or, what is cheaper, methylated spirits, are used as fuel. An ordinary cotton wick is employed; and a cap, which fits over the wick-holder, is placed on it when the lamp is not in use, so as to prevent the loss of spirit by evaporation.

A trough is required for the purpose of collecting gases. This may be an oblong tin box, having a tray at one end, on which gas jars can be placed. The tray is perforated with holes, so that the gas may pass through them into the jars. A pneumatic trough, as they are called, is represented in Fig. 7. In the absence of such an arrangement, a basin, pan, or pail, will answer every purpose. The gas jars are made of various sizes and shapes; two of which are represented in Fig. 8.

Fig. 6.



The mode of using the pneumatic trough is as follows:—Fill the trough nearly full of water, and dip the bottle or jar beneath the surface of the liquid, so that the whole of the air may be driven out. Then raise the jar, with its open part downwards, and let that rest on the tray of the trough. The jar will thus remain full of water, and, as the gas from a retort passes into it, the water will gradually escape. The following engraving illustrates the mode of making oxygen gas, a small furnace being used in place of the spirit-lamp. A jar, when filled with gas can be removed from the tray of the trough by passing beneath it a plate. This, by holding a little water, prevents the escape of gas, and so retains the latter inside the glass vessel.

Fig. 7.

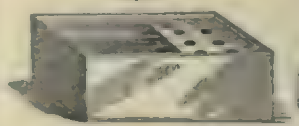


Fig. 8.

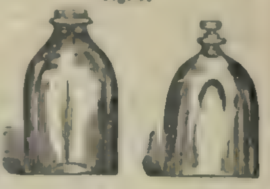

Fig. 9.

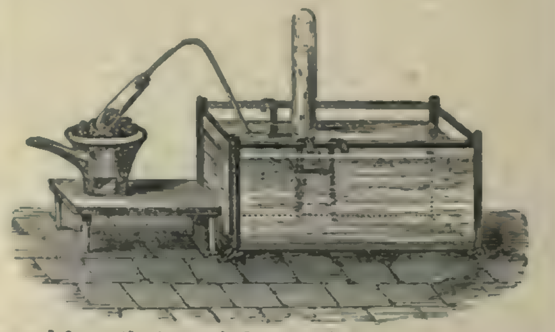

For many purposes, gas jars, open at both ends, are required; and when being filled with gas, the narrow end must be closed by means of a stopper or cork. Fig. 10 represents one of these jars; and inside it is a holder, useful in experiments with oxygen and chlorine. The holder consists of an iron wire, with a collar at one end, and a brass cup at the other. The material is placed in the cup, and, after being ignited, it is introduced into the gas jar. The student can easily make one of these, after the pattern shown in the annexed engraving. Gas-holders are very useful for holding quantities of oxygen, &c.; and one of the best kind is that represented in Fig. 12. It consists of a cylindrical metal vessel, having at the lower part an opening, which can be closed by means of a cap. At the upper part of the lower cylinder a stopcock is placed, through which the gas passes when it is in use. Between the cylinder and the trough over it are two pipes, fitted with stopcocks, through which water passes from the trough, when the gas inside the holder is required. These are filled by allowing water to pass from the trough into the cylinder until all air is driven out by the side stopcocks. All the stopcocks are then to be closed, and the bottom cap must be opened. The stem of a retort is then inserted, from which the gas passes into the cylinder, driving out the water by the bottom hole. When the holder is thus filled with gas, the retort must be removed, the cap screwed on, and the upper trough filled with water. One of the stopcocks, between the trough and the cylinder, may be opened, through which the water will pass, and force out the gas through the side stopcock. An india-rubber tube is to be fitted to this, to conduct the gas to any place it may be required. In making large quantities of oxygen, which

Fig. 10.

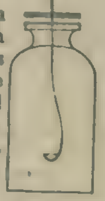

Fig. 11.

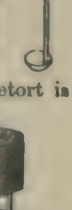

Fig. 12.

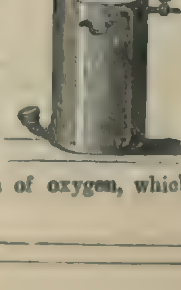
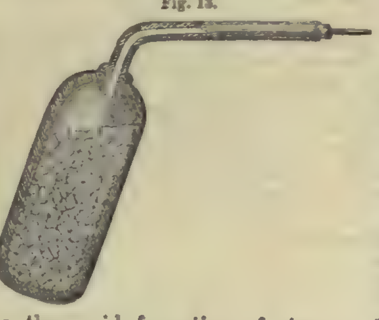


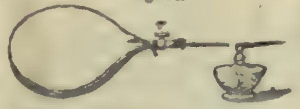
is frequently required in some experiments, a mercury bottle is used, into which a bent iron tube has been screwed. The bottle should be about half filled with the material, and great care should be taken to remove its outer orifice from water, through which the gas has to pass to purify it, lest, at the close of its manufacture, the liquid should rush back, and so endanger an explosion, owing to the rapid formation of steam. One of these arrangements is represented in Fig. 13.

Fig. 13.



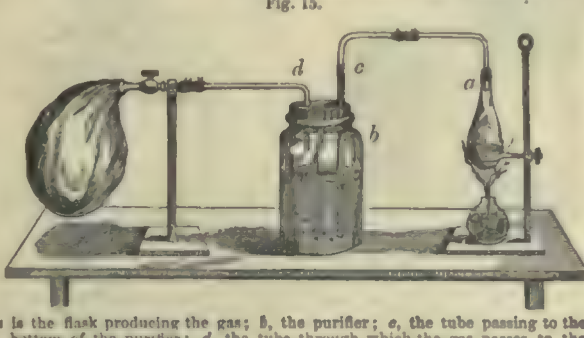
In many instances, bladders may be used to retain small quantities of gas. A large bullock's bladder should be chosen, and it must be carefully cleaned by means of cloths. The neck is then to be cut off, and a stopcock introduced into it. The neck of the bladder, and that of the stopcock, are then to be tied tightly together. One of these, fitted with a jet, useful in blowpipe experiments, is represented in Fig. 14.

Fig. 14.



In making some gases, powder, &c., is often given off from the flask, which would injure the bladder and stopcock, and also render the gas impure. This is easily prevented by means of a purifier, which may be a wide-mouth bottle with a cork in its neck. Into this two tubes are fitted: that from the vessel making the gas is to reach nearly to the bottom of the purifier, which must be three-parts filled with water; whilst the tube through which the gas passes into the bladder, is only just to reach inside the cork and neck of the vessel. Connections between the flask, &c., may be made by means of short india-rubber piping, which should be a little smaller than the tubes themselves; a little string will fasten the india-rubber tightly round the glass tubes. As the gas passes from the flask it will bubble through the water, which will retain impurities, and the pure gas will pass on to the bladder.

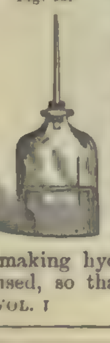
Fig. 15.



a is the flask producing the gas; *b*, the purifier; *c*, the tube passing to the bottom of the purifier; *d*, the tube through which the gas passes to the bladder.

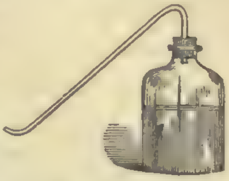
The above engraving, Fig. 15, illustrates this simple and yet effective plan of purifying gases.

Fig. 16.



Some gases, such as hydrogen, do not require heat for their manufacture; and gas bottles, of two kinds, or one bottle fitted with two sorts of tubes, are used. For experimenting with hydrogen, with respect to its flame, a straight glass tube, fitted with a cork, and ending in a jet, may be employed, such as is shown in the annexed engraving. But in making hydrogen, carbonic acid, &c., a bent tube is used, so that the lower end may be placed under water, or in any receiving-vessel. A convenient kind of this arrangement is shown in Fig. 17. Almost any kind of bottle answers for this purpose. They should only be about half filled with the materials, or the contents might run over, through the tube, and so spoil the experiment.

Fig. 17.



The apparatus we have described will be sufficient for most experiments on the gases: we shall therefore proceed to mention such as will be required for other purposes. Many substances require to be pulverised; and for this purpose a pestle and mortar is necessary. Those of Berlin porcelain, and unglazed, are generally useful; whilst some, for special purposes, should be well glazed, in order that no loss may be sustained by the powder resting in crevices or cracks of the material. Many substances which cannot be powdered in their natural state, may first be heated, and then thrown into cold water. Glass and flint are substances of this kind. Occasionally, as is the case with zinc, some substances must be heated before being powdered.

Flasks and test-tubes are always employed for heating and effecting solutions. But for the purposes of crystallisation, during which it is desirable that as much as possible of the surface of the liquid be exposed to the air, evaporating dishes are employed. One of these is represented in the annexed figure. The best material for the purpose is Berlin ware; but for ordinary experiments, stone-ware, or even watch-glasses, which are very useful, will answer very well. Those having a lip are to be preferred, as that facilitates the pouring of liquids. For some experiments, the inside of the dish should be highly glazed; whilst, for crystallisation, a rough surface is far better.

Fig. 18.

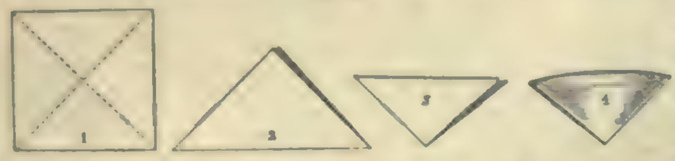
A water bath is often required for the purpose of drying precipitates and organic substances; the object being that their temperature should never rise beyond that of boiling-water. One is easily made by placing a small evaporating dish inside a larger one containing water. The outer one is heated by means of a spirit-lamp; whilst the inner one contains the substance to be dried. A tin saucepan answers extremely well for the water vessel, as on its rim almost any vessel can be supported. The instrument-makers supply such, properly constructed for the purpose; but these possess no advantage over the simple arrangement we have described.

After solution has been completed, it is often necessary that the liquid should be filtered. This is effected by means of glass or stone-ware funnels, of the ordinary shape, through filters made of proper paper; or, what answers generally as well, common white blotting-paper. Filters, ready cut, may be purchased at the operative chemists; but are easily made in the following manner:—Take a square sheet of white blotting-paper, as in No. 1, Fig. 19. Then fold its corners together, as in No. 2; again fold its corners, as in No. 3; and then open out one fold, cutting off the superfluous edges, as represented in No. 4. The filter will then be complete, but should be moistened with water when placed in the funnel, which facilitates the passage of the liquid to be filtered through it. Ribbed filters are sometimes employed; and they are made by plaiting together the folds of paper in a manner which we cannot properly describe, or illustrate by means of an engraving.

After a solution is made, the next process is that of testing, or adding to it certain solutions, which will bring out appearances by which the chemist can judge of the nature of the substance under examination. This is effected by means of test-glasses, which are made of various shapes. For many experiments, ale and wine glasses answer very well; for delicate experiments, however, lipped-glasses are needed. Generally speaking, any glass vessel answers the purpose.

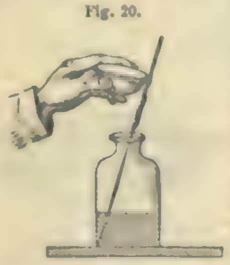
Dr. Faraday suggested, many years ago, a very ingenious mode of testing, boiling, and otherwise dealing with solutions. It is that of using slips of window-glass. Even the backs of plates, and sheets of paper, may be thus used. Test-tubes are also of value; and are, perhaps, especially useful to the beginner, as he can use them for so many purposes.

Fig. 19.



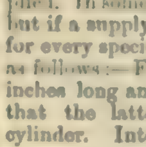
We may here suggest a very simple contrivance, which will aid the student in pouring liquids between unlipped vessels, such as flasks and bottles. If a liquid be poured out of such, it has a tendency to run down the side; but if a glass rod be placed so as to rest against the edge of the vessel out of which the liquid is being poured, and with its other extremity inserted inside the receiving-vessel, but not touching it, the liquid may then be passed from one to the other without the loss of a drop. The mode of doing this is illustrated in the annexed engraving.

Fig. 20.



In some cases an intense heat is required, as in the fusion of substances containing silica or flinty matter. For this purpose some form of furnace is needful. An ordinary fire-place may be used; coke being employed as a fuel. A most convenient furnace, suggested by Dr. Faraday, answers admirably; and having constantly employed it, we recommend its use to our readers. It is made by boring holes, an inch in diameter, at equal distances, through the outside of a blue pot, such as is used by refiners. The holes are easily made, and should be neatly finished off. An iron grid is dropped in so as to rest two inches above the lower series of holes, and the fuel may be small pieces of coke or charcoal. The furnace should be bound round by iron wire, so as to prevent it falling to pieces on being heated. One of these will last for a long time, and is useful for almost every purpose which a chemist can require. Its cost is very slight, being not more than a couple of shillings altogether. The annexed engraving represents one of these simple contrivances.

Fig. 21.

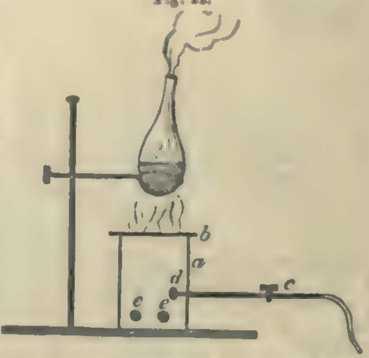


The instrument-makers sell furnaces of every variety of form, suitable for the purposes to which they may be applied. In some cases, an Argand spirit-lamp may be used; but if a supply of gas be accessible, a convenient furnace for every species of heating purpose may be readily made as follows:—Fix on the end of a cylinder of iron, eight inches long and three inches wide, some wire gauze, so that the latter may entirely close one end of the cylinder. Into the lower part of the cylinder introduce a gas-pipe, having first bored several holes beneath that one through which the pipe passes. These will admit a supply of air, which will mix with the gas as it issues from the gauze. If the gas be ignited, it will burn with a blue flame, affording little light, but an intense heat. The heat can be regulated with the greatest nicety; and the most gentle evaporation, or the fusion of siliceous compounds, can be carried on with the same arrangement. Fig. 22 represents the usual way of carrying out this useful mode of heating.

In most chemical laboratories, the gas furnace is considered indispensable; not simply because the heat produced by it is so easily regulated, but also on account of its cleanliness, and from not producing dust or sooty matter.

A very ingenious arrangement has lately been produced by Mr. Griffin, of Bunhill-row, London, which has come largely into use for chemical purposes, and is also employed by metallurgists in cases wherein an intense heat is frequently required. The principles of its construction are similar to those of the gas furnaces which we have already described; but as it can afford a temperature sufficient to melt cast iron, and to soften almost to the fusing-point, both wrought iron and platina, we shall introduce a description of its arrangement.

Fig. 22.

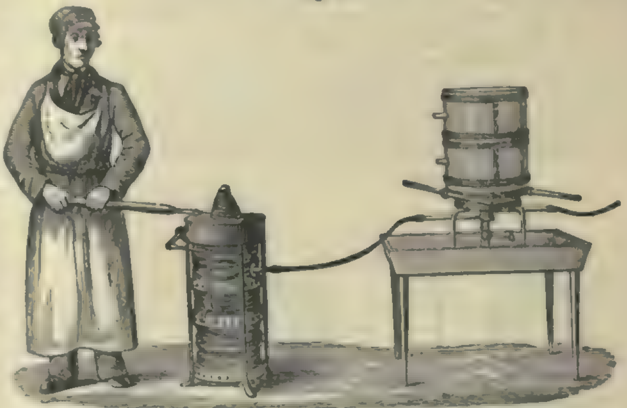


a is the iron cylinder; *b*, the sheet of wire gauze; *c*, the pipe supplying gas; *d*, the orifice whence the gas escapes into the cylinder; *e e*, are holes through which air enters the cylinder.

Our illustration (Fig. 23) will give an idea of this arrangement when in use. On the right is the gas-furnace placed on a table; in the centre we have the bellows which supply the air-blast, driven by a man, who at the same time can superintend the entire operation.

Fig. 24 is that portion through which the air and gas pass together. Fig. 25 shows the holes at the top of Fig. 24, which only represents them in section. These, in fact, form the heating portion of the furnace.

Fig. 23.



Mr. Griffin has adopted two different methods of applying heat. In some cases, he prefers to drive the heat downwards; in others, the heat is applied from beneath. The following engravings illustrate the plans by which the heat is applied from above.

Gas Furnace heated at the top, exhibited in Section by Fig. 26.—*a* is the gas-burner; *b* is the support for it, when used below the furnace; *c* is the iron tripod support for the furnace; *d d* are two perforated clay plates, adapted to the gas-burner, *a*; *e e* are two clay cylinders.

The interior of the furnace, as represented by Fig. 26, is built up as follows:—The clay plate, *d*, is put upon the tripod, *c*. Over the central hole in *d*, the clay cylinder (Fig. 27) is placed, and upon that cylinder two or three of the clay plates represented by Fig. 28. Upon these a porcelain or platina crucible is placed. If it be of platina, a piece of platina foil may be put between the crucible and the uppermost clay plate, to protect the crucible from contact with particles of iron, or against fusion with the clay. The crucible is to be covered by the plumbago jacket, Fig. 29. The space between this pile in the centre of the furnace and the two cylinders, *e e*, which form the walls of the furnace, is to be filled with flint stones, or gravel, washed clean and dried. The stones which answer best are rounded, water-worn pebbles, of half an inch to one inch diameter. These may be piled up to the top edge of the jacket, Fig. 29. The number of clay plates must be such as to bring the top of the crucible to the distance of two inches, or two-and-a-half inches at the utmost, from the flat face of the gas-burner, *a*. In some cases, merely one of the furnace cylinders, *e*, is necessary; in which case the crucible and its jacket is placed directly upon the cylinder, Fig. 27; and when only a moderate heat is required, even the packing with pebbles may be dispensed with. Another means of diminishing the heat is that of increasing the distance between the gas-burner and the crucible.

Fig. 24.

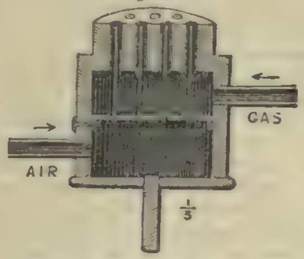


Fig. 25.

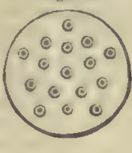

Fig. 26.

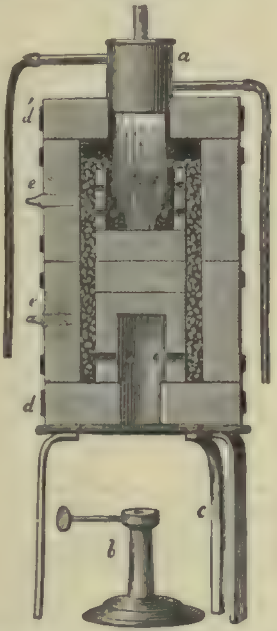

Fig. 27

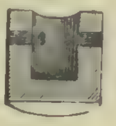

Fig. 28.

Fig. 29.

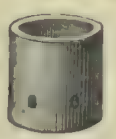

Fig. 30.

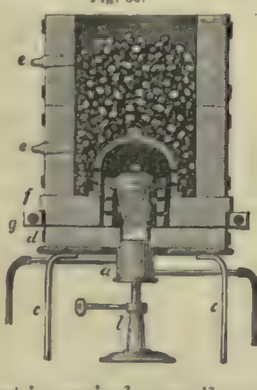

Fig. 31.

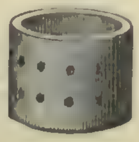

Fig. 32.

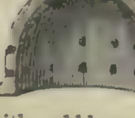
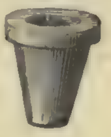


In Fig. 26, it will be seen that the gas-flame is driven, by means of the blast, directly on to the crucible. Another illustration represents that form of the furnace in which the heat is produced beneath the crucible. (See Fig. 30).

The packing of this variety of furnace is performed as follows:—The clay plate, *d*, is placed upon the tripod-stand. The crucible jacket, Fig. 31, or one similar, but of larger size, is placed upon the plate, *d*. The crucible and its cover is then put into its place, and is covered with the dome, Fig. 32, which must rest upon the lifter, *f*, and must be of such a width as to clear the crucible easily when lifted. The internal height of the dome should be such as just to clear the top of the crucible cover. Consequently, where crucibles of different sizes are used, domes of different sizes are also necessary. Observe, distinctly, that the crucible and its support are to rest upon the plate, *d*, and the dome upon the lifter, *f*. The furnace cylinders, *e e*, are now to be superposed, and the space between the dome and the cylinders, and that above the dome, are to be filled with small pebbles, as already directed. The gas may then be lighted; the blast of air set on; and the operation be allowed to proceed.

Fig. 33 represents a plumbago crucible, which is used to suspend the inner crucible over the gas-flame.—By means of such a furnace, six inches in diameter, three pounds of copper or cast iron can be fused in a quarter of an hour. From eight to ten pounds of copper or cast iron can be melted in an hour's time; and thus a portable and almost instantaneous source of intense heat is afforded.

Fig. 33.



The chemist requires various kinds of crucibles for his purposes. The student may supply himself with a few of the Hessian and English kind; and, for more delicate experiments, those of Berlin porcelain are to be preferred. Occasionally, a platina crucible is used; and it should always be placed in a Hessian one if employed in a furnace in which coke or charcoal is used. This precaution is unnecessary if a gas furnace be employed.

Besides the apparatus already mentioned, bottles for containing chemicals, stirring-rods, and a variety of minor articles, which will suggest themselves, will be required, which can be supplied at leisure. We must not omit to name, that some glass tubing, from an eighth to a quarter of an inch in diameter, is extremely useful, and can be readily converted to many purposes. The following are directions for bending it into any form that may be required.—For this purpose, soft tubing should be used. A piece of the proper length is to be cut off by means of a file; and the part that is to be bent must be held in the flame of a spirit or gas-lamp by the ends, until it is sufficiently softened to bend easily. The further ends are then to be gradually pressed downwards, care being taken that the red-hot portion is not bent into an angular form, but that a round edge is preserved, in shape similar to the letter U. If this be not attended to, the bent tube will almost certainly break at that part. Pieces of glass tube may be joined together by means of india-rubber connections;* or if the end of one piece be heated red-hot, and slightly inlaid by means of a piece of iron run round it, the end of the other piece may then be inserted, and the two fused together at a red heat, or by means of a common blowpipe. After a little practice, the student will be able to work readily with glass, providing it be of the soft kind. German glass tubes cannot be so easily managed, because they do not soften except at high temperatures.

We shall conclude our remarks on manipulation and apparatus, by urging on our readers the following precautions, if they desire to pursue chemistry successfully and economically. And first, it is of great importance that cleanliness be observed. An apparently clean glass may be chemically speaking, very dirty; for some tests are so delicate, that one part in 50,000 may be readily detected, of any substance with which the test affords a colour or precipitate. Indeed, extreme danger may ensue from neglect of this. For instance, were a drop of chloride of nitrogen to be placed on a greasy or oily dish, it would instantly explode, and break the vessel into fragments. Neatness and care should be observed in all experiments. This will induce a general habit, which will be of value to the student in every pursuit he takes in hand; and without them a person can never succeed in chemical science.

---

* See *ante*. p. 305.

Beginners are often tempted to use large quantities of chemicals, where experienced persons would employ but a small portion. This error often produces an exactly opposite effect to that intended. Thus, if a small quantity of iodide of potassium be added to a solution of bichloride of mercury, a yellow precipitate will be produced; a still larger quantity will afford a red precipitate; and one in excess will redissolve all the precipitate, and leave a transparent and colourless solution.

Heat should be applied gradually to all glass vessels, lest they should be fractured. A sand-bath is sometimes employed between the vessel and the source of heat. An iron or copper basin containing sand, answers well for this purpose, by allowing the heat to pass gradually, and so avoiding the risk which would be run by applying the flame directly. As we proceed, we shall suggest other precautions when needed, and thus endeavour, as far as possible, to ensure the successful performance of all the experiments we shall introduce illustrative of our subject.

CHEMICAL TERMS AND SYMBOLS.

Before entering on a description of the natural history of the elements and their compounds, we shall make a few remarks in reference to terms employed to designate various substances; and the symbols, the use of which tends to materially assist the student in his progress, and saves much time and space.

In the early days of chemical science, every one "did that which was right in his own eyes," when naming newly-discovered substances. Hence arose such terms as "Glauber's" and "Epsom salts," "cream of tartar," "aqua regia," and the like. In fact, the names then adopted, just illustrated the mental character of their inventors, who, at all times, leaned more to their imagination than to their reasoning powers for a guide. As the number of compounds increased, or became known with respect to their constitution, great inconvenience was felt, and the necessity of some system of nomenclature was recognised.

Without entering into historical details on this subject, we state that the present plan has the advantage over all others which have been proposed, by giving an insight into the composition of the object designated. This we shall perceive as we proceed, and the student will soon appreciate its value. In naming elementary bodies, the old plan is still maintained to some extent; but this is of slight consequence, because each has but little relation to the others, and, therefore, a distinctive title is advantageous, no matter whence its source. When, however, we speak of bodies compounded of elements, it is desirable that we should know of what they are composed. We will take, for instance, the classes of bodies called oxides, &c., acids, and salts. The term *oxide* is applied to any substance containing a metal united with such a proportion of oxygen as is not sufficient to make it an acid in its properties. Thus, the rust of iron, commonly so called, is termed *oxide of iron* in chemical language. If it have but one equivalent of oxygen to one of metal, it is termed the *protoxide;* if two of oxygen, the *binoxide;* and so on—Greek prefixes being used to indicate the relative proportions existing between the metal and the oxygen.

Combinations of metals and chlorine are called *chlorides.* Thus, common salt, which contains chlorine and the metal sodium, is termed *chloride of sodium.* Combinations of iodine, bromine, and fluorine, are similarly termed *iodides, bromides,* and *fluorides.* By this arrangement we at once perceive the nature of the compound from its title. We may proceed a step further with respect to acids. Generally speaking, the names indicate their origin; thus, sulphuric acid is obtained from sulphur, by its combination with oxygen; nitric acid from nitre; hydrochloric acid from chlorine and hydrogen; but still the system to which we have referred, is not so strictly carried out with many of these compounds, as is shown in the names oxalic acid, acetic acid, &c. When, however, we deal with salts, we find no exception to the rule; and we here must explain what we mean by that term. A salt is always composed of an acid and a base. Thus, in carbonate of soda, we have the *acid* as the carbonic, and the *base* is the soda. In all the salts, both base and acid are indicated. In this application of the present system of nomenclature, we find the greatest convenience; as the following instances will show, when we compare the new with the old names. Thus, "copperas" is now called sulphate of iron, because it contains sulphuric acid and iron; "white vitriol" is the sulphate of zinc; "Glauber's salts," sulphate of soda; "Epsom salts," sulphate of magnesia; "blue vitriol," sulphate of copper. Combinations of nitric acid with a base, are similarly named. Thus, nitre is called nitrate of potass; and so each salt bears its own character in its name.

There are other combinations which differ from acids, &c., to which we must also direct attention. Thus, the combinations of sulphur with metals are termed sulphides; of phosphorus, phosphides; of carbon, carbides. In earlier chemical works, the terms sulphuret, phosphuret, and carburet, were used; but these have been changed, because of the analogy existing between these substances and the chlorides, &c. Other terms analogous to these will be met with when we study the chemistry of organic bodies; but such will be duly noticed in their proper place.

When the proportion between acid and base varies, their prefixes are employed to signify the fact. Thus, we have *proto*-sulphate of iron, containing one equivalent of acid to one of metal. *Bi*-carbonate of soda, containing two equivalents of acid to one of base; and thus, not only are the names of the constituents afforded, but their relative proportions are also indicated.

These instances will be sufficient to introduce our readers to the principles of chemical names; and we shall now proceed to refer to symbols, by which elements, oxides, acids, salts, &c., are distinguished. It is desirable that the student should acquaint himself with that of each element, as it will much facilitate his progress. A table of symbols will be found prefixed to the next chapter, in which we shall commence the description of each element and its compounds.

Generally speaking, each element is distinguished by the initial letters of its name. Sometimes those of the Latin term are used in preference to the English. The following are examples of each:—

Hydrogen has the symbol of . . .	H
Oxygen	O
Sulphur	S
Iron—Ferrum	Fe
Tin—Stannum	Sn
Silver—Argentum	Ag

By such an arrangement, each element, having a separate symbol, is readily distinguished from all others. When compounds are designated, then the symbols of their constituents are used together, thus—

HO, hydrogen and oxygen, represent water.
Ag O, silver and oxygen ,, oxide of silver.
Ag Cl, silver and chlorine ,, chloride of silver.

If, however, there are more than one equivalent of either element, then such is shown by means of small figures; as—$S\ O_3$, sulphuric acid, which, when free from water, is a compound of one equivalent of sulphur to three of oxygen.

Occasionally, a combination of symbols is required; and, in that case, the symbols of each compound are arranged together, by means of which the entire constitution of the compound is shown: thus, sulphate of iron is represented as—$Fe O + SO_3 + 7HO$; that is, it is composed of one equivalent of oxide of iron, one of sulphuric acid, and seven of water.

In many chemical works, the sign + is omitted, and the symbols are written thus—$Cu O, SO_3, 5HO$, which is that of the sulphate of copper, or "blue vitriol." This, of course, saves space, and is equally as intelligible as the method above named.

We may now show how these symbols are employed in connection with the actual value of the separate equivalents of a compound; and we would advise the student to commit to memory the different values assigned thereto. He will thus readily become acquainted with that of any compound. A table of these equivalents will be found prefixed to the next chapter. The following skeleton table will serve the purposes of illustration. In it we have used whole numbers, so as to save any difficulty with fractional parts.

Skeleton Table of Equivalents and Symbols.

Name.	Symbol.	Equivalent.
Hydrogen	H	1
Oxygen	O	8
Carbon	C	6
Nitrogen	N	14
Sulphur	S	16
Calcium	Ca	20
Chlorine	Cl	36
Sodium	Na (Natrium)	23
Silver	Ag (Argentum)	108

In the above we have included the elements only; but in the next table, we have the equivalents of bodies which are composed of some of these elements.

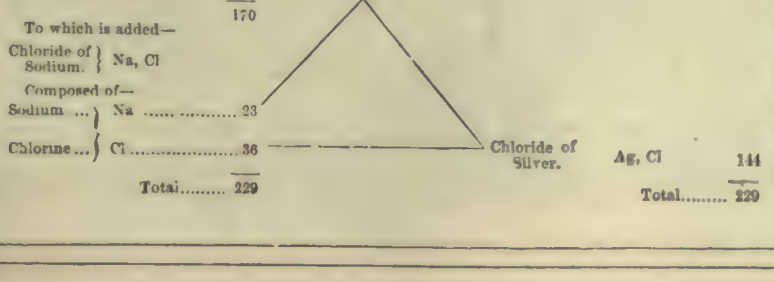
Skeleton Table of the Symbols and Equivalents of some Compounds.

Name.	Symbol.	Equivalent.
Water	HO	9
Sulphuric acid (dry)	SO_3	40
Sulphuric acid, with one equivalent of water, as found in commerce	SO_3, HO	49
Carbonic acid	CO_2	22
Chalk Carbonate of lime	$Ca O, CO_2$	50
Common salt Chloride of sodium	Na, Cl	59
Chloride of silver	Ag, Cl	144

It will thus be seen that the symbols and equivalents of a compound are composed of those of their elementary constituents.

We may now proceed to illustrate the method adopted for showing the results obtained in adding compounds in solution together, by which decomposition and the production of new compounds are effected.

Decomposition of Nitrate of Silver by means of Common Salt.



Materials used.
Name. Symbol. Equivalent.
Nitrate of Silver. Ag O, NO₅
Composed of—
Silver ...... Ag 108
Oxygen ... O..................... 8
Nitric Acid.
Nitrogen ... N 14
5 of Oxygen O₅ 40
170
To which is added—
Chloride of Sodium. Na, Cl
Composed of—
Sodium ... Na 23
Chlorine ... Cl 36
Total......... 229
Products.
Name. Symbol. Equivalent.
Nitrate of Soda. Na O, NO₅ 85
Chloride of Silver. Ag, Cl 144
Total......... 229

We have already done this to some extent in a previous page;* but did not there include the equivalents and symbols of the substances mentioned. In the preceding example, in which the decomposition of nitrate of silver is exhibited, each point is illustrated: and we recommend the student to study them carefully, so that he may have no difficulty in following our remarks in future pages. We have introduced the name of the materials employed, their symbols and equivalents, and those of the resulting compounds.

From the diagram, illustrating the decomposition of nitrate of silver by common salt, we find that 36 parts of chlorine leave the salt, and combine with 108 parts of silver, forming 144 parts of chloride of silver. Also that 54 parts of nitric acid, and one of oxygen, leave the silver in the nitrate, to combine with 23 parts of sodium, and so form 85 parts of dry nitrate of soda. We thus learn, that whilst the total amount of parts employed and obtained are equal—viz., 229 grains, ounces, or pounds—yet that the materials used, and the products of their mixture, are entirely different in every respect.

There are some theoretical considerations which might be noticed in reference to the formation of salts, by the addition of an acid to the oxide of a metal. Some would transfer the oxygen of the oxide to the acid. Thus, instead of indicating sulphate of copper, as $Cu, O + SO_3 + 5HO$; it would, according to such views, be $Cu + SO_4 + 5HO$. On this point, however, we shall have to remark hereafter. Dr. Daniell, of King's College, London, the inventor of the voltaic battery bearing his name, was, we believe, the first to broach the doctrine.

SPECIFIC GRAVITY, ISOMORPHISM, DIMORPHISM, ISOMERISM, ETC.

WE shall now refer to some matters connected with the physics of chemistry, in which the relative weight and forms of bodies are involved. We shall first explain how the specific gravities of solids, liquids, and gases are obtained; and then refer to some physical peculiarities noticed in crystalline and other bodies.

By the term "specific gravity," we mean that the same bulk of different bodies weighs differently; or, in other words, some substances contain, within any specific limit, more matter than others. For instance, if we fill a bottle of any size with mercury, and weigh it, and then pour away the metal and fill the bottle with water, we shall find, on reweighing it, that only one-fourteenth of the weight of the mercury is required to balance the water. In other words, mercury weighs, bulk for bulk, fourteen times nearly that of water. Almost every substance we meet with has thus a weight of its own, and this weight is called its specific gravity. With respect to solids, the difference is characteristic in all cases.

Now there is no difficulty in comparing the weights of equal bulks of water and mercury, because, as each is a liquid, it is easy to weigh equal bulks one against another; but this would be impossible if we were to attempt to ascertain the specific gravity of gold, iron, &c., in a similar manner; because, to render them fluid, we should have to employ so intense a heat as would instantly destroy our apparatus. This difficulty is easily overcome, in a manner we shall proceed to explain.

It is scarcely necessary to remark, that some standard of comparison is required, by means of which a uniform table of specific gravities may be constructed; and, by universal consent, water at a temperature of 60° Fah., in as pure a state as possible, has been fixed on. For this purpose it must be carefully distilled in glass vessels, and should then be kept out of contact with the atmosphere, to prevent absorption of air, which would lessen its own specific gravity.

---

* See *ante*, p. 301.

The principle on which the specific gravity of solid bodies is taken, is, that any body immersed in a fluid, displaces as much as is equal to the bulk of the solid, and that a ratio exists between the respective weights of each in reference to that bulk. Thus, we will suppose equal bulks of gold and iron to be immersed in distilled water. They will each displace exactly the same *quantity* of water; but if the equal bulks of water, iron, and gold, be each weighed, they will bear a ratio to each other of 1, 7, and 19 nearly. Now, these ratios are, in round numbers, the actual specific gravities of the substances named; and hence, if we can ascertain the ratio existing between the weight of any body, and that of the bulk of water displaced by it when immersed therein, we have at once the specific gravity.

Now, this may be done in two ways. The first we mention will only illustrate the principle; whilst the second is that always employed. First, a vessel may be exactly filled with distilled water, and a body, previously weighed, may be immersed completely in it. Of course, as much water as is equal to the bulk of the body will run over the sides of the vessel. If all this could be collected and weighed, then the weight of the immersed solid, divided by that of the displaced fluid, would be the specific gravity. But, practically, this is impossible; because a considerable portion of the fluid would be lost by adhering to the vessel as it runs over the side.

Secondly, the specific gravity of any body may thus be accurately found. Suspend the substance, by means of a horse-hair or filament of silk, to the pan of a pair of scales, and weigh it carefully. Then immerse the body in a vessel containing distilled water, taking care that all air-bubbles are removed, and that the substance is entirely below the surface of the liquid. It will be found that the solid does not weigh so much when in the water as in the air. Balance it by means of weights placed in the scale from which the substance is suspended, and, having ascertained how much is required, divide the weight of the body as obtained in the air, by the loss it sustained when weighed in water, and the quotient will be the specific gravity. The loss of weight represents that of the bulk of water, equal to the bulk of the solid by which it was displaced.

To illustrate this plan, the following instance will suffice:—A piece of lead weighed in the air just 45 grains. On being weighed in water it lost four grains. The 45 grains is thus to be divided by the loss of four grains; and the result, 11·25, is the specific gravity of the lead. In this way the specific gravity of all substances weighing *more* than their own bulk of water, may be readily taken.

The practical value of this process is very great; for by consulting a table of specific gravities of bodies, we can often have a guide to the proportion in which they may exist in any substance containing two or more of them. For instance, a piece of quartz may have a greater specific gravity, in its mass, than any part of it possesses. This indicates an admixture with some other substance. Supposing that to be gold, a certain ratio will exist between the two specific gravities; that is, of the mass and of the part; and this ratio will increase directly in proportion as the quantity of gold contained therein. When a rough approximation only is required as to the value of auriferous quartz, this plan may be readily employed; and, in some instances, we have found, on subsequent analysis, that the result thus obtained is very near the truth. Of course, the presence of other foreign bodies will entirely vitiate the result. In the case of alloys, the method may be also adopted, provided that not more than two metals are present.

When the specific gravity is required of a body lighter than water, the same plan is adopted, with the addition, however, that the body must be sunk in the fluid by having attached to it a heavier substance, the weight of which in air, and loss when weighed in water, have been first ascertained. The loss of weight of the heavy body is then to be subtracted from their joint loss when weighed in water, and the weight of the light body in air is divided by the amount so obtained; the quotient is the specific gravity of the light body.

The specific gravities of liquids may be ascertained in various ways; for all that is required, is the ratio of weight of equal bulks of the different fluids. A common plan is that of using a bottle capable of containing exactly 1,000 grains of distilled water at a temperature of 60° Fah. The bottle is marked at the place at which the surface of the liquid reaches the neck of the vessel, and the liquid whose specific gravity is sought, is poured into it until it reaches that point. The weight of the whole is then ascertained; and that of the bottle having been deducted from the total, the balance is that of the liquid, and its specific gravity also. The plan is remarkably simple; and all liquids may thus have their specific gravity taken, whether they be lighter or heavier than their own bulk of water. Thus, a bottle holding 1,000 grains of water, will contain 1,840 grains of sulphuric acid, 790 of pure alcohol, and so on; and thus these weights give the respective specific gravities of the liquids named—as 1·84 and ·79 compared to water, the standard, which equals 1.00

There is, however, one point to which we must draw attention; and that is, the fact that all bodies expand by heat. This may be neglected in reference to taking the specific gravity of solids; but the case is different with liquids, having a rate of expansion much greater; hence their specific gravities must either be taken at a temperature exactly that of 60°, or allowance must be made for their expansion for higher, or contraction through lower temperatures.

Another mode of taking liquid specific gravities is that of the hydrometer, of which there are numerous forms. It is constructed on the principle that a body will rise in a liquid of greater specific gravity, and sink in one the specific gravity of which is less than its own. These instruments are generally constructed of glass, which is so weighted, that one portion of the scale enclosed in it shall be level with the surface of distilled water when the hydrometer is immersed therein. If the liquid be heavier than water, then the stem of the hydrometer will rise, as would be the case if salt and water were the subject of experiment. If the liquid be lighter, then the hydrometer would sink; and so, by reaching the scale at the level of the liquid, the specific gravity is at once obtained.

The following cut illustrates the appearance of one form of the instrument; but, as we have already remarked, they vary much in shape, size, and according to the uses to which they are to be applied.

Fig. 34.

Occasionally, glass balls, which have been so weighted as to swim in any part of a liquid of the same specific gravity as their own, are used. This plan, however, requires a separate ball for each possible specific gravity; and hence its use is confined within very narrow limits. There are other modes of ascertaining liquid specific gravities, such as weighing solids in them, &c.; but the above are the best practical methods.

The specific gravity of gases is taken by very similar means to those we have described in reference to liquids. But special care is required, because the variations of atmospheric temperature and pressure have the effect of interfering with the accuracy of the results obtained. The rate of expansion in gases far exceeds that of either liquids or solids; and hence, it is absolutely necessary that the temperature and pressure of the atmosphere should be very carefully attended to.

In practice, a glass globe, or other vessel, is first weighed as filled with air; it is then exhausted of air by means of a good pump, and again weighed, so as that the weight of the vessel itself may be known

This is a very delicate operation, because so many circumstances interfere with the accuracy of the result. When the atmosphere is at a high temperature, it contains a large amount of moisture, and so vitiates the calculations which have to be obtained, unless due allowance be subsequently made. The same remarks apply to temperatures below that of 60°, which is the usual standard; because, in that case, the absence of moisture in the air below 60°, would also give false results. The gases are, therefore, carefully dried by passing them through a tube containing chloride of calcium, or through strong sulphuric acid, either of which has so great an attraction for aqueous vapour as to abstract it readily.

The weight of the exhausted flask, deducted from that obtained when the vessel is full of air, gives the weight of the air which the flask would contain. The gas which is to be weighed, after having been dried, is then passed into the flask, which should be again exhausted, and subsequently refilled with the gas. By these means any chance of admixture with air left in the flask by the first exhaustion is avoided. Great care, however, must be taken that the gas is in a perfectly pure state, otherwise its accurate specific gravity cannot be obtained. An allowance must be made, in the subsequent calculation, for the expansion or contraction of the gas, if its temperature be either above or below 60°. The necessary data for this purpose have already been given.* The flask, thus filled with gas, is then carefully weighed, and if its capacity be exactly 100 cubic inches, the ratio of its weight to that of 100 cubic inches of air will at once be found. If the flask be of greater or smaller capacity, its reduction to that of 100 cubic inches, or the ratio of the weight of air to that of any gas, and, therefore, its specific gravity, is simply an ordinary arithmetical question.

We must, however, add another element of interference with respect to the accuracy of the results thus obtained. It is that of atmospheric pressure, which may be entirely neglected in solids, and in most cases in liquids As the atmospheric pressure lessens, all gases proportionally expand; and as it increases, gases contract in bulk. Now the usual standard of the specific gravity of gases is dry air, at a temperature of 60°, and, under a mean pressure, equal to that which supports 30 inches of mercury in the barometric column. Any excess or deficiency of pressure is allowed for, and proper corrections are made. The subject has already been referred to;† and we shall not extend our remarks thereon.

The student will do well to repeatedly practise himself in taking the specific gravities of solids and liquids. With respect to gases, we may observe, that he cannot hope to obtain anything like accurate results until he is well used to experimental manipulation. If, however, he possess the necessary apparatus, he can try the weight of different gases, comparing them with that of the air: and for such purposes, it may be useful if we state, that dry air, at 60° Fah., and 30 inches barometric column, weighs 31·0117 grains for each 100 cubic inches. There are certain phenomena observed in some compounds, which are partly the result of physical and chemical actions, such as those of isomorphism, isomerism, and dimorphism. By the term isomorphism, we mean that bodies may have similar external forms, such as crystals, &c., and yet have entirely different chemical constitution. Isomeric bodies have similar chemical constituents in the same proportions, and yet their external form may differ, as in sugar and starch. Some bodies have two different forms, or one dimorphic, under different circumstances. Thus phosphorus has a rich yellow, and partly crystalline appearance at ordinary temperature; but if it be considerably heated, it loses all external regularity of structure, and becomes a shapeless red mass. These varieties of form, doubtless, depend on a peculiar arrangement of the atoms of a body, produced by the action of two or more forces. We shall leave a fuller consideration of these subjects to the next chapter, when we shall meet with numerous instances which will fully illustrate these peculiarities.

In the following page will be found a table of the elements, their symbols, equivalents, &c.; to which the attention of our readers is especially directed, as forming the basis of all the calculations involved in chemical science, and to which we have already referred in our previous pages.

CHAPTER II.

THE CHEMICAL CHARACTERS OF THE ELEMENTS, AND THEIR COMPOUNDS.

HAVING reviewed the various agencies and circumstances which govern chemical phenomena in every species of matter, we shall now proceed to describe the elementary bodies, and the compounds to which their union gives rise. We have already remarked that almost every writer on chemical science adopts a different arrangement in treating the subject; and we shall, therefore, not hesitate to adopt a similar course, more especially as our previous pages have contained ample remarks and experiments on subjects which ordinarily form the introductory matter of chemical treatises. For these, we refer our readers to the sections on Heat, Light, Electricity, and Magnetism; to which we shall frequently allude, and the subjects of which we shall presume that the student has become fully acquainted with.

We shall commence this portion of the subject by describing the properties of such of the elements as, by combining with others as bases, produce definite chemical compounds. Of these, are Oxygen, Chlorine, Iodine, Bromine, and Fluorine.

We shall next take up Hydrogen and Nitrogen, which will be succeeded by another group, including Carbon, Sulphur, Phosphorus, &c. The metallic elements will then be dealt with; and we shall divide these into three classes; namely, Alkaligeneous, Calcigeneous, and Metals proper. The combinations of Oxygen, Chlorine, &c., will be considered in connection with each metallic element; and the salts produced by the combination of such bases with acids, will be ranged under the description of the base itself.

By this plan, we hope first to give a general idea of those substances which, by their general action, have the power of making numerous and analogous compounds; and afterwards we shall deal with those bodies which act as bases to the former, and so either become the subjects of synthesis or analysis.

In this chapter we shall principally confine our attention to inorganic substances, or those in which vital action is not present. We shall, however, touch incidentally on many organic compounds, or those with which vital action is connected. In the following chapter, we shall chiefly deal with what has been called Organic Chemistry; and in those which succeed it, we shall take up the subjects of Analysis, Agricultural Chemistry, and the general applications of Chemistry to Arts and Manufactures.

Many of our future remarks will be almost unintelligible to the student, unless he have become acquainted with all the subjects which have already been treated on. As we have remarked in the various preceding sections, each has a direct connection with the other. This arrangement prevents needless repetition, and saves the time and trouble of both reader and writer. At the present time, each branch of science is so linked with others, as to make it impossible to separate them.

---

* See *ante*—Section 1, "Heat."

† See *ante*—Section 1, "Heat."

TABLE *showing the Symbols ; Equivalents, both on the Hydrogen and Oxygen Scale ; and the Specific Gravities of the Elementary Bodies.*

Name.	Symbol.	Equi. H = 1·00	Equi. O = 100·0	Specific Gravity.
Aluminium	Al	13·7	171·25	(W) 2·60
Antimony (Stibium)	Sb	129·0	1612·50	(W) 6·80
Arsenic	As	75·0	937·50	(W) 5·88
Barium	Ba	68·5	856·25	
Beryllium	Be	6·9	86·25	
Bismuth	Bi	213·0	2662·50	(W) 9·82
Boron	Bo	10·9	136·25

Yttrium	Y			
Zinc	Zn	32·6	407·50	(W) 7·15
Zirconium	Zr	33·6	420·00	

* and † are new metals, discovered by means of the spectrum analysis, and, at present, have been obtained in quantities too small to permit of their equivalents and specific gravities being given. Glucinum and Thallium are referred to under their respective heads.

Note.—The specific gravities above are distinguished by the letters A and W, which signify, respectively, that the standards are—

Air = A = 1·000.
Water = W = 1·000.

In consulting the above table, the reader may perceive some slight differences, when the equivalents, &c., are compared with others adopted in the following pages. These have been given as the nearest approximations to truth ; and where any degree of uncertainty existed, or information could not be afforded, as in erbium, niobium, &c., the spaces have been left unfilled ; such substances being exceedingly rare.

OXYGEN.

THIS elementary body is of the utmost importance in the economy of nature. It forms $\frac{8}{9}$ths of all water on the face of the globe. The atmosphere which we breathe contains one-fifth of its bulk of oxygen; and all the earths, oxides of metals, organic substances of nearly every kind, have it as one of their constituents. In its entire absence, the very existence of animated nature would cease. The earth would become a barren wilderness; every one of its productions would fail, and chaos would reign over the fair face of nature once more. To its gradual combination with other substances, we owe the natural heat of plants and animals. When such combinations take place more rapidly, we obtain our artificial heat, as in the combustion of wood, coals, and other fuel.

To its action on metals is due the development of that wonderful agent, Electricity, as seen in voltaic batteries, and in the vast laboratory of the mineral kingdom. All our sources of artificial light depend on it; and, indeed, it is the "one thing needful" in almost every phase of our existence, happiness, and comfort.

The chemist recognises its properties in the form of a gas; and in this state oxygen is heavier than the air—its specific gravity being 1·111 air = 1·000; it hence follows that 100 cubic inches will weigh 34 grains. Its equivalent, hydrogen being 1·00, is 8·00; and it combines, by volume, with that gas in producing water in the proportion of one of oxygen to two of hydrogen. It assumes the liquid or solid state when in combination with other bodies, as in water and the metallic oxides.

In the following pages, we shall not follow the plan usually adopted in scientific works, because we shall introduce a considerable variety of experiments, having for their object the elucidation of the facts we mention. In so doing, we expect that our readers wish to become practically acquainted with the subject, and we shall endeavour to assist them as much as possible in that respect. We have already described many kinds of apparatus which will be required, and shall afford descriptions of others which may be necessary for special purposes.

Oxygen may be procured, for experimental purposes, from various sources, some of which we shall fully describe. Amongst these are the following:—

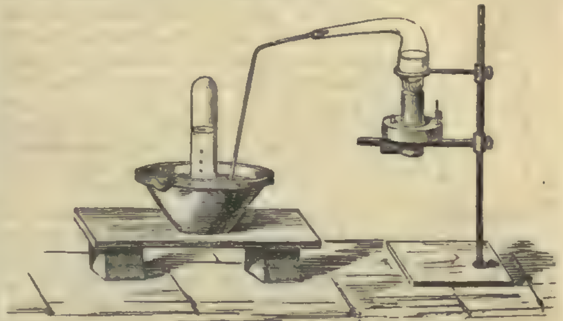
Experiment 5.—Introduce some powdered black oxide of manganese into an iron tube closed at one end, or into a gun-barrel, and into the open end of either vessel fit a pewter tube, so that its other end may dip beneath water. Apply heat, as of a common fire-place, to that part of the iron tube containing the manganese. After a short time, a quantity of gas will be given off, which, on being collected by means of the pneumatic trough and gas jars,[*] will be ready for experimental purposes.

When a large quantity of oxygen is required, a mercury bottle and bent tube are used; the vessel being but half filled with the oxide of manganese. The arrangement has already been described, together with a convenient kind of gas-holder.[†]

Experiment 6.—Into a small-sized glass retort,[‡] introduce some of the black oxide of manganese, and then add sufficient strong sulphuric acid to make the whole of a thick creamy consistence. Rest the bulb of the retort on a ring-stand, and allow its stem to dip below the water in a pneumatic trough. Apply a gentle heat to the mixture, and in a short time oxygen will be given off, which may be collected in the usual manner. The mode of conducting this and similar processes for making gases, is illustrated in the following engraving; in which, however, a bent tube is added to the stem of the retort, instead of dipping it beneath the water in the trough.

Oxygen may be obtained by heating other metallic oxides, &c.; but the following mode is always adopted when very pure oxygen is required; and unless the gas is wanted in very large quantities, it is altogether, perhaps, the best source for all purposes.

Fig 35.



Experiment 7.—Mix one part of chlorate of potass with half its weight of black oxide of manganese: introduce this into a retort, and apply the heat of a spirit-lamp or gas-furnace.[§] In a short time the whole mass will become incandescent, and oxygen will be rapidly given off, which may be collected in the usual way. Some little care is required, as if too great a heat be suddenly applied, the gas is given off with so much violence as to become unmanageable. By means of the mercury bottle and this mixture, we have frequently made thirty cubic feet in less than half-an-hour.

We should here warn those of our readers who are unacquainted with the nature of chlorate of potass, that although by itself it is a perfectly harmless substance, it gives rise to dangerously explosive substances when mixed with other articles. Amongst these are sulphur, phosphorus, and sulphuric acid; and, to a slighter extent, many organic substances, such as sugar, &c., have a similar effect. It should therefore be kept by itself; and to prevent any risk of admixture, the experimentalist should make a considerable quantity of the mixture of the salt and oxide of manganese, which he may keep by him, ready for use, in a glass bottle. This may be labled "oxygen mixture;" and when we use this term in our future pages, it will be in reference to this compound.

In heating the mixture, the oxide of manganese is not decomposed. It merely affords points of contact, by means of which the heat spreads more rapidly through the salt, and saves time. That such is effected, may be noticed by the following experiment.

Experiment 8.—Heat some chlorate of potass alone in a small retort or test-tube, fitted with a bent tube, by means of the spirit-lamp. The salt will melt, and will give off oxygen slowly.

Instead of retorts, a Florence flask and bent tube[‖] may always be employed. This is the most economical mode of procedure, as the fracture of the flask is of no consequence, from its trifling value. It is well that our readers should diminish, as much as possible, the expenses of their experiments; and, at the same time, thereby acquire a knack of substituting one arrangement for another.

By heating nitre in a similar manner to that adopted with chlorate of potass, oxygen may be obtained. There is, however, one objection to this plan; which is, that a considerable quantity of nitrogen is given off at the same time; which, of course, injures its purity. Another source of oxygen, which is necessarily quite pure, is that of the decomposition of water by means of voltaic electricity, which has been already fully described;[¶] but the practical difficulties and expenses preclude its use in ordinary circumstances.

A sufficient quantity of oxygen having been prepared, and collected in gas jars or bottles,[**] the following experiments may be tried, which will exhibit some of its leading properties.

Experiment 9.—Dip a lighted taper into a jar of oxygen. The light will be greatly increased, and the wick will burn much faster than in the open air.

---

[§] *Ante*, p. 306; Fig. 22.

[‖] See *ante*, p. 304; Fig. 3.

[¶] *Ante*—Section 3, "Electricity."

[**] *Ante*, p. 304; Fig. 8.

Experiment 10.—Blow out the light of a taper so as to leave a little of the wick red-hot. Whilst in this state dip it into a jar of oxygen, and it will immediately re-light. This may be repeated many times with the same jar of gas. The tapers best suited for this experiment are those used for lighting gas; but a common tallow candle answers nearly as well. (See Fig. 36).

Fig. 36.

Experiment 11.—Tie a small piece of charcoal to the end of a piece of thin brass or copper wire; make the charcoal red-hot, by holding it in the spirit-lamp flame. When red-hot, immerse it in a jar of oxygen; a most beautiful combustion will take place, sparks flying off on all sides. Boxwood charcoal answers best for this purpose.

Experiment 12.—Put a small piece of phosphorus, not larger than a pea, into the phosphorus cup or holder.* Remove the glass stopper or cork from one of the jars of gas, and set fire to the phosphorus by means of a taper. Dip the cup into the jar immediately, and a splendid light will be produced. This forms one of the most brilliant experiments in chemistry. The heat often cracks the jar; and as there is no sure way of preventing this, we recommend the use of the common preserve or sweetmeat bottle, as being of little cost in case of breakage. Fig. 37 shows the method of this experiment.

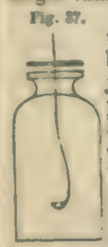

Fig. 37.

Experiment 13.—Put a small piece of sulphur into another holder, first lighting it, by heating the cup in the flame of a candle; introduce it into a jar of oxygen, and a fine blue light will be given out.

The two last experiments afford instances of the production of acids by burning the two substances in oxygen. These acids may easily be detected by tasting the water which is left on the sides of the glass whilst making the gas; this absorbs the fumes, and will be found strongly acid. The name of oxygen is, in fact, derived from two Greek words—"oxus," acid, and "gennao," to produce; the early chemists imagining that it was the sole acid-producer. The acids we refer to as produced above, are the phosphoric and sulphurous.

A distinction is made between acids produced by combinations of oxygen, and those produced by other substances. Sulphuric, nitric, and many other acids, depend for their qualities on the union of oxygen gas with other substances. The hydrochloric and other acids, however, have no oxygen in their composition; and hence it is proved, that oxygen is not the only element on which the production of acids depends. Its importance, in this respect, is of the highest kind. Of this, however, we shall have to speak more fully hereafter.

Oxides, as we have frequently mentioned, are combinations of oxygen with a metallic substance, by which both alkalies and earths are also produced. These distinctions, which have existed from the earliest days of chemical science, have a great convenience, as they classify the oxides according to their special characters. Thus, if oxide of iron, potass, soda, baryta, magnesia, lime, &c., were spoken of simply as oxides, their special characteristics and qualities would not be so evidently pointed out. Nevertheless, it is a rare case to find the earths in a state of absolute freedom from those substances to which the term is most usually applied; for, as in the case of clay, lime, &c., oxide of iron is generally present; and, indeed, the only source of all our metals is from rocks and sands, to which the term "earths" is usually applied instead of that of oxides.

There are also numerous instances in which an oxide may, by an increase of oxygen, be converted into a substance having acid properties: or, perhaps, we may put the question in another form, and state, that some substances will combine in such proportions with oxygen as to form both oxides and acids. The following may be selected as instances of these combinations:—Iron forms oxides, and also an acid—the ferric—when combined with variable proportions of oxygen; the same occurs with the metals arsenic, chromium, &c. Even with chlorine an acid is formed by oxygen;—hence the chloric and perchloric acids. But into these, and similar combinations, we shall have to make an extended examination.

Confining our attention to the production of ordinary metallic oxides, we may observe, that a vast variety is found in their appearance and general characteristics. Some metals, such as gold, silver, and platina, have very little attraction for oxygen; hence they may be exposed to atmospheric and aqueous influence, and yet remain unchanged for centuries. On the other hand, the metals potassium, sodium, &c., have so powerful affinity for it, as to abstract it from almost any of its compounds; as may be seen by the following experiment.

Experiment 14.—Throw a small piece of potassium on to some water. The liquid will be rapidly decomposed; and so violent will be the action, that a large amount of light and heat is liberated. The result is the production of potass, the alkali, or oxide of potassium, which will be dissolved in the water.

Between potassium and gold, the affinities of the metals for oxygen have a very extensive gradation; and yet such is modified by circumstances. Thus, not only are air and moisture favourable to the production of oxide; but heat and electricity have a very powerful effect, although that of the second force is generally subsidiary to, or derived from, that of heat. Hence, the process of oxidation is either slow or rapid, according to the circumstances in which the oxidising body is placed. The following experiments will fully illustrate this fact.

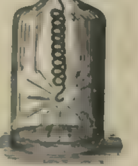
Experiment 15.—Hang a piece of polished and thin watch-spring in a jar containing some strong sulphuric acid. The metal must not touch the acid, and the vessel must be tightly corked. The polish will remain on the metal for almost any length of time, because the acid, by absorbing the moisture of the air in the vessel, prevents the formation of an oxide on its surface.

Experiment 16.—Expose the same piece of spring to air and moisture by placing it in a damp place. In the course of a day or two, its surface will become covered with oxide, owing to the oxidising action of air and moisture together.

Experiment 17.—Heat a piece of polished iron or steel in the flame of a spirit-lamp. Its surface will become rapidly covered with rich colours, owing to the formation of various oxides.

Experiment 18.—To one end of a piece of steel spring, or twisted steel wire, as thin as possible, and about ten inches long, tie tightly a piece of wick about an inch long, taken from the inside of a composite candle or a common taper. Pass the other end of the spring through a bung or cork, which will form a holder. On lighting the taper and dipping it into a jar of oxygen, the steel will catch fire, burning most brilliantly, and filling the interior of the jar with a red powder. Now here we have the rapid production of the oxide, which is caused by the influence of heat in promoting the chemical action of the pure gas on the metal. But the rapidity of this is exceeded in that which takes place when a powerful charge from a Leyden jar is sent through a fine steel or brass wire. By that means the metal is *instantaneously* converted into an oxide.

Fig. 38.



The reader will notice, by the last few experiments, how much chemical action is modified by extraneous circumstances. In fact, we have a double object in introducing these experiments here. One being to show the modifications which chemical action sustains in respect to oxidation; and the other, to introduce to the notice of the student, the necessity which always exists for the exercise of a comprehensive view when we attempt to explain or predicate the result of chemical affinities. The metal zinc also illustrates the varying rapidity and effects of oxidation; for if it be exposed to air and moisture, a superficial coat of oxide will form, which will protect the mass of the metal from further action; whilst if the same metal be burned in a jar of oxygen, or thrown into a ladle containing melted nitre, its oxidation is most rapid, and dense fumes of the oxide are given off from its surface. Even if some melted zinc be cast into a fire, its combustion will be very vivid, and the oxide will be produced in abundance, being attended by the production of a brilliant blue flame.

---

* See *ante*, p. 304; Fig. 10.

The process of combustion generally results in the production of an acid, when carbonaceous or organic matter is present. Thus, in experiment 11, in which charcoal was burned in oxygen gas, the resulting product would be carbonic acid; and, in most cases, it matters not whether the combination takes place rapidly or otherwise. Thus the act of breathing, or of inspiring air into the lungs, is attended by the combustion of carbon in the blood of the individual, as presented by the surface of the lung to the oxygen of the inspired air. In this instance, a very slow but complete combustion results, and carbonic acid is afforded. The act of breathing, and the rapid combustion of fuel, may be taken as extreme instances of the kind; but between these a gradation exists, in which the production of heat and carbonic acid is afforded. Thus, when the atmosphere has access to substances containing carbon of the fatty or oily kind, and in contact with fibrous matter, a slow combustion progresses. If circumstances are favourable, the rate of this combustion rapidly increases; and, eventually, spontaneous combustion ensues. To this we owe the frequent destruction of buildings in which hemp, jute, and cotton waste are stored. Even if these substances be in a damp state, the same result will occur. During fermentation or germination, the changes produced are of a similar nature to those we have mentioned. Oxidation, in fact, proceeds; and, as is well known, such is always, in these instances, attended with the production of heat. The heat set free at the dung-heap, and in the processes of malting, are cases which illustrate these observations.

We have previously remarked, that all sources of artificial heat depend on the presence of oxygen as necessary to combustion. Almost every material employed by man for the production of heat, contains carbon in some form or other; and, according to the rapidity with which the oxygen in the air is caused to unite therewith, so the intensity of combustion is increased. This is effected in the stove, fire-place, and steam-engine furnace, by means of chimnies which produce a strong draught, and so cause a rapid flow of oxygen with the air through the fire-bars. In the locomotive engine, the combustion of fuel is rapidly effected by means of the blast-pipe of the cylinder which conveys the waste steam into the funnel. In the iron smelting furnace, and in other metallurgical processes, intense heat is produced by an engine, &c.; and the domestic bellows is a similar class of article, and used for the same purpose. In some phases of combustion, oxygen is supplied in a latent state. This occurs in gunpowder, in which the nitre is the source of oxygen, and affords it in great quantities. In such cases, bodies can burn without access to the atmosphere; and, in most mixtures of the chlorates or nitrates with dry organic bodies, this readily takes place on heat being applied.

The general effect of oxygen in nature, is that of a life-giving principle. It breaks up the rocks, and converts the sterile land into a fruitful country. Through its action on the organic substances in plants, they bud forth into leaf, and produce the flower and seed. Every leaf is as a lung to a tree, and thereby plants are enabled to breathe and to exist. In animals, oxygen oxidises the carbon of the food, producing animal heat, as we have already shown; and thus its agency is so universal as to leave no object out of its influence.—It is desirable that the student should become fully acquainted with its general properties and character, as throughout the following pages we shall have frequently to refer thereto. A careful repetition of the experiments we have named, will therefore prove of great use in this respect.

OZONE.

It was discovered some years ago, by M. Schonbein, that a peculiar result was produced when water was decomposed by means of voltaic electricity; and many were the guesses of chemists and others as to its causes. When a little dilute sulphuric acid is submitted to the action of a voltaic battery having two platina poles, a strong odour is soon produced, which has almost exactly the same smell as may be noticed when a few sticks of phosphorus are put into a glass bottle with some water.

Ozone—so called from its smell—is thus produced, and it has lately been considered as having an individual character and properties. It has, however, never been detected in such a form as to be submitted to any process except that of testing for its presence; and hence, although we are acquainted with some of its chemical effects, those of a physical character have yet to be discovered. It has decided bleaching properties; promotes putrefaction, and produces chemical decomposition. It is considered to be either a product of oxygen, the active principle of oxygen, or a new element.

The tests for the presence of ozone are salts of manganese, and the iodide of potassium. The best mode of detecting its presence, is that of employing white blotting or filtering paper, which has been moistened with a solution of iodide of potassium and starch, such as arrow-root, &c. If free ozone be present, the iodide is at once decomposed, the iodine is set free, and the starch becomes of a blue colour.

Although but little is known of ozone, it has considerable interest attached to it, in a sanitary point of view. It has been found, that air charged with animal matter never exhibits ozone in a free state; and that, generally speaking, the more there is of free ozone in an atmosphere, the healthier it is for the purpose of animal existence. Any one who has once smelt ozone, will readily detect its presence in the air which chiefly occurs during clear and frosty weather. Occasionally, it may be noticed before the change of weather, and in small patches or districts of country. As we speak of our own experience only, it may happen that many of our readers may not be so sensitive to its action on the nasal organs. Such, however, may easily resort to the starch-paper test.

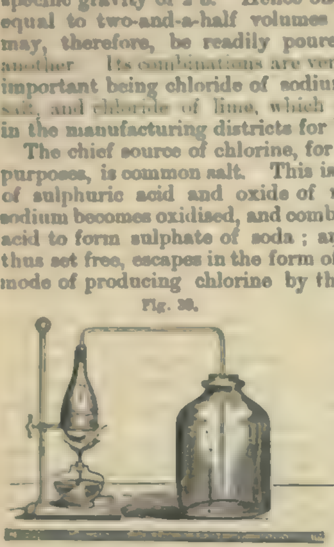
Some very interesting experiments were made, some time ago, in reference to the presence of free ozone. Whilst it could be instantly detected by the manganese test, in the middle of an open thoroughfare; the sides of the road next to houses, and courts and narrow openings running therefrom, indicated an absence of ozone. This fact shows that some intimate relationship must exist between the functions and products of animal vitality, and the presence of the substance. At the present time, the amount of free ozone present in the air, is registered at most meteorological observatories; and the reports of medical officers also embrace the same subject. The indications are measured by the relative discoloration which the iodide and starch paper undergo; a set of test-papers, of graduated tints, being kept as a standard of comparison. This subject will be again referred to, under the head of Meteorology.

CHLORINE.

For a long time, it was considered by chemists, that hydrochloric or muriatic acid had oxygen as one of its constituents; and until Sir Humphry Davy discovered chlorine to be an elementary, and, indeed, for some time afterwards, that opinion was maintained. At the present day, however, chlorine is placed amongst the elementary bodies, and is one of the most active agents in its chemical relations, next to oxygen, with which we are acquainted.

Chlorine, in its pure and uncombined state, is a gas of a yellow-greenish colour. It has an exceedingly strong, and, to some persons, offensive smell. If inhaled, it causes asphyxia, and acts violently on the animal membranes in the throat and lungs. Its equivalent is 35·5; but for ordinary calculations, it is assumed, in round numbers, to be 36, and is much denser than air, having a specific gravity of 2·5. Hence one volume of chlorine is equal to two-and-a-half volumes in weight of air. It may, therefore, be readily poured from one vessel to another. Its combinations are very numerous; the most important being chloride of sodium, the common table salt, and chloride of lime, which is so extensively used in the manufacturing districts for bleaching purposes.

Fig. 39.



The chief source of chlorine, for commercial and other purposes, is common salt. This is decomposed by means of sulphuric acid and oxide of manganese, when the sodium becomes oxidised, and combines with the sulphuric acid to form sulphate of soda; and the chlorine being thus set free, escapes in the form of a gas. A convenient mode of producing chlorine by this or other means, is represented in the annexed cut. The materials are put into a Florence flask, fitted with a bent tube; the latter passing to the bottom of a clean jar, the neck of which should be loosely fitted with a cork. The flask is supported in position by means of a ring-stand; and a gentle heat is to be applied by means of a spirit-lamp. We should here observe, that as chlorine is rapidly absorbed by water, it cannot be collected in the pneumatic trough; and mercury must not be used instead of water, because it is readily acted on by the gas. We may here caution our readers that the inhalation of chlorine gas produces the most painful effects. An assistant left some bottles unlabelled, and being unaware that such were filled with chlorine, we had the misfortune to find the evil effects of inhaling a considerable quantity, which resulted in loss of voice, and other severe and unpleasant symptoms. Should any of our readers be similarly unfortunate, their remedy will consist in immediately swallowing some unboiled white of an egg, and applying to the nose a moderately strong solution of ammoniacal gas (liquid ammonia of the shops).

Of course, the materials for producing chlorine from common salt, &c., should be added together in their equivalent proportions, to obtain the proper amount of chlorine by their mutual decomposition; but as they are exceedingly cheap, this is a point of no great importance when the gas is employed for laboratory or private experiments. There are, however, more convenient modes of obtaining chlorine on the small scale than that we have mentioned; and to such we must now refer.

Hydrochloric acid, to which we have already referred in our former pages, is a compound of chlorine with hydrogen gas; and if we can separate these elements, of course we may obtain the chlorine or hydrogen free. To separate the former is an easy matter. Some oxide of manganese may be introduced into the flask, represented in Fig. 39; and then sufficient hydrochloric acid is to be added to moisten the powder. The two should be well mixed, otherwise the oxide of manganese may remain as a dry powder on the bottom of the flask; and when heat is applied, the acid may by chance run down, and, touching the heated portion of the flask, will fracture it. After thus forming a kind of paste, more acid is to be added until a cream-like mixture is produced. The bent tube is to be replaced, and a gentle heat may be applied to the flask, when the gas will be speedily produced. Care should be taken that the materials in the flask do not froth up and pass over into the jar receiving the gas. This may arise either from too great a heat being applied, or from the materials being too dry from a deficiency of acid. The heat may gradually be raised towards the close of the process. The chlorine thus produced, being heavier than the atmospheric air, will displace the latter from the glass vessel into which it is passing, and, except for special experiments, it will be pure enough. If it be received in wide-mouthed stoppered bottles, the neck should be slightly greased with tallow, and the glass stopper may be then put in its place, being at the same time turned once or twice in the neck, so as to ensure a good distribution of the grease. The bottles, as with all others containing gases, should be distinctly labelled to prevent mistakes; and thus any quantity of chlorine may be prepared, and kept for experiments. Chlorine is frequently required in the chemical laboratory. The student may try the following experiments, for the purpose of becoming acquainted with the properties of the gas.

Experiment 19.—Suspend a piece of cloth or paper, dyed with any vegetable colour, and in a moist state, or a flower previously drenched with water, in a jar of chlorine. The colour will be speedily discharged, owing to the bleaching powers of the gas.

Chlorine, as we have already remarked, is largely employed for the purposes of bleaching, and in some departments of calico-printing, for discharging colours. It is used in the form of chloride of lime, which is prepared by passing gaseous chlorine over freshly slaked lime. We shall have to refer more fully to the use of chloride of lime, when we treat of the applications of chemistry to arts and manufactures.

Experiment 20.—Make a strong solution of litmus or indigo in cold water, and pour this into a jar of chlorine gas. The chlorine will be rapidly absorbed, and the coloured liquid bleached.

Water or moisture is essential to the bleaching powers of chlorine; hence the *dry* gas does not bleach vegetable colours.

Experiment 21.—Throw a few pieces of fused chloride of calcium into a jar of chlorine, and leave them for some time, so that they may absorb all moisture. Into the dry gas introduce a piece of dry coloured cloth or paper, but no bleaching effects will result. Indeed, it is generally supposed that the bleaching effects of chlorine really result from the decomposition of water. The chlorine seizes the hydrogen of the water, and sets the oxygen free; and this acting in a latent state on the colouring matter present, at once bleaches it. In former times, before the discovery of chlorine, all cotton and linen goods were bleached by exposing them to the action of the sun, air, and moisture—a process, however, which was exceedingly slow and tedious.

Chlorine has a limited power of supporting combustion, as may be seen by trying the following experiment.

Experiment 22.—From a wire fixed on a cork, suspend a small piece of taper; and having ignited it, immerse it in a jar of chlorine. The length of the flame will be increased, and it will become dull and smoky, depositing a sooty matter on the inside of the vessel.

The gas has a very great attraction for some substances; and the production of light and heat frequently results from some of its combinations as they take place.

Experiment 23.—Introduce some Dutch foil into a jar of chlorine. The leaves will immediately catch fire, and a chloride of copper will be produced. Antimony, &c., in a state of fine powder, which should previously be warmed, will also ignite in a jar of chlorine, and produce a chloride of antimony.

Chlorine forms chlorides when combined with metals, &c.; of which we shall speak when treating on those bodies. It also combines with nitrogen, iodine, and bromine, forming compounds therewith, which will be fully described hereafter. With hydrogen it forms the well-known hydrochloric acid, also called the "muriatic" and "marine" acid, in the old chemical works.

Hydrochloric acid, in its pure state, is a gas composed of one equivalent of chlorine, united with one of hydrogen. Its equivalent is therefore 36·5; symbol, H, Cl. In commerce, and in the laboratory, this gas is employed as a liquid acid, being in combination with water. In this state, and having a specific gravity of 1·21, it is composed of the gas united with six equivalents of water; its symbol is H, Cl, 6HO; the equivalent being 90·5.

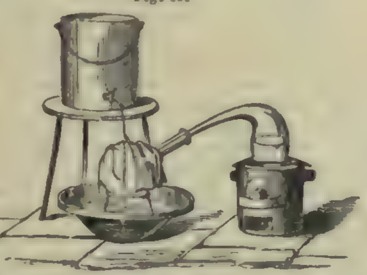
Hydrochloric acid gas is readily procured from common salt, by adding dilute sulphuric acid to that substance in a retort. A gentle heat is to be applied, and the gas will be given off in abundance. Owing to its great attraction for water, it seizes the aqueous vapour present in the air, producing white fumes. It may be collected in bottles, in a similar manner to chlorine. On pouring cold water, or putting a piece of ice into a jar of the gas, it is rapidly absorbed, and considerable heat is evolved. Its presence may readily be detected by means of a rod dipped in liquid ammonia, when dense white fumes of sal-ammoniac are afforded. Hence, if a bottle of the gas be taken into a stable, the presence of ammonia will be instantly detected by the production of the fumes named.

Hydrochloric acid is produced on a large scale during the manufacture of soda. The common salt is decomposed by means of sulphuric acid, and the gas given off is condensed by water.

For laboratory use, the acid may be prepared as follows:—

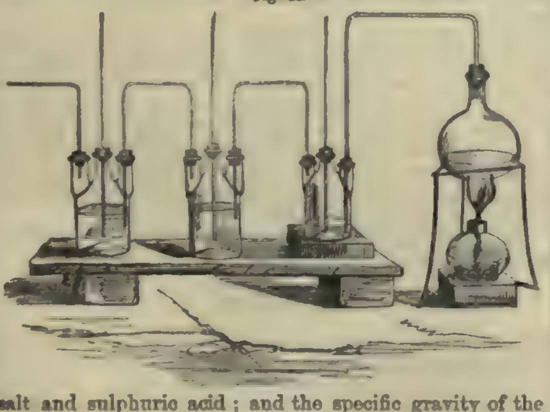
Experiment 24.—Introduce into a glass or earthen retort some common salt and water, and add to this nearly as much sulphuric acid. Apply heat by means of a spirit-lamp or furnace, and receive the gas in a Florence flask or globular receiver containing cold water, the stem of the retort just touching the surface of the water. Keep the outside of the receiver as cold as possible, by covering it with a cloth on which water is kept dropping. The gas will be rapidly absorbed, and the aqueous acid produced. The acid will be sufficiently strong for all laboratory purposes. The reason the stem of the retort is not placed *below* the surface of the water in the receiver, is, that the absorption of the gas takes place so rapidly that the liquid would rush into the retort, and perhaps break it. The following cut shows a convenient mode of carrying out this plan.

Fig. 40.

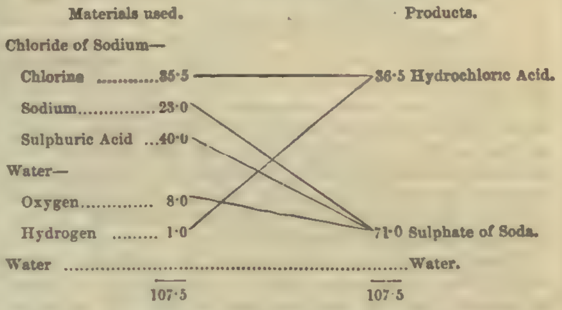


A different arrangement is used when a large quantity of the gas is prepared. Bottles with two or three necks and connecting pipes are used. These are made of glass or earthenware, and are of large size. The gas is produced, in globular vessels of iron lined with lead, from salt and sulphuric acid; and the specific gravity of the acid so prepared, will be greater than that produced by the process we last described, because the condensation of the gas is more perfect, a larger portion being dissolved in the water placed in the receiving vessels. The preceding engraving illustrates this process.

Fig. 41.



The chemical changes produced during the manufacture of hydrochloric acid may be thus represented:—



In the above diagram, the proportion of water forming crystallised sulphate of soda is omitted, so as to avoid confusion of figures to the uninitiated student. We have only, therefore, represented absolutely dry sulphate of soda as the product. We therefore notice, that 58½ parts of common salt should afford 36½ parts of hydrochloric acid gas, which, during absorption, combines with at least 54 parts of water, to form the strong aqueous acid.

We have hitherto simply spoken of acids in a very general manner; and as hydrochloric acid is the first to which we have drawn special attention, we shall avail ourselves of the opportunity of more particularly referring to the general characteristics of these substances.

Generally speaking, the test for the presence of a free acid, is a sour taste when it is applied to the palate; the power of converting vegetable colours of blue tint to a reddish hue, and of forming salts or salt-like bodies. In some cases, the acid, or sour taste, is scarcely distinguishable: the prussic acid is an instance of the kind. Carbonic acid has but feeble and transitory effects on vegetable blues; but, in every case, an acid has the power of forming a salt when combined with a base; or, what is equivalent thereto, a compound is formed, which answers in its analogies to a salt. The following experiment with hydrochloric acid, will serve the double purpose of illustrating the general properties of acids, and the special characteristics of hydrochloric acid.

Experiment 25.—Make a solution of litmus by boiling some of that substance in water. After the liquid has obtained a deep blue or purple colour, add a very small portion of liquid ammonia, to remove any free acid; and then dip into the solution some pieces of white blotting or filtering paper. They will, of course, become of a blue colour, and will produce the general test employed by chemists for detecting the presence of a free acid. Drop some hydrochloric acid on the blue paper, and it will at once become of a red tint. If such paper be brought into contact with almost any acid, the same effect will be produced. In the case of carbonic acid, the effect is slight, because that has but feeble acid properties, and is readily removed by evaporation. Most of the blue colours of vegetables are thus affected; but indigo is an exception. The acids found in fruit, &c., generally called organic—such as the acetic, tartaric, oxalic, citric, &c.—are also detected by their producing a red tint when tested by infusions of litmus or red cabbage. We may here suggest a very interesting occupation in connection with plants, fruit, &c. It is, that the student should supply himself with blue litmus paper, and the same coloured red, by means of a little weak vinegar. By the blue paper he may discover the presence of acid in vegetable juices; and, by the red. the alkaline character of others may also be detected.

We may, after this digression, return to consider some of the properties of hydrochloric acid. With potassium, sodium, and ammonia, it respectively forms the chlorides of those substances, the two best known being the common salt and sal-ammoniac. It forms chlorides with metallic bases, uniting with them in various proportions—in that of one equivalent, as in chloride of silver, or in three, as in the terchloride of gold. The proportions existing between that of chlorine to bases is similarly distinguished to those of oxygen.* Generally speaking, the chlorides are soluble in water; but this property varies considerably: thus chloride of potassium dissolves readily; whilst the chlorides of mercury are almost, or comparatively insoluble. The affinities of chlorine for its bases are generally very active, and second only to those of oxygen, which, therefore, mostly has the power of seizing the bases of the chlorides, and of setting the chlorine free, or leaving it to combine with some other substance. The various combinations of chlorine, forming chlorides, will be described in connection with their different bases.

Chlorine combines with oxygen to produce various compounds; such as enchlorine, chlorous, hypochlorous, hypochloric, chloric, and perchloric acids. Of these, the chloric is the most important in all respects; for it gives rise to the chlorates, some of which are largely employed for the manufacture of lucifer-matches, &c. Hypochloric acid is prepared by adding sulphuric acid to chlorate of potass; but as this product is dangerously explosive, only very small quantities (grains) of the ingredients should be employed; and then only in an open vessel. The acid is liberated in the form of a gas, which may be condensed by frigorific mixtures. We would warn our readers against attempting to use a test-tube for the purpose, having nearly lost the use of one eye whilst doing so ourselves.

Chloric acid is a compound of one equivalent of chlorine with five of oxygen; symbol—$Cl\,O_5$; equivalent = 75·5. It may be obtained by adding sulphuric acid to a solution of chlorate of baryta, which, like the chlorate of potash, is obtained by passing gaseous chlorine through a solution of the earth; the chlorate of potash being produced by passing the gas through a solution of that alkali. We have to speak more fully of these salts hereafter, both as to their manufacture and uses.

Perchloric acid is a combination of seven equivalents of oxygen with one of chlorine; and as it is of no great interest, we shall omit details of its manufacture.

A compound acid is produced by adding together two parts, in volume, of hydrochloric acid, with one of nitric acid, both in as high a degree of concentration as possible. The mixture is called *aqua regia*, and it is much used by metallurgists for the solution of gold. Platina and other metals are soluble in it; and it produces their chlorides, which will be duly noticed hereafter.

IODINE.

THE discovery of iodine at first arose from an accidental circumstance, and is of comparatively recent occurrence. It was noticed that the pans in which barilla had been manufactured, became very much corroded in some parts; and, eventually, chemical research accounted for the fact by showing the presence of a substance previously unknown as a distinct body. Iodine, as usually met with in commerce, is a substance in small metal-like scales, of a dark colour. On being heated, it affords a vapour of a rich purple tint—hence its name. The vapour condenses, and re-forms scaly particles. The symbol is I, and the equivalent = 127. As has been already named, its combinations are termed iodides.

For many years the uses of iodine were entirely confined to medical purposes, and especially as an antidote or preventative for the troublesome disease called *goitre*. Its presence in cod-liver oil has, doubtless, been highly beneficial in scrofulous and phthisical complaints. It is often administered in the form of its combination with oxygen and potass, as the hydriodate of potass. Since the discovery of photography, it has become of great importance; and, as such, is now a considerable product of the operative chemist's manufactures. The chief of its combinations, employed in photography, are the iodides of potassium, ammonium, and cadmium. Most of the compounds of iodine are readily decomposed by chlorine, to which it ranks next in importance with respect to its chemical characters and affinities. The following experiments will give a general idea of some of its leading properties.

Experiment 26.—Put a small quantity of commercial iodine into a clean Florence flask, and apply a gentle heat by means of the spirit-lamp. The iodine will rise as a purple vapour, and will eventually condense on the cold sides or neck of the flask, in minute, dark-coloured crystals or plates.

Experiment 27.—Dissolve a little iodide of potassium in *cold* water, and add a small portion of starch. No change will take place; but, on pouring into the solution a little sulphuric acid, the iodine will be set free, and a dark-blue colour will be observed. Starch is generally used as a test for the presence of free iodine; but the effects of the test are not evident if the solution be hot. Similarly, the presence of starch in vegetable matter may be detected by means of iodine.

Iodine combines readily with some of the metals, either in its state of vapour, or when in combination with other bodies, as the following experiment will show.

Experiment 28.—Expose a plate of silver to the vapour of iodine; a yellow iodide of silver will soon be formed on its surface. In this manner iodine was extensively employed on silver plates for the Daguerreotype process, which was, at one time, the chief method of obtaining pictures by the action of light.

Experiment 29.—Add a little of the solution of iodide of potassium to one of the bichloride of mercury in water; a yellow precipitate of iodide of mercury will be produced. On the addition of more of the iodide of potassium, the yellow colour will change to a deep red; and on a still further addition, the precipitate will be entirely redissolved; the iodide of mercury being soluble in an excess of that of the iodide of potassium.

Iodine is but slightly soluble in water; but is readily dissolved by alcohol, which thus forms what is termed the tincture of iodine, much used in medicine. It unites with chlorine, bromine, nitrogen, and hydrogen; forming with the latter an acid—the hydriodic. With nitrogen, it produces an explosive compound, which is analogous to the chloride of nitrogen, of which we shall treat on hereafter. It unites also with sulphur and phosphorus, producing light and heat at the moment of its combination with the latter substance: an explosion is afforded; hence great care is required when these substances are brought into contact. Iodine may readily be set free from its combinations by means of chlorine, as is illustrated in the following experiment.

Experiment 30.—Dissolve some iodide of potassium in water, and add a little starch or arrowroot. Pour into this a solution of chlorine in water.† The iodine will be at once set free, and the starch be converted to a blue colour.

Hydriodic acid is a combination of one equivalent each of iodine and hydrogen; symbol, IH; equivalent, 128. It is prepared from iodide of phosphorus. Iodine unites with oxygen in three forms; the most important of which is iodic acid, which is composed of one equivalent of iodine to five of oxygen; symbol, IO_5; equivalent, 167. It forms iodates with bases, which are analogous to the chlorates and bromates; they have no special application in the arts and manufactures.

The remaining combinations of iodine will be noticed in connection with their bases.

BROMINE.

BROMINE, like iodine, is a product of kelp, and is found in sea-water, in the salt called bromide of sodium, &c. It is a dense orange-coloured liquid; has an offensive smell—hence its name; and is corrosive in its action on animal substances. It is soluble in water and alcohol in almost any proportion; and being highly volatile, must be kept in well-stoppered bottles. Its symbol is Br, and the equivalent=80·0.

---

* See *ante*, p. 314.

† See *ante*, p. 316.

Combined with metals and other bases, it forms the substances called bromides. Like iodine, its chief use is in connection with photography, in which it has been employed in the state of vapour, to increase the sensitiveness of the iodide of silver on Daguerreotype plates; and, in the form of bromide of potassium, it is considerably used in paper-printing processes.

It is prepared from hydrobromic acid, which is a combination of hydrogen and bromine; symbol, HBr; equivalent, 81. This acid is analogous in its constitution to the hydrochloric, hydriodic, and hydrofluoric. Its preparation is somewhat difficult; bromide of phosphorus being decomposed by means of water, when phosphoric acid and the hydrobromic are produced.

Bromic acid is a compound of bromine with oxygen, in the proportion of one equivalent of the former to five of the latter. Its symbol is Br, O_5; equivalent=120. We shall describe other combinations of bromine under the head of their bases.

FLUORINE.

Fluorine is a substance which has but little commercial value, and is never met with in a free state. It is obtained from Fluor or Derbyshire spar. Its symbol is Fl, and the equivalent=18·9. Its most known combination is that of hydrofluoric acid, in which it is combined with hydrogen.

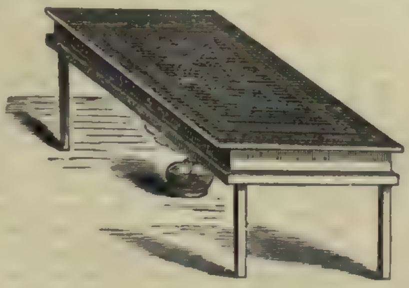
Hydrofluoric acid may be readily obtained by heating some coarsely pounded fluor spar, together with strong sulphuric acid, in a leaden vessel. A glass one cannot be used, because the acid acts powerfully on that substance. The fumes of the acid and the liquid should be carefully avoided, as they produce the most painful wounds if they come in contact with the skin.

Hydrofluoric acid, besides its occasional use in the laboratory, is much employed for etching glass; and the method of conducting this process may be seen in the following experiment.

Experiment 31.—Make a tray of lead by bending up the sides of a sheet of that metal so as to form a rim on all sides. Support this tray on a stand, and throw inside it some coarsely pounded fluor spar, to which some strong sulphuric acid may be added. Cover a glass plate with beeswax; and on this, when cold, make any sketch by means of a needle-point, so as to expose the glass surface. Then place the plate, with the sketched part face downwards, over the mixture of fluor spar and acid last mentioned, so that its edges may rest on the edges of the tray. Apply a gentle heat by means of a spirit-lamp, when the hydrofluoric acid will rise in vapour and attack the exposed surface of the glass. By these means such portions will be completely etched out; and on the wax being removed, the design will appear beautifully traced on the glass surface.

The best wax for covering the glass is that obtained by melting wax candle-ends. It should be run over both sides of the glass, lest the vapour of the acid might attack both sides. Some pretty effects may be produced by first sketching the design, with a soft black-lead pencil, on paper. This drawing is easily transferred to the wax surface by pressing the pencilled paper thereon. This will form a guide for the subsequent tracing by the needle-point. By such means the figures are produced on the ornamental sheets of glass so much used for sashes, in place of Venetian blinds. The preceding figure illustrates the mode of carrying out the experiment we have been describing.

Fig. 42.



HYDROGEN.

Next to oxygen, hydrogen stands of the greatest importance in the list of elements. By the combination of the two, we have the water of the ocean, of our rivers, &c. Combined with carbon, hydrogen enters into the composition of most vegetable and animal substances: as carburetted hydrogen, a product from coals, it is extensively used as fuel and for illuminating purposes; and the same results are obtained from vegetable and animal oils, through its presence in them. Its other numerous compounds will be noticed as we proceed.

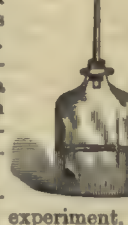
Hydrogen is the lightest known body in nature, its specific gravity being 0·069; that of air being 1·000; it therefore weighs but a little over one-fifteenth part of its bulk of atmospheric air. For this reason it has been employed to fill balloons, both in its pure and compound states.

Hydrogen may be procured, in various shades of purity, from water, coal, oils, &c. The following experiments will afford instances of the kind.

Experiment 32.—Pour some dilute sulphuric acid on some iron nails contained in a saucer or evaporating dish. Large bubbles of gas will speedily arise; and if a lighted match be brought near them, they will at once ignite.

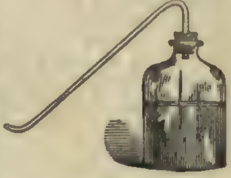
Experiment 33.—Put a few iron nails, or some shavings of zinc, into a glass bottle, and fit into its neck a cork containing a glass tube, one of the edges of which has been drawn to a jet. Add some dilute sulphuric acid to the metal, and fit in the tube. Gas will be given off; but this should be allowed to escape, because, being mixed with air, it would explode, and perhaps burst the bottle if the gas were ignited. After sufficient time has elapsed to remove all the air from the bottle, apply a light to the jet, when the gas will burn with a yellowish-coloured flame. The annexed figure shows the kind of bottle required for this experiment.

Fig. 43.



When a considerable quantity of hydrogen is required for the purposes of experiment, a bottle with a bent tube attached to it, such as is represented in the annexed engraving, may be employed; and the gas is to be collected by the pneumatic trough, in a similar manner to that mentioned for oxygen. It must, however, be borne in mind, that hydrogen is so much lighter than air, that it will at once escape if the vessel containing it be held mouth upwards. The following experiments, illustrating the levity of the gas, may impress the fact on the memory of the student.

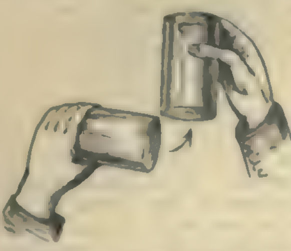
Fig. 44.



Experiment 34.—Hold a glass vessel with its mouth over the jet of the bottle described in Experiment 33. The gas will rise into the vessel, and so expel the air. This may easily be proved to have taken place by applying a light to the mouth of the vessel, when the gas will at once catch fire.

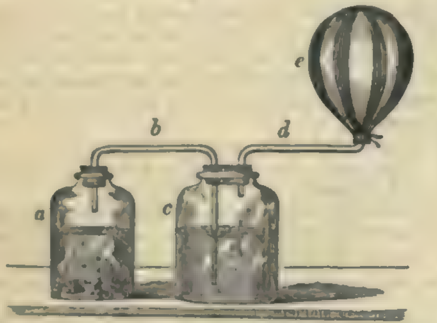
Experiment 35.—Fill a glass vessel, as in the last experiment, with hydrogen, and then bring near to it another vessel, also with its mouth downwards. Incline that already filled with gas beneath the mouth of that filled with air, and gradually allow the gas to pass from one vessel to the other, in the way illustrated in the following engraving (Fig. 45). That the gas is really transferred by these means will be at once proved by applying a light to each vessel, when that which has previously contained air will at once be seen to contain hydrogen by its contents being ignited.

Fig. 45.



The light specific gravity of hydrogen may be pleasingly illustrated by means of small balloons made of gold-beater's skin. These, if filled with hydrogen, will, on being liberated, at once ascend in the air. As the material of which they are composed is, however, easily acted on by the acid employed to generate the hydrogen, the following arrangement is recommended to purify the gas before it is allowed to pass into the balloon.

Fig. 46



In the above engraving, *a* represents the vessel in which the hydrogen is generated; *b* is a bent tube fitted into the neck of *a*, and running nearly to the bottom of the vessel *c*, which is to be three-parts filled with water. This tube, and *d*, which rises out of the neck of the vessel *c*, and to which the balloon, *e*, is attached, are to be fitted air-tight in the purifier by means of a cork. The gas will thus pass from *a* through *b*, into the vessel containing the water. It will here be cleansed from acid, and, rising in bubbles to the surface, will escape by *d*, which only just passes into its neck. The balloon, when filled, is to be tied at its neck, to prevent the escape of the hydrogen. In balloons of large size coal gas is always employed; which, although much heavier than pure hydrogen, answers well for the purpose.

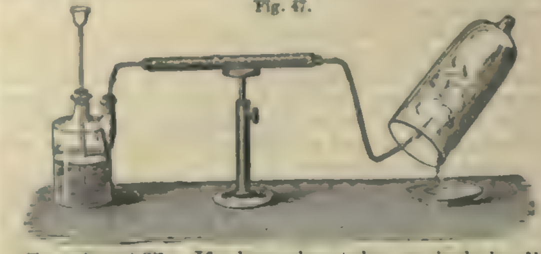
Hydrogen may be obtained from water by other means than those we have suggested. If steam from water be passed through an iron tube, heated to redness, it will be decomposed, and its oxygen uniting with the iron to form an oxide, the hydrogen may be collected in the usual way at the pneumatic trough, by fitting a bent pewter tube to the end of the iron one.

Hydrogen is obtained in the purest state by decomposing water by means of voltaic electricity. The best mode of doing this has already been described in the section of Electricity.*

The most important compound of hydrogen is the well-known liquid water, which, in its purest state, consists of eight parts of oxygen, united with one of hydrogen by weight. The gases unite, by bulk, in the proportion of two volumes of hydrogen to one of oxygen. The symbol of water is HO, and its equivalent = 9. The following experiments illustrate the production of water by the union of its elementary constituents.

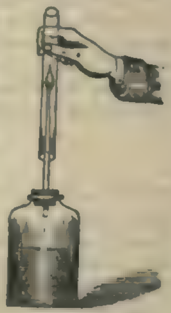
Experiment 36.—Hold a cold glass vessel over the jet of the bottle described in Experiment 33, whilst the gas is burning. The vessel will soon become coated with dew, owing to water being produced by the combustion of the hydrogen in contact with the oxygen contained in the surrounding air. Another mode of conducting the experiment, is that illustrated in the following engraving, in which the gas is first conducted through a tube containing chloride of calcium, to free it from moisture.

Fig. 47.



Experiment 37.—If a long glass tube, an inch in diameter, be held so as to inclose the jet of the hydrogen bottle in the way shown in the annexed engraving, some singular musical sounds are produced. The pitch of these sounds depends on the diameter of the tube; the bass being produced by those of a large, and the shriller tones by those of a small diameter. Any intermediate sound can be produced; and this plan has been proposed as a means of forming a new kind of musical instrument. This effect results from a series of vibrations being produced,† which arise from numerous explosions caused by the combination of the hydrogen with the oxygen of the acid. Of this, the next experiment gives a better illustration.

Fig. 48.



Experiment 38.—Into a strong glass vessel, introduce, by means of the pneumatic trough, one part of oxygen and two parts of hydrogen, by volume. For this purpose, an ordinary soda-water bottle answers exceedingly well. Apply a lighted taper to the mixture, when an explosion will instantly take place. After the expansion consequent thereon has ceased, it will be seen that the gases have lost their gaseous condition, and the result will be found as pure water in the form of vapour, or condensed in dew-like drops on the side of the vessel. This is simply a more rapid way of producing water by the combination of its elements, than those we have described in the preceding experiments.

The oxy-hydrogen blowpipe is a means of producing the most intense heat by the combustion, through a proper jet, of a mixture of oxygen and hydrogen gases, in the same proportion as that in which they form water. For the sake of safety, the two gases are kept in separate reservoirs, and are not allowed to mix, except at nearly the point of their combustion. The application of this arrangement to the purposes of illumination, and to optical instruments, has been already fully explained under the section on Light;‡ and a drawing of the most improved form of jet which can be used for the purpose, has also been given. We may here add, however, that by means of the oxy-hydrogen jet, the otherwise most infusible substances may be rendered liquid—such as porcelain, platina, wrought iron, &c.

The general uses of water are too well known to require any lengthened remarks on our part. In the laboratory it is employed as a general solvent, and pure water is therefore an object of constant requirement. This is obtained by the distillation of river or spring water in glass retorts, when great purity, as in toxicological analyses, is desired. In ordinary cases, the steam proceeding from any metal vessel, as a kettle, &c., may be condensed by means of a pewter tube, which should be kept cool by damp cloths. In most large towns, distilled water can be readily obtained; and, in many cases, ordinary rain or river water may be employed. Water of the ocean always contains many soluble matters, such as chloride of sodium, chloride of magnesium, iodide and bromide of potassium, &c. This on evaporation, forms clouds; and these again, being condensed as rain, fall in fertilising showers, to eventually form rivers which run to the ocean. Rain-water, when collected at a distance from towns, is generally almost pure; but near those places it becomes contaminated by matters suspended in the air—such as nitric acid, sulphur, and ammonia. After rain-water has percolated through strata of earth, and is again seen as rain or spring water, it will have dissolved both organic and inorganic matter, and this to a very large extent. The inorganic matter may vary from 2 to 100 grains per imperial gallon; and that of an organic nature differs similarly in quantity. The purest water, in a chemical sense, supplied in Great Britain, is that obtained from Loch Katrine, in Scotland; which is conveyed to Glasgow, a distance of forty miles; whilst the wells in the neighbourhood of London, are, generally speaking, highly contaminated with all kinds of impurity. The following table shows an analysis of various sources of the water-supply of London, &c.; and has been extracted from the report of the medical officer of the city of London, to the Common Council.

---

* See *ante*, p. 194; Fig. 54.

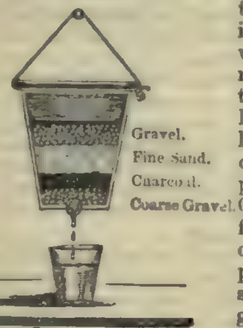
‡ *Ante*, p. 62.

Table of Impurities in Water-Supply from various sources.

—	Total per gallon.	Organic per gallon.
	gr. or deg.	gr. or deg
Distilled water	0·0	0·0
Loch Katrine water, new supply to Glasgow (March)	2·35	·605
Manchester water supply (March)	3·33	·680
Portland-road well	58·03	7·84
Chelsea (Thames Water)	19·72	1·76
Southwark ,, ,,	21 96	2·40
Lambeth ,, ,,	20·44	2·64
West Middlesex ,, ,,	21·76	2·40
Grand Junction ,, ,,	21·36	1·80
East London (River Lea)	21·03	1·36
New River	19·72	1·72
Kent (from the Chalk strata)	25·16	2·64

Nearly all the water supplied to London, is either obtained from the New River, which rises in Hertfordshire, or from the Thames near Hampton Court. Being now always filtered before it is supplied for domestic use, it never contains any notable quantity of suspended matter. In many districts, however, turf, sand, &c., are found in considerable quantities: it is necessary to filter the water before use; and we shall describe an arrangement that may be employed for the purpose—an engraving of which is subjoined.

Fig. 49



To construct one of these simple and effective filters, the common garden-pot is the only necessary vessel, into the bottom hole of which a piece of sponge or rag may be placed. On this, inside the pot, a layer of coarse gravel is laid; over this, one of charcoal, broken into small pieces, but not powdered. On the charcoal a layer of fine sand is placed; and, over it, one of gravel. A piece of calico or flannel should be placed over the gravel, so that when water is poured thereon, it may not run in channels through the different substances. A string may be tied round the rim of the pot, and the arrangement may thus be hung from a nail. Besides the filtering effect, the charcoal has the power of retaining offensive animal and vegetable matter; so that the results are both mechanical and chemical in the removal of the impurities. The preceding engraving will fully illustrate the method of making one of these filters; and shows the succession and position of each of the substances employed.

We may here make a few observations on the impurities of water, as generally found in that supplied for domestic and other such purposes, so far as they affect sanitary and commercial matters. A table already given, states the proportions of organic and inorganic substances present in water from various sources; and the nature of these substances we may inquire into.

It is very essential, for culinary and manufacturing purposes, that water should be as free from lime and earthy matter as possible; and the presence of these is the cause of the hardness of some kinds of water. Lime itself is but sparingly soluble in water; but when the latter contains carbonic acid, then chalk or carbonate of lime is readily dissolved in considerable quantities, as the following experiment will prove.

Experiment 39.—Pour an ounce of lime-water—that is, water in which slaked lime has been dissolved—into a glass vessel, and add to it some common "soda-water," which contains a large amount of carbonic acid. A white precipitate of chalk is first formed; but eventually, the excess of carbonic acid present is so great, that the chalk so formed will be dissolved and held in solution.

If water thus impregnated with lime be afterwards boiled, the excess of carbonic acid will be driven off, and the chalk will be deposited in the vessel. Hence hard waters are mostly rendered softer by the process of boiling, their earthy matters being thus separated from them. It is owing to the presence of earths, &c., in water, that the tea-kettle becomes so constantly furred. The same result takes place, on a very large scale, in boilers used for steam-engines, and becomes a source of great annoyance and positive danger at times. The earthy matter settles on the bottom and sides of the boiler, and there produces a solid and stone-like mass. This prevents the passage of heat from the fire through the metal of the boiler to the water, and thus the iron occasionally becomes red-hot, when the earthy crust is thereby detached, allowing the water to touch the overheated surface. On this occurring, a sudden and rapid production of steam ensues, which, having no adequate means of escape, frequently causes dangerous explosions.

Hard water can be rendered soft by the addition of lime to it, provided its hardness arise from the presence of an excess of carbonic acid, as we have already mentioned. This seems at first sight paradoxical, but is easily explained. By the addition of lime to water containing a large quantity of lime in solution, a portion of the carbonic acid united thereto is abstracted; and the result is, that some of the lime already present is thrown down in the solid state. The following experiment will illustrate this fact.

Experiment 40.—To the water saturated with lime, produced in the last experiment, add some more *lime-water*. A white precipitate of insoluble chalk will be produced, and a portion of lime previously existing in solution will be removed.

In a similar manner, hard water may be rendered soft, on the large scale, by the addition of lime-water to it. Dr. Clark, of Aberdeen, patented this process some years ago, for its application to water before its supply to towns, when much lime was present. We believe that the plan was long employed at the Charlton and Woolwich water-works, the water being drawn from a chalky soil, and largely impregnated with lime thereby.

Sulphate of lime, or plaster of Paris, is often met with. It is always present in both the Thames and New River waters, and in most rivers in Great Britain. Its removal is not possible by any chemical means on the large scale; and the only plan to soften water of this kind is to boil it, or to add small portions of carbonate of soda when it is used for domestic purposes.

The remaining inorganic impurities, such as oxide of iron, sulphate of magnesia, &c., are either present in such small quantities as to be of no consequence; or, on the other hand, abound so much as to constitute what are termed mineral waters.

Mineral springs are frequently found in rocky and other districts; and the water is charged with gases, salts, &c., of various kinds. Amongst the gases are carbonic acid and sulphuretted hydrogen. Oxide, or generally carbonate of iron, is frequently present in considerable quantities; so much so as to deposit a deep-red coating on all the objects it comes in contact with. Sulphate of magnesia, or Epsom salts, is a common constituent of mineral waters; and common salt is generally found also in various proportions. The water of the ocean contains numerous salts, as we have already mentioned; and it has been lately asserted that silver is also present to a slight extent, which, however, in the aggregate, would form a prodigious quantity of that metal in the ocean. In some parts of Cornwall, the water flowing from the mines is largely impregnated with copper; and the metal is extracted therefrom by throwing into the streams scraps of old iron, such as the *débris* of the pots and pans of London, which are sent to the mineral districts in large quantities for that purpose.

On the continent of Europe, especially in some parts of Germany, mineral springs abound; and such places are sought for by invalids for the purpose of partaking of the waters. We may remark, that chemical analysis has so far succeeded in detecting the presence of all the salts contained in such waters, as to permit of their manufacture in any place; and there is scarcely a doubt that more Seltzer water, &c., is manufactured yearly in London than has ever been imported from the original and recognised source.

With respect to the value of mineral waters, in a medicinal point of view, much exaggeration has doubtless been made. Change of scene and society, pure mountain air and exercise, have a more beneficial effect on the human system than any medicament which can be administered; and to such may be rather assigned the improved state of health which the valetudinarian experiences on visiting a spa, than to the effect of its waters of which he partakes, although they may exert an assistant office.

The organic impurities of water is a subject of the deepest importance, in a sanitary point of view. In direct proportion as organic matter of any kind is present, so the fitness of such water for drinking purposes diminishes. In many districts moss is gathered as the water runs down the mountain sides, and along the banks of the stream; and this is readily noticed if the water be allowed to drop on a rough stone surface, which will then become covered with a green coat of vegetable matter. Such generally occurs in mountainous districts. In towns, the wells often contain animal matter, and its products in solution; and in the city of London, there are wells which are simply the result of the drainings of the churchyards to which they are adjacent. The water obtained from such sources has a very pleasant and cooling taste, from the presence of nitre; this arising from the nitrogen afforded during the decomposition of animal matter. If such water be exposed to the atmosphere during summer-time for a few days, it will give off a most offensive smell. Indeed, persons partaking of it are simply imbibing the products of the decomposition of the bodies of their ancestors, in a soluble form; and the effect is often manifest in the production of diseases, such as diarrhœa and cholera. Districts supplied with water from such sources are certain to be the most unhealthy during summer-time, and are fitting fields for the ravages of the complaints we have mentioned.

We may here call attention to what we believe will eventually become a source of great danger to the health of large towns. We refer to the position of cemeteries, so commonly found in the suburbs. London itself is encircled with these burial-places, nearly every one of which is located on a sandy soil. Tons of human remains are yearly deposited in them; and, as these decompose, the soluble matter will be carried away with the percolating water, afterwards to be pumped up for drinking and other purposes. Of course, many years will be required to pass away before the results we have hinted at take place; but eventually, chemical analysis and sanitary reports will more than likely show, that the proximity of burial-grounds to large cities will produce an evil of no ordinary, and, perhaps, of incurable magnitude.

In animal and vegetable life, we need not remind our readers that water exercises the most important functions. It fills the cells of the tree with sap, and courses, in the form of blood, through the veins of the animal. By means of it, the food is conveyed, in a suitable form, to afford flesh and muscle; the salts, which produce bone, are dissolved by it, and are presented in a suitable condition for that purpose. We must, however, dismiss this, and many other such matters, until we more fully treat on organic and agricultural chemistry.

Hydrogen combines with oxygen, in the proportion of one equivalent of the former to two of the latter, to form what is called the peroxide of hydrogen; symbol, HO_2; equivalent = 17. This, like water, is a liquid; and, although a very interesting production in a chemical point of view, has no general use or interest. It is prepared by a somewhat intricate and difficult process, by means of peroxide of barium and hydrochloric acid. The peroxide of hydrogen and chloride of barium are produced, and the baryta is precipitated by sulphuric acid, the chlorine being removed by means of a salt of silver. The combinations of hydrogen with chlorine, iodine, bromine, and fluorine, have been already noticed: those with other substances will be duly mentioned as we proceed.

NITROGEN.

In our former pages, we have spoken at some length on the qualities of one of the gases present in the atmosphere, and showed that oxygen is a powerful supporter of combustion, and essential to the existence of all animate bodies. The air, however, contains another gas, by means of which the active properties of oxygen are modified, so as to render them suitable to the organisation and circumstances of vitality, and to the properties of this gas. Nitrogen, and its leading compounds, we must now draw attention to. Its symbol is N; equivalent = 14; and its specific = 0·972; air = 1·000.

The properties of nitrogen are almost entirely of a negative character. It does not support combustion; has no smell or taste; is scarcely absorbable by water. It derives its name from nitre, of which it is a constituent; it is occasionally called *azote*, from the fact that animals cannot breathe it in a pure state. It has, however, no direct poisonous qualities; and fatal effects resulting from inspiring it, arise from the absence of life-sustaining powers. It, however, exerts great influence in animal life, as it forms a constituent of flesh, and various compounds produced or consumed by animals. It is a chief constituent of ammonia and nitric acid; and many products of the vegetable kingdom contain it as an essential element.

The readiest mode of procuring nitrogen for the purposes of experiment, is that of removing the oxygen of atmospheric air by means of burning phosphorus. The atmosphere is not a chemical compound in the strict sense of the term, but rather a mixture of oxygen and nitrogen gases; and hence, phosphorus and other burning bodies readily remove the oxygen by combining with it, leaving the nitrogen free.

Experiment 41.—Place a small piece of phosphorus on a piece of cork floating in a basin of water; and having ignited the phosphorus, invert over it a tall glass jar full of air, pressing the mouth of the vessel beneath the surface of the liquid. A few bubbles of air will at first escape, owing to the expansion of the air by heat. Eventually, however, the water will rise inside the glass jar to the extent of about one-fifth of its capacity. The white fumes of phosphoric acid produced by the combination of the phosphorus with the oxygen of the air, will be gradually absorbed, and a colourless gas will be left, which can then be removed into another and smaller glass jar, by means of the pneumatic trough, in the ordinary manner. There are other means of procuring nitrogen, which, however, have no advantage, in a practical point of view, over that above described.

Experiment 42.—Having filled a small glass jar with nitrogen, remove it, mouth downwards, from the trough, and introduce into it a lighted taper, which will be immediately extinguished. Afterwards, raise the jar, mouth upwards, and try its contents again, after a few seconds, by means of a lighted taper. The gas, owing to its levity, will escape, and the taper will burn as in the atmosphere, because the external air has taken the place of the nitrogen.

These experiments illustrate the fact that nitrogen does not support combustion; and that it has, like hydrogen, a less specific gravity than the atmosphere.

The Atmosphere.—The most important use of nitrogen is that found in the air we breathe. Were it composed entirely of pure oxygen, it would be impossible to extinguish a fire which had once been kindled. All animal and vegetable life would be too highly stimulated, and our present state of existence would be rendered impossible. A hundred cubic inches of air weigh about 31 grains; and as it has been already often stated, dry air at a temperature of 60°, and a barometrical column, equal to support 30 inches of mercury, is taken as a standard for the specific gravity of all other gases. The following tables give an approximate statement of the composition of atmospheric air:—

Composition of the Atmosphere.

1. By weight—	
Oxygen, the active element	23
Nitrogen, the negative element	77
	100
2. By measure—	
Oxygen	21
Nitrogen	79
	100

But in the above, we suppose that absolutely pure air is estimated: such, however, is never found in nature; carbonic acid and other gases being always present with aqueous vapour, in variable quantities.

We cannot enter here into any extended account of the physical character of the atmosphere. We may, however, state, that it is considered to encircle our earth to the extent of 45 miles from its surface; hence a column of air of that height, one of water 32 to 34 feet high, and one of mercury of about 30 inches high, on the average, balance each other. The barometer—which will be fully described under the head of Pneumatics—is employed to measure the variations of atmospheric pressure, which, at the surface of the earth, at the level of the sea, is equal to about 15 lbs. on the square inch; diminishing as the height of the atmosphere from the surface increases. Hence, the higher the atmosphere, the less the pressure it exerts on any surface. The causes of the barometric variations, or of the pressure of the atmosphere, are very numerous; and, until lately, had defied accurate or approximate rules. Owing, however, to extensive observations taken in all parts of the world, the science of meteorology, in which are included such subjects, is rapidly advancing to a high position; and it is even now possible to foretel, with tolerable accuracy, the occurrence of any extraordinary atmospheric fluctuation.

It is a remarkable fact, that although we cannot view the atmosphere in the light of a chemical compound, its constitution never varies to any great extent. The air obtained from the top of a mountain, and that on the plains, at first is identical in composition. Local and accidental circumstances cause some variations. Thus, in crowded cities, more carbonic acid and other gases are present than in the open country. Again, after a thunder-storm, small quantities of nitric acid have been detected, that acid being generally formed when the electric spark is sent through air. Sulphuric, sulphurous, and hydrochloric acids, ammonia, common salt, sulphuretted hydrogen, &c., may also be noticed; but the presence of these depends on causes which are entirely local and controllable.

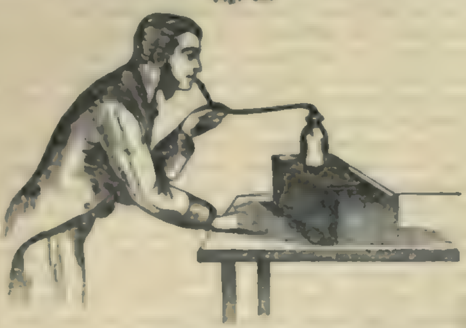
There are various methods employed to analyse the air; but of these we shall have more fully to speak when we consider the subject of chemical analysis. The method we recommended for procuring nitrogen for the purposes of experiment, illustrates these. The object always is, to remove the oxygen either by combustion or absorption. The former is generally done by means of hydrogen, when water is formed by the combination of that gas, with the oxygen contained in the air undergoing examination. A solution of protosulphate of iron, with a gas we shall presently describe—the binoxide of nitrogen—is employed when the process of absorption is adopted; such a solution having great attraction for free oxygen, and thus removing it from the air.

We need scarcely here dilate on the necessity of pure air for the maintenance of health, as we have already made extended remarks on that subject when speaking of ventilation, under the section of Heat. We may, however, point out the remarkable fact, that gases of very different specific gravities, have the extraordinary power of rapidly diffusing themselves with each other. Thus, if a tube be divided by a thin bladder, or diaphragm of plaster of Paris, and one end be filled with hydrogen, and the other with carbonic acid gas—the latter, which has a great specific gravity, weighing twenty times at least as much as its bulk of hydrogen, will, if placed in the lower end of the tube, gradually rise and diffuse itself with that gas, which again will descend, and equally diffuse itself with the carbonic acid gas. Thus the constitution of the atmosphere, whilst kept uniform, under ordinary circumstances, by this law of gaseous diffusion, is, as we have already intimated, deteriorated by other gases. Hence arise miasma, and those evil results produced on the animal economy by vitiated air and noxious gases. These subjects have been the study of many leading British and continental chemists; and although chemical science has not largely benefited by their researches, still society at large has reaped great advantages in a sanitary point of view. The general effect of the atmosphere on the animal system, in reference to the processes of digestion, &c., will be considered when we refer to the nature and uses of food.

We now proceed to speak of the combinations of nitrogen with other substances. With oxygen it forms the protoxide, binoxide; hyponitrous, nitrous, and nitric acids. The protoxide of nitrogen is, as its name implies, a compound of one equivalent of nitrogen to one of oxygen; its equivalent = 22. It is a colourless gas; has a sweet taste, and is distinguished by its peculiar effects in exciting laughter on being inhaled into the lungs; hence its common name of "laughing gas." As many of our readers may feel inclined to try experiments with it, we give full directions for its preparation and inhalation.

Experiment 43.—Put two ounces of nitrate of ammonia into a retort, or Florence flask with a bent tube. Place this on the ring-stand, and let the stem of the retort or flask dip into the pneumatic trough, or in a basin. Instead of using cold water in these, a solution of two ounces of sulphate of iron or green vitriol, dissolved in a gallon of warm water, should be employed, the object being to purify the gas as it passes through the liquid. A gas jar, open at one end, and corked at the other, is now to be filled with the water in the trough, and arranged so that the stem of the retort shall dip under its lower edge. A gentle heat is to be applied to the retort, by means of the spirit-lamp, till the salt contained in it melts. Laughing gas will then pass over, and will gradually fill the glass jar—of course driving out the water. When no more gas passes over, remove the retort from the ring-stand, and let the jar of gas stand over the water for some time, so that any gases present, which, if breathed, might do serious injury, may be absorbed. The gas may be collected in a bladder, if one be screwed to the neck of the gas jar; but a simpler plan is as follows:—Have ready a cork, which will just fit the neck of the glass jar filled with gas, and into this cork fit a piece of pewter tube, which must pass through a hole bored in the cork. To this a piece of india-rubber piping, about three feet long, should be attached, ending in a small piece of metal tube, which will serve as a mouth-piece. Our diagram, Fig. 50, will explain the construction of the arrangement. On the right is the pneumatic trough, in which the jar of gas stands. From the jar the india-rubber tube passes, and through this the person taking the gas inhales it. After removing the cork from the jar, and substituting the one just now described, the person taking the gas should place the mouth-piece in his mouth, close the nostrils with the fingers, and inhale the gas into his lungs, until a peculiar appearance is seen in his eyes—say after a few seconds of time. The effects produced on different constitutions vary materially. Some persons indulge in immoderate fits of laughter, whilst others have a tendency to fight. Great care should be taken to restrain the person from doing injury to himself or others, as he is utterly incapable of controlling his actions. Females should never have this gas administered to them, for obvious reasons; and, in every case, great caution should be observed. The effects, however, speedily pass away, and the individual suffers no inconvenience from the temporary excitement of which he had been the subject.

Fig. 50.



The binoxide of nitrogen consists of two equivalents of oxygen to one of nitrogen; equivalent = 30. It is sometimes called the nitric oxide, in old chemical works. It is prepared by dissolving copper filings in dilute nitric acid in a retort. The gas may be collected in the usual manner in ordinary gas jars; and if perfectly free from air, it is colourless. On the admixture of air or free oxygen, however, it readily combines therewith, producing, at the same time, a deep red gas, which is hyponitrous acid. The latter is composed of three equivalents of oxygen to one of nitrogen; equivalent = 38.

Nitrous acid contains four equivalents of oxygen to one of nitrogen; equivalent = 46. It may be prepared by distilling nitrate of lead in a retort; and is frequently a product of the decomposition of nitric acid, which then assumes a yellow or reddish colour. Nitrous acid, by itself, is an orange-coloured liquid, and its salts, produced by combination with bases, are termed nitrites. Its compounds are unimportant, and uncertain as to their constitution.

Nitric acid is the most important combination of nitrogen with oxygen. It contains five equivalents of the latter element to one of the former. Its symbol is NO_5; equivalent = 54, when in a pure state. In its ordinary condition it is united with water, and forms the ordinary *aqua-fortis*, when in a comparatively diluted condition. Nitric acid of the greatest strength has a specific gravity of 1·520; when quite pure, it has but a very faint yellow colour. The light of day, or the solar rays, speedily decompose it, producing a mixture of nitric and nitrous acids, by which its colour is deepened. It is obtained by distilling a mixture of nitre, sulphuric acid, and a little water, in a retort, receiving the vapour which passes over in a receiver, which should be kept cool, so as to condense the acid. A similar arrangement to that already described for preparing hydrochloric acid, may be used.* It has an intensely sour taste; turns the human skin to a deep yellow colour; reddens litmus; and, with bases, forms the salts called nitrates. Nitric acid is largely used in commerce for a variety of purposes. With hydrochloric acid it forms aqua regia, which is used to dissolve gold and platina. The chemists employ it in the laboratory, for the purpose of oxidising bodies, and as a general solvent, as it ordinarily produces salts soluble in water. It may be distinguished from other acids by its smell, and by bleaching a solution of indigo. Nitric acid is occasionally present in the atmosphere after a thunder-storm; and it may be produced by passing repeated electric sparks through a mixture of oxygen and nitrogen. It is often found in water, &c., through which animal matter has passed in a state of decomposition; but is so discovered in combination with potass or soda. With potass it forms the ordinary saltpetre of commerce, which is largely employed for the manufacture of gunpowder. When cotton wool is digested in strong nitric acid, or a mixture of nitric and sulphuric acids (which must be cooled before being used), the character of the cotton is completely changed; for, after having been well washed with water, and dried, it becomes highly explosive; and, by these means, *gun-cotton* is produced. In most of its characteristics, it is analogous to chloric acid; and is similarly constituted to the iodic and bromic acids. Its various salts we shall describe in connection with their bases.

Ammonia—symbol, NH_3; equivalent = 17.—This compound of nitrogen and hydrogen is of great importance in many respects. It enters largely into the composition of animal substances, or is the product of their decomposition; and the various salts it produces, with acids, such as the sulphate, carbonate, and hydrochlorate (sal-ammoniac), have large uses in the arts, commerce, and manufactures. Ammoniacal gas, which is the form in which ammonia is produced, may be readily obtained by heating the carbonate or sal-ammoniac with lime, in a test-tube or retort. The gas so afforded has a strong pungent smell, which is highly characteristic; is rapidly absorbed by water; reddens vegetable yellows, such as turmeric, &c.; and affords dense white fumes of sal-ammoniac on the vapour of hydrochloric acid coming in contact with it, by which its presence may readily be detected. Thus ammonia is continually given off in stables, and other places in which animal matter is putrefying; and if a stopper or rod, moistened with the acid, be exposed therein, the hydrochlorate is at once produced in the form of a white smoke.

Whilst the composition of ammonia is well known to be that of three equivalents of hydrogen to one of nitrogen, some peculiar effects, produced by the following experiment, have led to the idea that a metallic substance, to which the name of ammonium has been given, really exists.

Experiment 44.—Put a small piece of sodium into a little mercury, and pour thereon a solution of sal-ammoniac. The alloy will greatly increase in bulk, and yet remain solid.

Now, of late years, it has been strongly urged, that the result so produced arises from a combination of mercury with the hypothetic metal ammonium. We may, however, state, that all attempts to obtain the latter in a free state, have been fruitless; and if the metal really do exist, it has hitherto eluded the grasp of our most able chemists. Ammonia, in every case, behaves with acids much after the manner of a metal, and all the proofs of its existence resolve into analogies only, at the present time.

Ammonia may be obtained from such substances as horse-hair, and other animal matters, by heating them. This especially occurs when hartshorn shavings are strongly heated; hence the term "hartshorn," as frequently applied to it in commerce.

Experiment 45.—Heat some hartshorn shavings in a test-tube, and hold over the mouth a rod moistened with hydrochloric acid. Fumes of sal-ammoniac will at once appear. The same result may be produced by heating hair, flesh, or feathers; for in all these, hydrogen and nitrogen are present, and by their combination ammonia is produced.

---

* See *ante*, p. 317; Fig. 40.

A large quantity of ammonia is afforded at our gas-works, by the distillation of coal in producing coal gas. In fact, the ammoniacal liquor of the gas-works goes largely to swell the dividends of the gas companies. Coal contains but a small per-centage of nitrogen; but this uniting with the hydrogen, produces the ammonia, which partly condenses, as a dark-coloured liquor, with the water evaporated from the coals. The presence of ammonia in coal gas may be readily detected by holding a piece of turmeric paper over an open gas-tap, when the paper will speedily turn to a brown colour. An immense quantity of ammonia is thus annually wasted; and during its passage through brass tubes and connections, it exerts a very prejudicial effect. Besides being thus produced from coal, ammonia may be obtained from some kinds of vegetables—amongst the fungus or mushroom kind, is an instance.

When we enter on the discussion of the constitution of animal substances, and the uses of nitrogen in vital organisation, we shall perceive how important a part that element plays in those conditions. As we have already observed, there are few animal bodies but what contain it, and most of them produce ammonia on being subjected to destructive distillation.

The chief salts of ammonia are the sulphate, nitrate, hydrochlorate, and carbonate. The sulphate is largely used as a manure by farmers, and is always a component part of common soot. Guano contains both free and combined ammonia; and hence one of its great advantages for agricultural purposes. The nitrate has not much use in ordinary life: it is, as we have already mentioned, employed to manufacture laughing gas.

Sal-ammoniac, chloride of ammonium, or hydrochlorate of ammonia, as the same salt is indifferently called, has numerous uses in the arts and manufactures. It is employed by metallurgists, dyers, and others, for various purposes, and is an important article of commerce. The carbonate forms what is commonly called "smelling salts." Both sal-ammoniac and the carbonate may be readily sublimed by means of heat; and this plan is employed for the purpose of their purification.

The other salts of ammonia, such as the acetate, oxalate, &c., are of chief use in the laboratory—the last being employed as a test for lime, with which it forms an insoluble salt.

Nitrogen forms other compounds with hydrogen; namely, imidogen, which contains one equivalent—symbol, NH; amidogen, which contains two—symbol, NH_2; and the hypothetic ammonium, which we have already noticed—symbol, NH_4.

Chloride of Nitrogen.—This is the most explosive substance with which we are acquainted. Its composition is that of one equivalent of nitrogen to three of chlorine; symbol, $N\,Cl_3$. Its preparation is attended with extreme danger, unless the utmost precaution be observed. The best plan is to make a tray of sheet lead, which must be perfectly free from dirt or grease, and into it a strong solution of sal-ammoniac is to be poured. A jar of chlorine gas, mouth downwards, is then to be placed in the solution, when the chloride of nitrogen will gradually form as small globules. After a little has been formed, the jar may be removed, when the chloride will be found at the bottom of the dish. If it be touched by any greasy substance, it will instantly explode with a loud report, and the dish will most probably be bent or broken in all directions. It is impossible to be too careful in preparing this substance; and we strongly recommend all our readers to be satisfied with the description rather than the investigation of the substance.

Nitrogen forms also an explosive compound with iodine, which is analogous to the chloride; its symbol is NI_3. This iodide of nitrogen is prepared by adding some liquid ammonia to iodine—the same precaution being employed as in the last instance.

The fulminates of different metals will be considered under their respective heads; and the various organic compounds in which nitrogen plays a conspicuous part, will be dealt with hereafter. The union of carbon and nitrogen, producing cyanogen and its compounds, will be described in the section on Carbon.

CARBON.

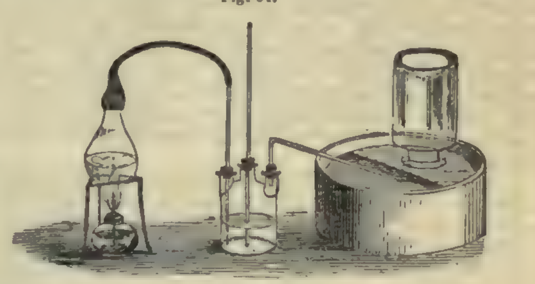
Carbon, in its ordinary state, is universally distributed in nature. We find it in nearly all animal and vegetable substances. It is familiar to us in our coals; and in this form is one of the most valuable products of our country. It floats, as carbonic acid, in the air we breathe; is part of ourselves, and constitutes the major portion of the plants of all kinds which surround us. Strange to say, that most valued of all gems, the diamond, is but carbon in a pure and crystallised state; and exists in striking contrast with another form of carbon—the soot which defiles the appearance of our houses and persons. Combined with hydrogen, it affords us coal gas; with hydrogen and oxygen, it forms sugar and starch; with oxygen, in various proportions, it produces acids; and to its other combinations we are indebted for alcohol, ether, animal and vegetable oils, with numerous other substances we cannot here stop to enumerate.

The purest form of carbon with which we are acquainted, is the diamond; and next to this is the well-known substance, "black-lead;" which, however, does not contain a particle of lead in its composition. The most ordinary form of carbon is that of wood charcoal, which is, however, mixed with earthy and saline matters. Its symbol is C; equivalent = 6.

Carbon combines with oxygen in two proportions, to form carbonic oxide and carbonic acid. Carbonic oxide, CO, equivalent 14, is often produced during the combustion of substances containing carbon. It burns with a pale-blue flame, and is the cause of the lambent flame which is often noticed arising from brick-kilns. It can only be found in the gaseous form; and, during combustion, produces carbonic acid gas by uniting with the oxygen of the atmosphere. It may be prepared as follows:—

Experiment 46.—Heat, in a test tube, or Florence flask fitted with a bent tube, some oxalic acid in crystals, to which some strong sulphuric acid is to be added. Carbonic oxide will be produced, together with carbonic acid. The gas may be received in the ordinary manner, in jars, over the pneumatic trough; which, however, should be filled with water containing a solution of potass. A better plan is to pass the gas through a solution of potass, in an intermediate vessel containing potass in solution, in the manner represented in the following engraving.

Fig. 51.

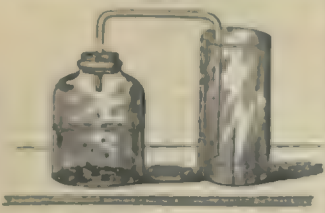


When sufficient of the gas has been collected, a taper may be applied to the mouth of the jar, with its rim held downwards; as the gas has a specific gravity of 0·97, or less than that of the air. The colour of the flame may thus be readily noticed.

Carbonic acid results from the union of one equivalent of carbon with two of oxygen: its symbol is CO_2; equivalent = 22. This gas has a greater specific gravity than air, it being equal to 1·527. It is not poisonous, but destroys life if respired, through the absence of oxygen. It is produced in large quantities during respiration, combustion, fermentation, &c.; and we shall suggest a few experiments illustrating these facts, and its general characteristics.

Experiment 47.—*Its production.*—Use the hydrogen bottle illustrated in Fig. 44; and introduce into it a quantity of marble, or chalk, broken into small pieces, but not powdered; on this pour a little water, and add half as much hydrochloric acid, so as to half fill the bottle. Fit in the bent tube, and let it dip into a tall glass jar, so as to reach to the bottom, as in Fig. 52. The acid will take the lime away from the marble, and the gas will pass into and fill the jar. This gas is very heavy, and will not escape until the glass is full: at the same time a small piece of card may just be placed over the mouth of the vessel, to prevent the action of currents of air.

Fig. 52.

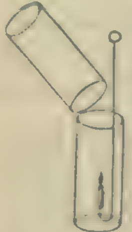


Experiment 48.—Dip a lighted taper into the jar; the flame will be immediately extinguished.

Experiment 49.—Into a glass jar put a small piece of taper or candle, by tying it to a wire (Fig. 53), and let the candle rest at the bottom of the jar, after having first lit it. Now take another jar filled with the gas, and pour its contents into the first one, in the same way as if water were being poured out. Owing to its great weight the gas will pass into the vessel holding the taper, and extinguish the flame (Fig. 54). These two experiments illustrate the deadly nature and weight of the gas; and suggest very simple means of preventing loss of life, to persons who have to descend into mines, vats, or other places where this gas is often found.

Fig. 53.

Fig. 54.



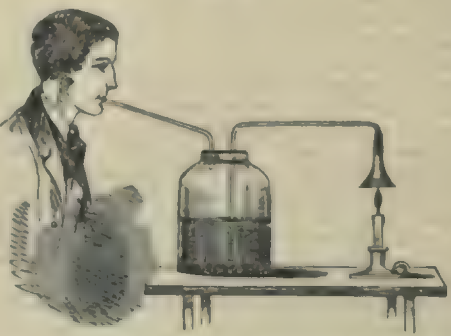
Experiment 50.—Half-empty a jar of this gas by tilting it on one side for a few seconds; then dip in a lighted taper. It will be found that the taper will burn until it reaches the part where the heavy gas is, when it will at once go out. This simple experiment shows how it often occurs that human lives are lost, by persons descending deep wells or vats, which frequently contain large quantities of carbonic acid gas. In the upper part no gas will be found; whilst, owing to its density, it may be in quantities in the lower part. Every deep vessel or place should thus be tried by means of a lighted candle, before any person is allowed to descend into it. If the flame be not extinguished, then little danger can arise; on the other hand, if it be extinguished, no attempt should be made to descend until some means have been adopted to ventilate the place. This may be done by letting down large chauffers of burning coal, which will produce currents of air; or quantities of slaked lime may be cast in, so as to absorb the carbonic acid gas.

A very large amount of carbonic acid is produced by the combustion of candles, coal, coke, and charcoal; and that produced from the last-named material has often been employed for suicidal purposes. Lime-water is the best test for the presence of carbonic acid, as the gas instantly forms chalk, or carbonate of lime, on coming in contact with the lime held in solution. Lime-water is readily made by shaking up some fresh-burnt lime with cold water, and decanting off the clear transparent solution, which alone must be used. The following experiments will illustrate the fact that carbonic acid is produced by respiration and combustion.

Experiment 51.—Pour into a small glass a little lime-water, and then, by means of a glass tube, blow from the mouth into the water. After a short time, the lime-water will become milky, owing to the carbonic acid driven from the lungs combining with the lime, and forming chalk.

Experiment 52.—Arrange a piece of apparatus as in the diagram, Fig. 55. On the right is a small funnel suspended over a candle; the funnel is connected with the purifier used in making oxygen (see Fig. 15); and the air is drawn from over the lighted candle through lime-water contained in the purifier, by sucking at the small tube. The gas produced by the burning candle will form chalk in the purifier with the lime-water; and thus the products of combustion are shown to be the same as those obtained from the breath as expired from the lungs.

Fig. 55.



Similar results obtained as above from the products of respiration and combustion, may not at first sight appear easy of comprehension by some of our readers; we, however, can readily explain them. The candle contains carbon as one of its constituents; and during combustion, that carbon becomes converted into carbonic acid. The food we partake of also contains carbon; and this, in the blood, comes in contact with the oxygen of the air on the surface of the lungs. It there undergoes a slow process of combustion, and produces carbonic acid gas. Indeed, there is every possible analogy between the production of heat in our furnaces and in our lungs, by an identical process carried on at different degrees of intensity. The following experiment will prove the presence of charcoal in sugar.

Experiment 53.—Make a strong solution of sugar in hot water, and add to it some concentrated sulphuric acid. The latter will seize the water in the sugar, and set free its charcoal, as a dense, spongy, black mass.

We have already noticed that carbonic acid is present in the atmosphere; we may here, therefore, call attention to the fact, that whilst poisonous to animals, it forms the food of plants. The leaves of trees act as lungs, and, by means of them, the carbon of the carbonic acid in the air is absorbed into their structure. Thus, three-fourths of a tree are gathered from the air. What is poison to us, becomes the food of plants: they purify what we poison, and return to us the oxygen, so essential to our existence, from the carbonic acid which we have cast off from our lungs.

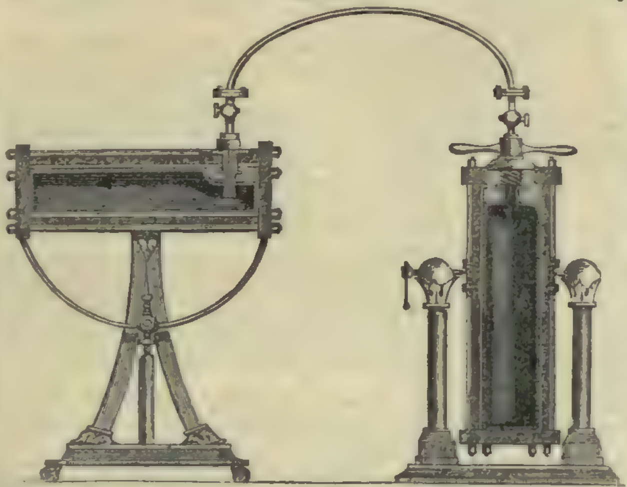
Carbonic acid is the cause of the effervescence of malt liquors, sparkling wines, soda-water, &c.; and although deathly to the lungs, acts as a healthy stimulant to the stomach: hence arises the invigorating and freshening effect of the beverages to which we have referred.

By means of considerable pressure, carbonic acid may be liquefied, and even brought into a solid state. This may be effected in a strong bent glass tube, by placing the materials at one end, and receiving the gas at the other. It is, however, more conveniently managed by means of a strong metal apparatus, constructed for the purpose; which is illustrated in the following engraving. It consists of two parts, joined by means of a pipe. The vessel on the right-hand side of the cut is that into which the materials are introduced; and the gas passes thence by means of the tube, into the receiver.

If the gas be allowed to pass out of the receiver while in a liquid state, it evaporates so rapidly as to be converted into a powdery substance, resembling snow. If this solid carbonic acid be mixed with ether, it produces the most intense cold obtainable by any means, owing to the rapid evaporation which takes place.

We need scarcely state, that great danger always attends the performance of such an experiment as the condensation of carbonic acid gas; and some lives have been lost thereby, through the explosion of the apparatus. It has been proposed to employ carbonic acid gas as a motive agent, in place of steam; but the application has never yet been practically adopted.

Fig. 56.



The composition of carbonic acid gas may readily be ascertained, and the presence of carbon therein proved, by filling a Florence flask with the gas, into which a piece of potassium, of the size of a pea, may then be dropped; the heat of the spirit-lamp may be applied, when the metal will seize the oxygen of the acid, setting the carbon free as a black powder. On the other hand, the presence of carbon may be proved in the diamond, by burning that gem in oxygen, when carbonic acid will be produced, which will at once form chalk with lime-water.

Carbon has peculiar properties of absorbing into its pores gases of all kinds; and, in every case, it has highly anti-septic properties. For this purpose, it may be procured from wood, cones, peat, &c.: all that is required is, that it should be highly porous. Putrefying animal matter may be covered, to a depth of a few inches, with small pieces of wood charcoal, and no smell whatever will arise from it. It has been employed by Messrs. Stenhouse and Watson, as a purifier of air to hospitals, &c., when such buidings are situated in unhealthy positions. Its use as a dentifrice is well known. Charcoal enters largely into the composition of gunpowder; for which purpose the best qualities are sought for. The explosive effect of gunpowder and gun-cotton is due to the sudden liberation of carbonic acid and other gases, during the combustion of the solid materials.

With sulphur, carbon forms a peculiar liquid, called bisulphide of carbon. This is prepared by passing the vapour of sulphur over pieces of charcoal heated red-hot, and contained in an iron tube. Bisulphide of carbon is a common product of the distillation of coals; to which reference has already been made in the article on artificial illumination.*

We must also refer our readers, for a full description of the composition of fatty matters, both animal and vegetable, and the nature and composition of the products of their distillation, and that of coal in producing the various combinations of carbon and hydrogen, olefiant gas, carburetted hydrogen, paraffin, &c., to the same subject; in which they will find the fullest details. We may, however, add, that since that portion of this work has gone to press, a new source of mineral oil has been discovered in North America, which seems inexhaustible, and which promises to reduce the cost of illuminating agents to a great extent.

Carbon and Nitrogen.—A very interesting series of compounds is produced by the union of carbon and nitrogen, and bases: of these we shall first mention cyanogen.

Cyanogen is a bicarbide of nitrogen; being composed of one equivalent of nitrogen united to two of carbon. Its symbol is Cy; equivalent = 26. It is obtained by heating cyanide of mercury in a test-tube, fitted with a bent glass tube; and it may be collected in the usual way by means of the pneumatic trough. This gas has a smell like prussic acid, of which it is a constituent; it burns readily, and is highly poisonous.

Cyanogen produces hydrocyanic, or prussic acid, by uniting with one equivalent of hydrogen. Hydrocyanic acid is generally prepared from the ordinary prussiate of potass, by means of sulphuric acid. These materials, with water, are placed in a retort, and the acid is distilled over in a dilute state. It is highly poisonous; has a smell like bitter almonds; and forms salts, which are commonly termed prussiates, some of which we shall have to notice hereafter. Cyanogen unites with metals forming the substances called cyanides. These are largely employed in electrotyping processes; and their manufacture and uses have already been extensively dealt with under the head of Electro-Metallurgy. Cyanogen also unites with sulphur, forming what is termed sulpho-cyanogen and the sulpho-cyanic acid.

The union of carbon with iron, producing steel and other combinations—already referred to, but not yet described—will be taken up in connection with the substances, as we examine each separately.

OXYGEN, HYDROGEN, NITROGEN, CARBON, ETC., AND THEIR FUNCTIONS IN ANIMAL STRUCTURE AND SUSTENANCE.

In our previous pages, we have frequently remarked on the different compounds on which animal life depends; and have shown that oxygen, hydrogen, nitrogen, and carbon, are each necessary to the formation of animal substances. We shall now proceed, by way of illustrating the laws already explained, to call attention to the nature of animal organisation, and the functions which the elements, already considered, exercise thereon; and for that purpose shall avail ourselves of an able article, translated by Dr. Bronner, from the works of Professor Moleschott, of Zurich. We have ventured to make some alterations in those parts in the original, which are more fitted for perusal by professional persons only, or have been previously considered; but have retained all which bear on the questions we have already discussed. The general reader will perceive the intimate relationship which exists between vitality and chemical action, and will also acquire a knowledge of the constituents of organised substances. It will also be noticed, how few are the elements which are employed to produce a multitude of results. These, with the exception of two or three mineral substances, have already passed under review.

This subject will be again referred to when we enter on the question of organic analysis; and the perusal of the succeeding article will prepare the reader for a close examination of chemical facts, whilst it assists in the generalisation of them. The nature of the blood is first considered, with its uses in producing animal tissues, &c. The author then proceeds to point out the substances producing healthy and life-giving blood in each kind of food; concluding with general observations on the different kinds of diet required to meet the varied wants of mankind. His remarks are as follow:—

§ 1. *On the Formation of the Blood.*—In former times it was conjectured, and, as it were, instinctively asserted, that the human body changes its material and properties at certain epochs of life; and this has been proved to demonstration by the investigations of physiologists during the present century. Though we cannot determine whether the body is renewed entirely in seven years, as is popularly believed, or in a much shorter period, as science has endeavoured to prove; yet we know that all nutriment passes only through the body. By this, however, is not meant, that what has been received by the mouth is immediately voided. On the contrary, the different ingredients of which our daily aliment is composed, become, in reality, essential constituents of the body itself. We may, therefore, consider that which is rejected to be only the dross which has gradually become unfitted for the functions of life in the different organs of the body.

---

* See *ante*, p. 119.

The essence of the ingested nutriment passes from the digestive canal into the circulation, during which process it is transformed into blood, and thus conveyed to the several organs of the body. There it undergoes certain alterations, and returns as waste material into the venous blood, from which certain organs secrete and discharge it externally.

§ 2. The first change, therefore, which nutriment undergoes, after leaving the alimentary canal, is sanguification. The aggregate of the changes which solid and liquid foods undergo up to sanguification, is called digestion. The various organs of the body which unitedly produce these changes, are termed by physiologists, the digestive organs.

From the mouth, into which the saliva is poured by a number of glands through corresponding ducts, the aliment descends into the stomach. In the coats of the stomach are glands, smaller and simpler in construction, but far more numerous than the salivary glands, and which, during the process of digestion, secrete a peculiar fluid, termed gastric juice. Next after the stomach come the small intestines, into which the liver and pancreas, two large glandular organs, pour their secretions—the former the bile, the latter a fluid somewhat similar to saliva. In the coats of the intestines, also, are numerous small glands supplying the intestinal juice. The large intestines follow; the lowermost, a tenth part of which is called the rectum, terminating in the anus.

Besides the secretions enumerated above, there is found a considerable quantity of mucus throughout the whole intestinal canal. This mucus is materially different in different places, owing to the admixtures which it receives in the several parts of the canal.

Saliva, gastric juice, bile, pancreatic and intestinal juice, combined with mucus, are themselves products of the blood; from which, having been elaborated by various glandular organs, they flow, as before stated, into the digestive canal. Thus do the fluid combinations, which have themselves been furnished by the blood, contribute, in return, to the accomplishment of all those transformations of the nutriment, which are necessary for sanguification.

§ 3. *The Alimentary Principles.*—In order to understand these various alterations, it is necessary to make ourselves acquainted with the constituent parts of the nutriment we employ. Let us imagine, for instance, a kind of aliment so compounded that it alone shall be sufficient to maintain life. Nature furnishes such an example in milk. This article contains salts, sugar, fat, and a substance very nearly resembling albumen or the white of egg, which is the principal constituent of cheese, and is hence called caseine.

These four principles constitute by far the greater proportion of all nutritious aliment. We say the greater proportion, not the whole; for either fat or sugar may be absent singly in nutritious food, but not both together. Salts, fat, and albumen, or salts, sugar, and albumen, are three components which, together, are absolutely necessary for the nutrition of the body. They are examples of three groups of alimentary substances, which represent the essential part of all solid and liquid food. To express these groups in more general terms, we have—

1. The inorganic.
2. The organic destitute of nitrogen.
3. The organic possessing nitrogen.

The essential distinction between these three classes, lies in the particular nature of their composition.

The more important elements of nutriment are—

Potassium.
Sodium.
Calcium.
Magnesium.
Iron.
Fluorine.
Chlorine.
Phosphorus.
Sulphur.
Oxygen.
Hydrogen.
Carbon.
Nitrogen.

The seven elements, from potassium to chlorine, belong principally to the mineral kingdom; they compose the inorganic aliments—that is to say, those which exist without any mediate or immediate intervention of living beings; as, for instance, common salt. The instruments of living beings are called organs; and all those substances are called organic, the production of which depends upon the mediate or immediate activity of plants or animals; for example, sugar and alcohol are organic substances.

Nitrogen, carbon, and hydrogen are to be found in all living bodies, whilst entirely absent in many minerals. Therefore they may be denominated, in a stricter sense, organic elements. It is true they appear also in the inorganic world, just as inorganic elements appear also in the organic.

Intermediate between these two groups are oxygen, phosphorus, and sulphur, being nearly as much organic as inorganic elements.

§ 4. There are combinations of two inorganic elements in our nutriment; amongst these common salt, which consists of sodium and chlorine, holds the principal place. A combination very similar to common salt is that of chlorine and potassium, the latter of which represents the chief element of potash. We shall hereafter speak of common salt and chloride of potassium, under the appellation of compounds of chlorine. Both are distinguished by their free solubility in water.

To these combinations, each consisting of two elements, fluoride of calcium may be added, which is to be found in very minute quantities in wheat, in milk, and in blood, and is known to most readers as fluor spar. It is composed of fluorine and calcium. Water dissolves it only at a high temperature, and even then very sparingly.

It may seem strange that common salt is not called a salt by chemists; the salts of chemists are even not similar to common salt in taste. Therefore, as we mentioned before, salts are only an example of the class of inorganic elements. In chemical language, a salt is a combination which does not consist of two elements, but of a combination of two parts, each containing two elements.*

The number of salts is exceedingly large. In treating on the subject of food, it will only be important to refer to the oxy-salts; these consist of different elements of a metal forming, with a little oxygen, a base called an alkali, and of a non-metallic substance, with a large quantity of oxygen, forming an acid.

Almost all bases have a corrosive taste, like lime; almost all acids a sour one, as sulphuric acid; but this is not an essential quality either of bases or acids. A really significant characteristic of bases is their attraction for acids; and of acids, their tendency to unite with bases. These duplex combinations of bases with acids constitute salts. The matter which is commonly employed as a test of both acids and alkalies, is litmus, which is a blue pigment, prepared from a hard, granulated, grayish-white plant, belonging to the class of lichens, which, under the name of Swedish moss, is imported principally from Sweden. Acids turn the litmus red; while bases or alkalies restore its natural colour. The general reader may at any time aid his imagination by thinking of lime as the representative of the bases, sulphuric acid of the acids.†

If, in the combination of a base and an acid, the base predominate in quantity, therefore communicating to the compound its peculiar properties, the salt is called basic, and acid if the acid have the preponderance; if neither predominate, the salt is called neutral salt.

The bases of the salts of our nutriment are constituted out of the first four elements, which are called above, in a stricter sense, the inorganic. They are all metals, and,

* See *ante*, p. 306.

† *Ante*, p. 303.

in forming bases, they combine with a small quantity of oxygen. We pass now briefly to enumerate these bases.

The combination of potassium with oxygen is potash; soda is composed of sodium and oxygen, just as common salt is composed of sodium and chlorine: soda is often elicited from common salt by the introduction of oxygen, which expels the chlorine. Potassa and soda are called alkalies in a stricter sense; they readily dissolve in water. Calcium with oxygen constitutes lime; and magnesia, a substance very similar to lime, is formed from oxygen and magnesium. Magnesia is the base of the well-known medicine, carbonate of magnesia. For the future we shall include lime and magnesia under the common name of earths; they differ from alkalies principally in being much less soluble in water, and in having a slighter affinity for acids.

Iron combined with a higher proportion of oxygen than that which with calcium forms lime, is called oxide of iron, which, in combination with water, produces iron-rust. It differs from the earths and alkalies in being insoluble in water.

All the above-named bases appear in aliment, only in union with acids, forming salts. The most important acids are constituted of those elements which we have called intermediate between inorganic and organic substances.

Sulphur forms, with a large proportion of oxygen, sulphuric acid, generally known by the name of oil of vitriol.* Phosphorus, combined with still more of oxygen than sulphuric acid contains, is called phosphoric acid, which constitutes with lime the solid material of bones.† To these may be added carbonic acid, which produces the sparkling bubbles of champagne, and is a compound of carbon with a smaller proportion of oxygen than is found in sulphuric acid.‡

The alkalies, potash, and soda appear in our food, compounded with the three above-mentioned acids. They form neutral salts with sulphuric acid, sometimes acid salts with carbonic acid, and always basic salts with phosphoric acid. Of these three classes, the last-mentioned enter by far the most largely into the composition of our food.

Amongst the earthy salts, those formed with phosphoric acid again prevail. These are always basic, and can only be dissolved with difficulty in pure water, but become easily soluble if a little acid be added.

The sulphate of magnesia, known to everybody as Epsom salts, is soluble in water; but sulphate of lime or gypsum can only be dissolved with great difficulty.

Finally, the oxide of iron enters into our food in combination with phosphoric acid; and the salt thus formed, though insoluble in water, is dissolved by acids with tolerable ease.

The inorganic principles of nutriment are therefore as follows:—Compounds of chlorine and alkali salts, both soluble in water; earthy salts and phosphates of iron, which dissolve in water with difficulty, or not at all.

§ 5. The organic alimentary substances without nitrogen are in part compounds of carbon, hydrogen, and oxygen, which are capable of being transformed into fat, and we therefore call them *constituents of fat.* In part they consist of different kinds of fat itself, all of which are compounded of the same three elements.

In most constituents of fat, these elements are combined in the same relative proportions; and two of them, hydrogen and oxygen, in the same as that in which they are found in water.

All fatty substances contain the same proportion of oxygen, and proportions of carbon and hydrogen mutually equal, though varying in different kinds of fat. In comparison with hydrogen, fat itself contains much less oxygen than water or the constituents of fat.

The most important constituents of fat are starch, gum, and sugar. We shall often include these under the name of *starchy substances.* Starch is only soluble in boiling-water, but the other two easily in cold.

Of the fatty substances we must here mention *oleine*, *margarine*, and *stearine.*§ Oleine is the chief component of all oils, and denotes their characteristic part, which slowly coagulates by cold. Besides oleine, oils contain a fat which hardens more readily, and may be obtained in crystals, glittering like mother-of-pearl. On this account, and not because it is actually found in mother-of-pearl, it is called mother-of-pearl fat, or margarine. Stearine is the firmest of all fats. It is the principal solid substance in the fat of mutton and beef, where it is combined with margarine and oleine. Stearine candles contain stearine and margarine.‖

While most constituents of fat are identically composed, sugar only containing more hydrogen and oxygen than the others, there is in oleine, with the same quantity of oxygen, more carbon and hydrogen than in stearine, and in stearine more than in margarine

The above-named fatty substances are not soluble in water, and cannot as such be united with other substances in soluble combinations. As though saturated in themselves—that is to say, without any inclination to combine with other substances, and, so to speak, standing impartially between acids and bases—we may call them *neutral fats*, just as the salts in which acids and bases are in equilibrium are termed neutral salts. By the admixture of alkalies, neutral fats are separated into two substances, one of which is called the sweet principle of oil, or *glycerine*, a substance compounded of carbon, hydrogen, and oxygen; the other, and by far the greater part, is a *fatty acid*, which combines with the alkalies to form a *soap*. Thus oleine yields oleic acid; stearine, stearic acid; and margarine, margaric acid. As glycerine, which has been separated from neutral fats by potash or soda, is of the same composition, from whatever fat it is extracted—it follows that the remaining acids retain the same proportion of carbon and hydrogen, as the primitive neutral fats; that is to say, oleic acid contains more carbon and hydrogen than stearic acid, and stearic acid more than margaric acid.

The compounds of fatty acids with potash are called potash-soaps; and those of soda and fatty acids, soda-soaps. Soaps, therefore, may be regarded as analogous to salts, the acids being an organic substance destitute of nitrogen, the basis an inorganic body.

§ 6. Another group of *organic alimentary principles* are those *containing nitrogen*, which are compounded of a greater number of elements than fat and its constituents contain. Of these constituents of food, we have only to mention the albuminous substances. All albuminous aliments contain nitrogen, carbon, hydrogen, oxygen, and sulphur, and most of them phosphorus also. The white of a hen's egg gave its name to these substances, which have been properly united into one group. The proportions of nitrogen, carbon, hydrogen, and oxygen, of which they chiefly consist, show a most surprising, if not complete agreement; recent chemical investigations having proved, that, with respect to the four latter elements, their composition is almost identical. Before this, however, the great similarity of their properties had led to their being comprised under one general name. Four of them, the caseine of milk, the principle of the yolk of eggs, the gluten of grain, and the globuline in the crystalline lens, as well as in the globules which float in the blood, are distinguished by not containing any phosphorus. The quantity of sulphur is different in these several instances, just as that of phosphorus is in those which contain this element. In the following list the albuminous substances are given in order, according to the quantity of sulphur they contain; those which possess the higher proportion being placed first:—The albumen of eggs, the albumen of blood, fibrine and globuline of blood—both of which contain an equal quantity of sulphur; the principle of the yolk of eggs, gluten, caseine, soluble vegetable albumen, coagulated vegetable albumen, and legumine. The largest proportion of phosphorus exists in legumine; the albumen of eggs stands next, which, however, contains scarcely a quarter of the phosphorus of the former; and last of all, fibrine and albumen of blood. The amount of phosphorus in

---

[§] See *ante*, p. 93.

[‖] *Ante*, p. 95.

soluble and coagulated vegetable albumen has not yet been determined; but the quantity of sulphur and phosphorus is always very small in comparison with that of the other elements.

Amongst the albuminous principles, soluble vegetable albumen, legumine, albumen of the blood, albumen of eggs, globuline and caseine, are, when fresh, soluble in water; the principle of the yolk of eggs dissolves with great difficulty; coagulated vegetable albumen, gluten, and fibrine of the blood, not at all. The different kinds of albumen, in a stricter sense, coagulate if boiled in water, as everybody has seen in hard-boiled eggs. The globuline of blood coagulates by warmth alone; legumine and caseine by acids in a warm temperature. We know how quickly milk curdles and turns sour in warm weather.

All albuminous principles, insoluble as well as soluble, are, in a coagulated state, dissolved at a somewhat higher temperature by a solution of potash, and are, from this solution, precipitated by acids in a solid form.

§ 7. *Digestion.*—After this brief description of the most important alimentary principles comprising our nutriment, we shall resume the account of digestion.

The whole of digestion is included under two grand processes. First, the alimentary principles must be dissolved, or very minutely divided; and secondly, if different from the constituents of blood, they must be transformed into these. Let us now see how these changes take place by the action of saliva, gastric juice, bile, pancreatic, and intestinal juice, upon the compounds of chlorine, the salts, the constituents of fat, the fatty substances, and albuminous matter.

All fluids which flow to the digestive organs contain a relatively large quantity of water, at a temperature of 98° Fah. Common salt and chloride of potassium are easily dissolved in this water, as well as the phosphoric, sulphuric, and carbonic alkaline salts.

In the liquid of the gastric juice is a free acid. The earthy salts, therefore, which we before described as hardly or not at all soluble in pure water, but easily so in acid, are by this means reduced to a dissolved state.

Owing to the higher temperature peculiar to all the fluids of our body, a part of fluoride of calcium is dissolved; but the greater part of it, and of the oxide of iron, remains undissolved. This explains why the alvine evacuations always contain so much iron. Here also the gastric acid plays an important part, inasmuch as it dissolves a portion of the iron, which is thoroughly indispensable to the blood.

Starch by itself is not soluble in the water of the digestive fluids; but saliva, the mucus of the mouth, pancreatic and intestinal juice, have, in combination with each other, in a remarkable degree, the property of transmuting starch into gum, and gum into sugar. Thus, starch is not only indirectly dissolved, but is subjected in that process to such changes as render it capable of being assimilated with the substances of the blood; for sugar is transformed into lactic acid by the action of the bile; lactic acid into butyric acid while progressing through the alimentary canal; and butyric acid is the first link in the series of fatty principles which are found in living bodies. Oleic and margaric acid differ in their composition from butyric acid only by containing more carbon and hydrogen in proportion to their oxygen.

The last effect of digestion upon all the constituents of fat is transmutation into fat itself. Starch and gum are transformed into sugar, sugar into lactic acid, lactic acid into butyric acid, and butyric acid into other fatty substances.

Neutral fats are principally digested by the action of pancreatic juice, assisted by the bile. These fluids divide the fat into particles so small, as to be capable of easily penetrating through the membranes moistened by the bile. Another smaller portion of the fat is actually dissolved, for the carbonic alkali of the bile first effects a saponification of the fat, then the continuous action of the pancreatic juice transforms it into fatty acids and glycerine: thus stearic acid and glycerine arise from stearine; oleic acid and glycerine from oleine. The fatty acids combine with the alkalies to form soaps, which are soluble.

All the fluids of the digestive canal act as solvents upon the albuminous substances; and to this dissolving action almost all the components of these fluids contribute. It is especially so with the free acid of the gastric juice; in the next place, with the predominating alkali of saliva, bile, pancreatic, and intestinal juice; then with organic substances, water, and the salts of all digestive juices. By the action of the acid of the gastric juice, the soluble albuminous substances are first coagulated; but they are again dissolved by degrees, by means of a power which the gastric acid exercises upon undissolved albuminous substances, supported by the alkalies of the intestinal and pancreatic juice. The most important agents in the dissolution of albuminous matter are, however, the organic components of the gastric and intestinal juices.

By the dissolving action of the digestive juices, and by the peristaltic grinding motion of the walls of the digestive canal, food is changed in the stomach into a pulp called *chyme.* This, by degrees, is rendered more liquid, until it becomes a thick, milky juice, which physiologists call *chyle.*

This chyle is essentially a mixture of dissolved compounds of chlorine, of salts, sugar not yet entirely transmuted into fat, of lactic and butyric acids, of finely divided and saponified fats, and of soluble albumen. Here, also, the latter may be regarded as representing the remaining class of albuminous substances; and this so much the more, as these after-liquefactions have become, in the highest degree, similar in their properties to soluble albumen; but still they retain their original composition.

§ 8. *The Chyle.*—Thus the liquefied alimentary principles flow over the inner surfaces of the intestinal walls, in which are numerous vessels, long and narrow canals with thin walls, into which the greater part of this milky chyle exudes. These vessels are, therefore, called *lacteals.* Not only their walls, but also those of the blood-vessels, are permeable by liquids; and, therefore, a considerable part of the chyle also exudes into the blood-vessels of the intestines.

When digestion is nearly finished, the lacteals teem with a white milky juice, which owes its colour to the fat they have taken up; for if no fat have been digested, we find in these vessels only a clear, transparent juice, scarcely deserving the name of chyle.

The very numerous and smallest lacteals gradually unite themselves into larger trunks, which, at certain points, run very near each other, repeatedly widening and contracting, something like a string of beads, and pursuing irregular windings, held together by cellular tissue, and forming, as it were, lumps or knots, which have been improperly called intestinal glands.

The lacteal vessels, after having passed through these knots, by uniting in gradually larger trunks, form at length one duct. By the junction of this trunk with two vessels, which convey a white, watery fluid from other parts of the body, and are called *absorbents,* another canal is formed, which passes through the cavity of the abdomen and chest near the vertebral column, and is called the *thoracic duct;* through this the chyle flows into the blood.

The composition of the chyle, which has been absorbed by the lacteals, differs very little from the liquid which, during digestion, is contained in the lower part of the small intestines. Before these vessels, in their convolutions, have become united into knots, the properties of their contents are almost entirely the same as they were in that part of the intestines from which they were taken. The quantity, however, of solid matter held in solution in the liquids varies; accordingly, the chyle contains more water in the lacteals than in the intestinal canal. This facilitates the transition of matter from the intestinal canal into the lacteals. The water in the latter has a great affinity to the substances which, in a dissolved or liquefied state, flow over the interior walls of the intestines. The chyle of a person fasting is more watery and thin than that of one who has had a plentiful meal.

Up to the formation of the knots just mentioned, the lacteals commonly contain an alkaline solution of compounds of chlorine and salts, among which common salt and phosphate of soda predominate, with a certain quantity of sugar; also, if any amylaceous substances have been present in the food, neutral fats, as well as oleic and margaric soaps—that is to say, compounds of oleic and margaric acid with soda and potash; and, lastly, albumen and fibrine.

The last-named substance is not yet quite identical with the proper fibrine of the blood, of which the characteristic property is that of spontaneously coagulating without the application of heat or acid when withdrawn from the living body. The fibrine of the chyle, which has in other respects the same properties, acquires this quality only on its way from the intestinal canal to the blood-vessels, and after having left that part of the lacteals which is convoluted into knots.

In the lacteals also begins the development of a red colouring matter, which, besides nitrogen, carbon, hydrogen, and oxygen, contains some iron. The quantity of the latter is as constant as it is small in proportion to that of the four first-named elements. This substance must necessarily be formed from one of the albuminous principles, and an iron salt of the chyle. It is the occasion of the light-red colour so often remarked in the superior part of the thoracic duct. This constituent of the chyle, containing iron and nitrogen, is called *colouring matter of the blood*, because blood possesses no other constituent of this colour.

How far the formation of blood has now advanced, will best be seen if we pass to the description of the blood itself.

§ 9. *The Blood.*—In the blood of man, vesicles are suspended containing a red substance, and white, granulated corpuscles. The former are called *coloured*, the latter *uncoloured blood globules.*

The fluid, in which the blood globules are continually in motion in the living body, is always impregnated with three different kinds of gas—oxygen, carbonic acid, and nitrogen. Apart from these gases, the blood consists of a solution of salts, albuminous substances, fat, and sugar. When withdrawn from the veins or arteries, the blood deposits a red dot, leaving a yellowish liquid. The former contains principally the fibrine and coloured matter of the blood; the latter is albumen and salts. Fat is equally distributed in both. This separation into clot and liquid arises from the property of fibrine to coagulate, as soon as the blood is removed from the influence of the living body. While coagulating, the fibrine incloses the blood globules, and therefore the clot retains the red colour. In the vessels of the living body, fibrine always exists in the dissolved state. This is in part effected by the salt and the predominance of alkali in the blood; but only in part, because the salts and alkalies are not able to keep the fibrine in a soluble state out of the body. The supposition may, therefore, be justified, that the fibrine leaves the blood and blood-vessels of the living body before it has become ripe for coagulation. Out of the body, fibrine undergoes this development in the blood itself, and coagulates, even where temperature, motion, and protection from the external air have been maintained, artificially, as much as possible as it had been during life. We consider the oxygen contained in the blood itself to be the chief cause of this change.

The coloured globules consist of a white capsule, containing a red liquid: this capsule being of an albuminous substance, is so transparent that it becomes entirely invisible when the colouring matter has been washed out of the globules by a sufficient quantity of water. The red colouring matter, which is contained in the blood globules, besides several salts, fat, and albumen, is invisible through its pellucid enclosure. Iron is the element which, in the colouring matter of the blood, is united with nitrogen, carbon, hydrogen, and oxygen, just as sulphur or phosphorus is in the albuminous substances. Its presence is indispensable for the formation of the colouring matter; therefore is iron so efficacious in many diseases, when the blood contained in the finest vessels, and shining through the skin, has lost its colouring matter. This red pigment of the blood, when fresh, is soluble in water, and is still more so in alkalies, which are even capable of dissolving it in a dry state. The alkali in the blood facilitates, therefore, the solution of the colouring matter.

No albuminous substance is so abundantly dissolved in the blood as pure albumen, which, remaining in the liquor after its separation from the clot, coagulates only at the boiling-point, just like the white of an egg. Traces of caseine are found with the albumen in the blood.

Fresh blood manifests an alkaline action with litmus. This is to be attributed to the presence of a basic phosphate of soda. Amongst the salts of the blood, phosphate of soda and bicarbonate of soda predominate. To these salts may be added the compound of potash with the same acids: besides the sulphates of soda and potash, the phosphates of lime, magnesia, and oxide of iron, are all conveyed to the blood with the chyle.

In our own times chemists have succeeded in detecting fluoride of calcium among the constituents of the blood.

Just as of all other albuminous matters existing in the serum of the blood, albumen, strictly so called, is the most abundantly represented; so also common salt, or chloride of sodium, predominates among the inorganic substances. Chloride of potassium is present in relatively smaller quantity.

Blood contains, if examined when taken quite fresh from the living body, oleine and margarine. But they are very rapidly decomposed into oleic and margaric soaps, by the influence of the albuminous substances and the carbonates of potash and soda in the blood. With them another fatty substance is also present, remarkable for the amount of nitrogen and phosphorus which it contains; and a second, distinguished from most vegetable and animal fats by its phosphorus.

Analogous to the neutral fats, consisting only of oxygen, hydrogen, and carbon, we find a compound intermediate between fat and wax, containing less oxygen than the former, and incapable of being saponified, bearing the name of bile-fat, only because it had first been discovered in the bile.

Sugar is always found, only in a small quantity, in the blood. Before it reaches the circulation, it has been for the greatest part transformed into fat.

In order to give an idea of the proportionate quantity of the constituents of the blood, in round numbers, we add the following summary review. A thousand parts of blood contain—

Fibrine	2
Blood globules . . .	131
Albumen	71
Compound of chlorine and salts .	5
Fat	2
Water	789
Total	1000

ORIGIN OF THE SOLID SUBSTANCES OF THE HUMAN BODY.—§ 10. The blood is conveyed from the heart to all parts of the body. The heart propels it, by regular contractions, into the vessels, which have also a regular pulsation, and are called *arteries.* These ramify in smaller and smaller vessels, which at length, from their minute size, are called *capillaries*, and pervade in very great number all the organs of our frame. By means of the arteries, every part of the body receives arterial blood.

The dissolved substances of the blood pass everywhere through the walls of the capillaries, forming thus what is called the *juice of nutrition.* As the fluid from which crystals are precipitated is called mother-lye, so we may call this juice of nutrition mother-juice of the solid constituents of the body; for all vesicles or cellules, fibres, and formless deposits, composing the several solid parts or tissues, are formed from the substances dissolved in the juice of nutrition. This mother-juice, at the same time, owes its immediate origin to the blood.

§ 11. As the transudation of the blood is dependent on its 789-thousandths of water, all solid parts of our body are, and most of them very abundantly, saturated with this liquid. But the water of the blood never passes through the capillaries without salts.

A certain quantity of the inorganic constituents of the blood is therefore to be found in all tissues. Some of them are, however, remarkable for a very especial affinity to certain tissues. Thus, in the bones, basic phosphate of lime predominates not only above all other inorganic substances, but also above all their other components. The affinity of common salt to the cartilages is equally conspicuous. The muscles, on the other hand, contain an equally large portion of chloride of potassium, the quantity of common salt being but small. Thus, while the blood contains much more common salt than chloride of potassium, the muscles possess much more of the latter than of the former.

Fluoride of calcium is another inorganic constituent, which, whilst contained in the blood only in a small quantity, forms a necessary material for certain tissues. Bones and teeth regularly attract this substance from the blood. Herein, also, we may recognise one of those peculiar affinities of tissues for certain inorganic substances of the blood, which are so frequently met with.

Carbonate of lime, or chalk, which of itself is insoluble in water, has not yet been discovered in the blood; but it is possible that it may pass as such through the circulation into the bones; for the carbonic acid and chloride of potassium of the blood, have the power of keeping small quantities of carbonate of lime in a dissolved state; and one part of the carbonate of lime is formed out of the sulphate of lime, which reaches the blood with the water and other nutriments we take. This sulphate of lime is decomposed by carbonate of soda, so as to form sulphate of soda and carbonate of lime. This new compound is a characteristic constituent of the bones.

§ 12. With a small quantity of most of the inorganic compounds in the juice of nutriment, a part also of the albumen of the blood passes into all tissues.

But certain laws of affinity prevail also amongst the albuminous substances, which determine their appearance in a regular way. Thus the crystalline lens of the eye appropriates the globuline of the blood; the walls of the blood-vessels, caseine; and the muscular tissue, fibrine.

It is true the latter is not entirely identical with the fibrine of the blood; for it is not in the muscles in a dissolved state, but forms fibres, which are characteristic of flesh. And yet this fibrine of the muscles is more easily dissolved in water containing a few drops of hydrochloric acid, than coagulated fibrine of the blood.

The influence of these laws of affinity is still more extensive with regard to those tissues which contain modified albuminous substances. To these belong *horn*, *gelatine*, and *the substance of the fibrous tissues*.

Horn is composed of nitrogen, carbon, hydrogen, and oxygen, in proportions altogether similar to those of the albuminous substances. It covers the outward surfaces, it lines the walls of all cavities of the body; for the epidermis, nails, hair, the coating of the mucous membranes lining the cavities of the intestines, the windpipe, mouth, and other interior parts of our body, consist of horny substances.

But though these parts, so different externally, are all called horny substances, on account of their affinity in composition with the horns of cattle, they are by no means identical; for, apart from the differences of their qualities, which certainly are not very considerable, they contain certain quantities of sulphur, which element, besides nitrogen, carbon, hydrogen, and oxygen, is to be found in all of them. The smallest quantity of sulphur is contained in the epidermis, and the coating of the mucous membranes; the nails contain more, the hair most. The two latter are with very great difficulty soluble in acetic acid. All horny substances agree with each other, and with the albuminous substances, in their solubility in potash, from which solution they are precipitated by acids.

We have to distinguish two kinds of gelatine: the one is prepared from the cartilages, the other from the bones.

Bone-gelatine is obtained by boiling bones in water. A saturated hot solution, which has been thus prepared, coagulates, when cooling, into a thick gelatine, which swells by the addition of cold water, and is dissolved again when boiled. In short, this substance is the well-known glue, which plays such an important part in the ordinary affairs of life; it is the same substance, better known as jelly, into which veal broth coagulates in cooling. But gelatine is not, as such, contained in the bones; it is produced by a slight transmutation, which this organic basis of the bones undergoes in boiling. Therefore bones are called a gelatine-yielding tissue, which appellation is justly extended to many other component parts of our body; that is to say, to those fibres which, accumulated in bundles, invest most instruments of our body, and connect them with each other. For the last-mentioned property they are sometimes called binding tissues, though generally known as cellular. The stratum of the skin beneath the epidermis, the exterior covering of the lungs, intestines, muscles, nerves, bones, and of many other organs, consist, for the greatest part, of fibres, which, as well as the bones themselves, yield gelatine when boiled. The bones furnish a clear evidence of the affinity of the gelatinous tissues for phosphate of lime.

Nitrogen, carbon, hydrogen, and oxygen, with a very small quantity of sulphur, compose the bone-gelatine. This is soluble in hot water; and has the important property of not being precipitated from this solution by acetic acid.

Similarly to the bones, the cartilages yield, when boiled for a length of time, a peculiar gelatine, called gelatine of cartilage. This contains the same elements as the bone-gelatine, only in other proportions. While it agrees with the latter in stiffening to a jelly when the hot solution cools, it is the distinctive character of gelatine of cartilage—that strong acetic acid produces a precipitation from a solution of it in water. We refer here again to the above-mentioned affinity of the tissue yielding gelatine of cartilage with common salt.

Whilst horn and gelatine possess an essential similarity in their composition to the albuminous substances of the blood, by containing sulphur, the elastic fibres are without this ingredient. But the latter still contain nitrogen, carbon, hydrogen, and oxygen, in such a proportion as to remind us directly of the albuminous substances in spite of this difference. Their absolute insolubility in water, as well as their resistance to acetic acid and potash, prove, however, that with respect to their properties they deviate the farthest from the albuminous substances. In these dissolving media they keep for days entirely undissolved.

Elastic fibres are found in an abundant quantity in the ligaments, which unite together the different bones of the spine; besides being found in the lungs, the walls of the arteries, and isolated in many other parts of the body.

That horn, gelatine, and the substance of the elastic fibres, are justly to be regarded as modified albuminous substances, is proved by the fact, that, with the exception of a very small quantity of fat containing nitrogen and phosphorus, no other compounds of nitrogen are present in the blood than the albuminous matters, which also alone contain sulphur. Horny substances and gelatine, both of which contain sulphur, can thus only have their origin in the albuminous principles of the blood. Perhaps it might be suggested, that the fat of the blood, which contains nitrogen, may produce the substance of the elastic fibres; but the quantity of this fat is much too small for the considerable quantity of elastic fibres in our body to be derived from it. The conclusion that the albuminous compounds are the only originating source of the horny substances, gelatine and the elastic fibres, is rendered unquestionable by the fact, that none of these substances are found as such in the blood.

§ 13. In fresh tissues, fatty substances are only present in the form of neutral fats, as oleine and margarine.

There is scarcely any part of the body from which these neutral fats are entirely absent. There is, however, very little fat in the lungs, and less in the teeth. It exists in great abundance under the skin; in the bones as marrow; in the mesentery, by which the intestines in the abdominal cavity are, as it were, suspended; in the orbit of the eye; and in the female breasts. The smoothness and roundness of the forms of females and children are chiefly attributable to the layers of fat, which cause the soft convexities of their skin. This fat is much less abundant under the skin of men; and the forms, therefore, of their bones and muscles are much more strongly defined.

Oleine and margarine are mingled in very different proportions in different parts of the body; and margarine coagulates more readily than oleine. It follows, that the greater the predominance of oleine and margarine in any part of our body, the greater also will be the lubricity and fluidity of the fat; as, for instance, in the marrow of the bones, and in the fat under the skin. The firmer fat again, which, for instance, surrounds the kidneys, contains more margarine than oleine.

We find the bile-fat of the blood unchanged in the brain; but the latter contains, besides this, oleine, margarine, and another kind of fat, in which carbon, hydrogen, and oxygen, are combined with nitrogen and phosphorus. Without this peculiar fat the brain cannot exist. It is remarkable that this brain-fat has been detected not only in the blood, but also in the yolk of eggs.

§ 14. Sugar is a regular constituent of the liver; the muscles contain also a peculiar kind of sugar, called sugar of the muscles. Lactic acid—a substance soluble in water, and compounded of carbon, hydrogen, and oxygen, exactly in the same proportion as in sugar of grapes—is found in the muscles in considerable quantities. In the brief description of digestion, we saw that, by the influence of the bile, lactic acid is formed from sugar. It is more than probable, that, in the muscles also, lactic acid is produced from their peculiar sugar; in short, the constituents of fat are also present in the different tissues, though in a very small quantity.

§ 15. *Organs of Secretion.*—The sum of the processes which we have described in a former section, in order to explain the origin of the solid constituents of our body, is designated by physiologists as nutrition in the strictest sense. Not all matters, however, which transude through the capillaries from the blood are to be considered as having a direct share in the origination of the solid constituents. A very great proportion of the transuded matters does not contribute to the nutrition of the tissues, but remain as a liquid; which, having been attracted or prepared by certain organs from the blood, is collected into receptacles, and out of these discharged into certain cavities of the body, or altogether out of it. These receptacles are often simply canals, called secretory ducts of the organs; whilst the organs themselves are called glands. In other cases, the secretory ducts lead, before they discharge the liquid, into wider reservoirs, called bladders. Thus we have a seminal bladder, a gall bladder, and a urinary bladder.

The fluids, which are attracted and collected from the blood by the glands, are, in some respects, of a special and immediate use in relation to the body, by assisting the functions of reproduction and digestion. All fluids which co-operate for these two essential functions, in preserving the species and the individual, are included under the general head of secretions. In all secretory fluids there is contained more or less water, which is a necessary condition of transudation generally.

§ 16. We begin with the ovum, not only on account of its importance in the preservation of the species, but because, next to the tissues, it is the firmest of the products of secretion. It forms, therefore, a kind of transition from the tissues themselves to the secretions. As the human ovum, in the earliest state of its development, can only be perceived by a high magnifying power, its investigation has been incomplete. We know certainly only this, that it consists of an albuminous substance, combined with oleine, margarine, brain-fat containing phosphorus, bile-fat, sugar, and the inorganic constituents of the blood.

§ 17. The seminal fluid can also be subjected only to a very imperfect analysis; but its chief constituent, the seminal principle (spermatine), is, in its essential properties, so nearly analogous to albuminous substances, that we may, without hesitation, classify it with them. Should future investigations confirm the slight distinction already observed, the seminal principle will still be proved to be a compound very similar to the albuminous substances; but it is not real albumen, as it does not coagulate by boiling. The seminal fluid contains, moreover, some true albumen combined with soda. Some fat and inorganic substances are also found in it; but their properties and proportionate quantities have not been accurately investigated.

§ 18. An albuminous compound, which as such is found in the blood, though in small quantity, is abundantly collected towards the end of pregnancy and after confinement, in the breast or lacteal gland of the female. It is the caseine, which, as contained in milk, forms an essential alimentary principle for the infant.

Caseine is the substance which coagulates at the surface of boiling milk, in the form of folded, wrinkled membranes, which, as often as they are taken off, are succeeded by others. It is completely and rapidly separated in thick flakes, if milk, which when fresh is alkaline, is boiled with an acid—for instance, with acetic acid. In this way milk is separated into a firm part, which contains, besides caseine, a great quantity of fat; and into a liquid, in which are sugar of milk, the rest of the milk-fat or butter, certain inorganic substances, and the acid which has been added; this last liquid represents the well-known whey.

The sugar of milk is a constituent of fat, like the sugar of grapes, into which the former can easily be transformed by acids. Sugar of milk differs from the sugar of grapes in being incapable of vinous fermentation by the addition of yeast. This fermentation consists in the change of sugar of grapes into spirit of wine and carbonic acid; but as acids transform sugar of milk into sugar of grapes, the former also is mediately fermentable. Sugar of milk is soluble in water, and consists, like lactic acid, of carbon, hydrogen, and oxygen, in the same proportions as sugar of grapes.

It is peculiar to sugar of milk, that its sweet taste is very slight. Here also we see, as formerly, when speaking of acids and salts, that taste is a very deceptive test of chemical distinctions. As sugar of grapes is found in the chyle and blood, and corresponds in its composition and properties very nearly with sugar of milk, the latter is therefore to be derived from the sugar of grapes, and also from the amylaceous substances of our nutriment, which are transformable into sugar.

When we speak in ordinary life of butter, this has a much wider signification than chemists attach to the name of butter-fats, or butyrine. In the latter sense, we understand by it a neutral fat—fluid at ordinary temperatures—which, when combined with alkalies, produces a soap, the acid of which, when free, is very volatile, and possesses a strong acute smell and taste of butter. This acid is, therefore, called butyric; but in butter, butyrine is mixed with oleine and margarine; and by the saponification of butter, we not only obtain alkali-salts of oleic, margaric, and butyric acids, but also of three other fatty acids, which, like butyric acid, are remarkable for their volatility and pungent smell. We shall call them caseic, sudoric, and capric acids (capronic, caprylic, and caprinic acids of other authors)

While butyric acid, with other fatty acids found in our bodies compounded with glycerine or alkalies, contains, in proportion to oxygen, the least quantity of carbon and hydrogen, the two latter elements are more abundantly represented in the three other volatile acids of the butter—namely, caseic, sudoric, and capric acids; the first containing the smaller quantities.

As milk contains, among its inorganic constituents, common salt and chloride of potassium, which is similar to it, as well as the compounds of potash, lime, magnesia, and oxide of iron, with phosphoric acid, it is apparent that the most important base, and the most important acids, together with the compounds of chlorine of the blood, are represented in milk; that is to say, all the inorganic substances to which different tissues possess a distinct and peculiar affinity, are there represented.

§ 19. Saliva, gastric juice, bile, pancreatic and intestinal juice, have already been discussed, according to their several parts in the digestive process. We have briefly to review them here also, as they take an important place among the substances transuding from the blood, through the walls of the capillaries. An albuminous compound, which, from its presence in saliva, has been called the saliva principle (ptyaline), oleic and margaric alkalies, bile-fat, a fat containing phosphorus, and all the inorganic substances which are contained in the blood, clearly bespeak the origin of saliva, which appears in the mouth, mixed with mucus.

In the saliva, as it flows from the secretory canals of the salivary glands, alkali predominates. Why, at the same time, the fluids of the mouth are so seldom found acid, is not yet thoroughly known; as, according to the most recent researches, even pure mucus of the mouth, unmixed with saliva, appears to possess alkaline properties.

§ 20. Gastric juice, furnished by the small glands of the stomach, also contains an organic substance, which, like the albuminous matters, is neither alkaline nor acid, but consists of nitrogen, carbon, hydrogen, and oxygen; and is, at all events, closely allied with the albuminous matters, though it differs from them in some less essential properties. As it cannot be denied that this combination has a highly important influence in dissolving the albuminous substances, the digestion of which is one of the first conditions of the formation of blood—it has, therefore, not improperly been called, *par excellence*, the digestive principle, or pepsin. The digestive principle is, however, very vigorously supported in its dissolving action by a free acid, to which the gastric juice owes the property of reddening litmus. This is to be considered, according to the most recent investigations, as hydrochloric acid.[*]

Among the inorganic substances of gastric juice, we have besides to mention the compounds of chlorine with sodium and potassium, calcium, magnesium, and iron, and with the phosphoric salts.

§ 21. In the secretion of the liver, there are two peculiar organic acids, one of which, containing only nitrogen, carbon, hydrogen, and oxygen, is called *cholic acid;* the other, which, besides the four elements mentioned, contains a very inconsiderable quantity of sulphur, may be called sulphurised cholic acid. Apart from the liver, no trace of these acids is to be found in the blood. They are therefore not elaborated in the general circulation, but by the action of the liver.

A sweetish-bitter taste is not only peculiar to these acids, but also to their combinations with sodium. In the latter form they are soluble in water.

The combination of both these acids leaves no doubt that the albuminous substances of the blood are essential to their formation. Oleine, margarine, and gall-fat, accompany the combinations of potash with cholic acid and sulphuretted cholic acid.

The bile owes its yellowish-green colour, sometimes inclining to brown and sometimes to green, to several organic colouring matters containing nitrogen; and its alkaline character to phosphate of soda, a salt in which the alkaline ingredient predominates. The other inorganic substances are common salt, chloride of potassium, carbonated alkalies, and the phosphorates of lime, magnesia, and oxide of iron.

§ 22. The pancreatic juice is a fluid containing so much albumen, that it coagulates by heat almost as completely as the white of eggs itself. The alkaline property of this secretion, certainly, greatly contributes to its carrying with it so much albumen from the blood into the cells of the pancreas. The albumen of the pancreatic juice, however, does not entirely correspond to that of the blood. Both are precipitated by alcohol from their solution in water; but if we dry the albumen of the blood which has been precipitated by the alcohol, we cannot dissolve it again in water; while the albumen of the pancreatic juice is even then soluble.

Besides margarine, and some other organic substances which have been very imperfectly examined, because of the difficulty of procuring pure pancreatic juice, we find in this liquid common salt, chloride of potassium, phosphorates, carbonates, and sulphates of the alkalies, and lime combined with carbonic and phosphoric acids.

§ 23. With all digestive fluids is mixed a certain quantity of mucus, which is alkaline in the mouth, and is said to be neither acid nor alkaline in the empty stomach. In the intestines this mucus is not only mixed with all the above-mentioned digestive fluids, saliva, gastric juice, bile and pancreatic juice, but contains also a peculiar secretion attracted from the blood by certain small glands in the walls of the intestines. These glands, however, are small, and the quantity of their secretion is scanty; but the quantity of the other digestive fluids mixed with it is abundant. Therefore we know of this intestinal juice nothing more than that it possesses alkaline properties.

Mucus contains, first, a peculiar element of which little is known, but from which it derives its property of cohering in threads; secondly, a number of horny cellules, detached from the interior coating of the intestinal canal; and finally, a combination of carbonate, phosphate, and sulphate of soda, phosphate and carbonate of lime, and oxide of iron.

§ 24. *Decomposition and Transition.*—It is a fundamental property of the organic substances of our body, that their combinations possess very little permanence. A perpetual process of transition from one state of being to another, constitutes a grand circle, of which the nourishment of man himself forms but one little segment. The life of plants and animals is not only a direct result of this constant change of matter, but all organic life is a continuous process of alternate combination and decomposition, to which higher and lower influences, cooperating in essential harmony, contribute. What plants absorb from the soil and the air, they transform into substances on which the herbivorous animals feed; and by the latter they are retransformed into animal food for the support of carnivorous classes, as well as for those which feed upon a mixed diet. To the latter class, man himself belongs. Then that which is given off in an uninterrupted series of various kinds of decomposition by men, animals, and plants, during life and after death, returns again into the air and soil as material for the growth of another generation of plants. Here again the process of transition recommences, and a perpetual and ceaseless revolution is pursued.

It is during life itself that this decomposition takes place. In the very tissues, a regressive metamorphosis, so to speak, has already begun; for the oxygen of the air, which we incessantly inhale, is conveyed to all parts of our body. And no element exerts a mightier influence in the formation and dissolution of organic combinations than oxygen.[†] Exposed to the continual action of this element, which all kinds of vegetation are unceasingly giving forth into the atmosphere,[‡] no organic combination of our bodies can maintain its permanence. Albumen, gelatine, and fat, fibrine and sugar, all are gradually rearranged into compounds, containing at every step an increased quantity of oxygen. These revert from the tissues into the blood, from which they are attracted by certain glands, collected into receptacles, and at last ejected externally. This ejection is called excretion.

§ 25. *Connection of Excrementitious Bodies with the Tissues.*—Decomposition continually goes on in the tissues; for what physiologists of a former age had rather conjectured than proved, has been triumphantly demonstrated by more recent investigations; and it is now known that the constituents of the tissues gradually deposit a sediment, which, being unfit for the functions of the organs in which it accumulates, is conveyed back to the blood, in order to be excreted from it.

---

[*] See *ante*, p. 317.

[†] See *ante*, p. 313.

[‡] See *ante*, p. 315.

The most important substances which are excreted, have, in the course of physiological science, been traced from the blood into the tissues. The blood contains urea; the vitreous humour of the eye does also; carbonic acid is present in a large portion in the blood, and is likewise to be found in every solid part of our bodies; and carbonic acid and urea are the principal products of decomposition, which the lungs and kidneys abstract from the blood, in order to remove them as waste material from the body.*

A process which ceases not even for a second, and in which one development is continually following another without any cessation, can evidently be marked at certain stages of the transformation only. Therefore we cannot make out, in an uninterrupted chain, the whole series of intermediate conditions through which the albuminous and adipose substances pass, before being wholly decomposed into those simple products, urea, carbonic acid, and water. But since, through the increasing number of investigators, aided by instruments of greater delicacy, more and more points of transition have been found in the series conducting from the constituents of the blood, through the tissues, to the excretions, we are able confidently to assert, that we are pursuing our investigations in the right direction.

We cannot, at present, draw any distinct limit between substances belonging to the development, and those belonging to the tissues. But no greater praise can be bestowed upon the physiologist, than that he breaks through the barrier by which it has too often been attempted to enclose certain parts of nature, and to blockade the understanding of man. The transitions of nature are numberless. The boundary-lines between the several classes of natural bodies lose their distinctness in proportion to the extent and depth of our scientific knowledge.

To the substances transitional between development and regressive transformation, belongs a combination consisting of nitrogen, carbon, hydrogen, and oxygen, which is found in the juice of flesh, and which may be called the *flesh-principle*, or kreatine. It is not yet known what intermediate substances connect this principle with the albuminous compounds from which it originates; we only know, that by the mere presence of acids, which are never absent from the flesh, kreatine is transformed into an alkaline substance, which is to be found, not only in the flesh, but also in the urine. This substance may be called the flesh-basis, or kreatinine, and considered as decidedly an excrementitious body, which has passed into that stage in the tissues themselves; being formed from the albuminous matters, and having passed beyond the intermediate state of the kreatine. The acid peculiar to the flesh, technically called inosinic acid, which is to be found in the muscles, associated with lactic acid, most probably belongs also to the products of regressive transformation, although it has not hitherto been discovered in any excretion, but only in the flesh itself.

Like the flesh-principle, so are the peculiar basis and acid of the flesh, compounded of nitrogen, carbon, hydrogen, and oxygen. The flesh-principle is transformed into flesh-basis by the subtraction of water only. Flesh-acid is remarkable for containing a high proportion of oxygen. While the flesh-principle, as such, combines neither with bases nor acids, the flesh-basis unites, as its name indicates, with acids, and the flesh-acid with alkalies. Flesh-basis and flesh-acid are easily dissolved in cold water; the flesh-principle with more difficulty, requiring boiling-water, which dissolves it in great abundance.

These illustrative examples may be sufficient to establish the general proposition, that the formation of the excrementitious bodies begins in the tissues themselves, and that the function of the excretive glands is mainly to attract and elaborate these substances from the body; for the products of the regressive metamorphosis pass from the tissues into the blood, and from the blood into the excretive organs.

§ 26. *Excreting Glands.*—If among these glands the most important place is ascribed to the respiratory organs, the conviction is founded upon the fact, that the functions of the lungs can least of all bear interruption without disturbing, or altogether destroying, the activities essential to life. That element in the surrounding atmosphere, therefore, which is absolutely necessary for respiration, may be called vital air. This vital air is the oxygen, which is the mightiest agent in producing the metamorphosis of tissues.

The air we breathe is a combination of oxygen with a large proportion of nitrogen, a little aqueous vapour, and still less carbonic acid. While the oxygen at every inspiration enters the lungs in order to impart to the blood its proper composition, the carbonic acid of the atmosphere, on the other hand, originates from the breath given out at every expiration from the lungs of men and animals. Valuable researches have shown that this carbonic acid penetrates from the air into the leaves of plants, in order to supply the principal nutriment to these numberless green and flowering products of nature, which form such an essential condition of animal life: not as nutriment alone, for it is the vegetation of the earth which gradually decomposes the carbonic acid which it has absorbed, and whilst it keeps the carbon for the formation of its own tissues, exhales the greater part of the oxygen; the latter being called, as we have seen, and with the greatest propriety, the vital air of men and animals.†

The carbonic acid which we breathe out is, as before mentioned, to be traced so far back as the tissues themselves; from these it penetrates into the capillaries in order to pass into certain canals, in which the blood flows in a direction opposite to that of the arteries. These canals are called *veins*, and are distinguished from the latter by not possessing pulsation.

The blood which the arteries have conveyed from the heart to the remotest organs of our body, having been changed by the substances which it has lost, and by others which it has taken up during its course, flows through the veins back again to the heart, thus forming a true circulation. This circle is completed by the capillaries, which connect the arteries with the veins.

The venous blood contains an abundant quantity of carbonic acid; but this product of decomposition does not originate exclusively from the tissues, and pass therefrom into the veins, inasmuch as the arterial blood itself is already impregnated with a certain quantity of carbonic acid, formed in this part of the circulation. The venous blood, however, contains more carbonic acid than the arterial, the former receiving an additional supply of this gas from the tissues.

Besides the great circulation from the heart, through the tissues, and back again to the heart, there exists also a small circulation of the blood; for all the blood of the veins, which flows into a special compartment of the heart, is propelled therefrom into the lungs, and returns from these into the heart, after having been changed in a peculiar way. The blood flowing from the heart to the lungs is dark-red, even brown-red, containing but little oxygen and much carbonic acid; and this is the character of the venous blood in general. But in the lungs, to which an abundant quantity of oxygen is conveyed with the inhaled air, carbonic acid and aqueous vapour pass from the venous blood into this organ, and are compensated by the inhaled oxygen which transudes into these vessels. By this process the blood becomes light-red, containing less carbonic acid and water than that of the veins. The blood thus transformed, returning from the lungs, is now called arterial, as it corresponds with that of the arteries. It is the blood of the arteries themselves, because it is conveyed to them by the heart, in order to permeate all tissues again with nutritious juice.

---

* See *ante*, p. 326.

† See *ante*, p. 315.

In its course from the heart through the tissues, the venous blood is therefore formed, which in the great circulation flows back again to the heart; and this blood, which in nourishing the tissues has undergone such important changes, is supplied again with oxygen while passing through the lungs, and thus adapted, in return, for the nutrition of the tissues; in short, it is transformed again into arterial blood.

As the ovum represents, among the secretions, a transition stage between these and the tissues, the lungs may be considered as organs, holding, in respect of their functions, an intermediate position between reception and separation. Carbonic acid and water are the excretions which they give out, and in return they take in oxygen. Without oxygen, no arterial blood, and without arterial blood, no nutrition could be produced. If the nutrition be interrupted, the functions of all tissues are deranged. The muscles cannot contract themselves, the nerves lose their irritability, the reasoning faculty of the brain is disturbed, if the blood cease to furnish these organs with their peculiar combinations; and this latter process is dependent on the supply of oxygen; for all organic constituents of the blood are gradually transformed by oxygen. The albuminous and fatty substances have, without any exception, so great an affinity for oxygen, that they are gradually decomposed into combinations containing it. Oxygen passes also through the capillaries into the tissues themselves; therefore the venous blood contains less oxygen than the arterial, and the manifold decomposition becomes possible to which we have already stated the tissues are subjected.

We recognise in the flesh-principle, the flesh-basis, and the flesh-acid, a few of the intermediate stages through which the albuminous substances pass by the influence of oxygen. The last results of this influence are the urine-principle, or *urea*, carbonic acid, and water. The different fats are also transmuted into carbonic acid and water, with even greater readiness than albumen, as their greater amount of carbon and hydrogen facilitates their combustion with oxygen. Thus, we daily exhale through the lungs, in form of carbonic acid and water, about one-third part in weight of the nutriment we have taken. As this combustion depends upon nothing else than a combination of oxygen with other elements, it follows clearly, that the inhaled oxygen, the affinity of which acts slowly but without interruption, burns down entirely all the organic substances of the blood.[*] For this process four or five days only are requisite.

This act of combustion, in great part, explains why the temperature of the human body continually exceeds that of the surrounding atmosphere. The difference between the temperature of the latter and of our own body is, in scientific language, designated as *proper heat.* This proper heat varies according to the temperature of the external air, while the actual heat always remains the same. The average amount of the latter is 98° F., without fluctuating a single degree during health.

§ 27. Though a part of the albuminous matters of the blood is lost from the body with the exhaled air, in the form of carbonic acid and water, still the kidneys are the principal organs which withdraw the waste albuminous bodies from the blood; for the urine, which is excreted by the kidneys, collected in the bladder, and voided externally by the urethra, is a solution in which urea, uric acid, flesh-basis, and flesh-principle are contained; all being substances whose amount of nitrogen, carbon, hydrogen, and oxygen, evinces their origin from the albuminous substances.

The flesh-basis and flesh-principle we have already described. They are present in the urine, but in very small quantities. This excretion contains also, in a somewhat greater quantity, uric acid—a substance scantily soluble in cold water, which, however, is dissolved in the urine as a urate of soda. Urea is easily soluble in water, and is contained in the urine in the most abundant quantity.

Besides the uric acid, the human urine sometimes also contains some lactic and butyric acids, with another acid nitrogenised, and peculiar to the urine of herbivorous animals, which chemists call uric acid of horses, or hippuric acid, as having been first detected in the urine of those animals.

But none of these acids have been found in the urine in an uncombined state. The acid reaction, however, of this excretion, is produced by an inorganic salt, termed acid phosphate of soda, in which the acid predominates. The more important concomitants of this salt in the urine, are common salt and alkaline sulphates; but chloride of potassium, and the phosphates of lime and magnesia, are also found in the urine, which sometimes also contains traces of iron and of fluoride of calcium.

The quantity of urine voided in twenty-four hours, amounts to about one-third of the weight of the nutriment taken in the same time.

§ 28. *Constituents of the Secretions.*—It is a very general popular belief, that the excrements are only formed from the undissolved remains of food. Though these constitute a not inconsiderable portion, it is quite a mistake to suppose that this excretion is not essentially mixed with other constituents, owing their origin to the blood; for how could we doubt that the capillaries, which exist in the intestinal walls in such abundance, would allow any substances to transude into the intestinal cavity, as this transudation is the indispensable condition of any transition of dissolved substances into these blood-vessels? All animal membranes, which are moistened on each side by different fluids, permit substances to pass through in such a manner, that the matters transuding from one side are replaced by those which similarly pass from the other. The excrements are also mixed with a proportion of digestive fluids, mucus, products of decomposition from the bile, horny cellules from the mucous coating of the intestines, and other substances, which, when once secreted, do not return again to the blood.

The undissolved remains of our nutriment, which form the excrements with the substances just mentioned, are in part the insoluble, or hardly soluble constituents of the food, as the elastic fibres of animal food, and the cellular principles of vegetable nutriments, of which we shall treat in detail hereafter. There will also be found in the excrements such aliments as of themselves are soluble in the digestive fluids, if the quantity of the latter have been too small in proportion to the nutriment to effect its solution. Thus, a very great variety exists in the composition of the organic constituents of the excrements.

Of the inorganic constituents of our food, the rectum discharges, more especially the earths, the lime and magnesia salts, together with a considerable quantity of iron, on which, as well as on the constituents of the bile, the colour of the excretions is principally dependent. The soluble salts of the alkalies are also to be found in these excretions, partly transuded from the capillaries of the intestines.[†]

§ 29. *Excreting Powers of the Skin.*—Besides the lungs, the kidneys, and the rectum, the skin has to be mentioned as another most important organ of excretion. Not only do the capillaries of the skin keep up an uninterrupted discharge of carbonic acid, and take in oxygen in return; but this organ is also abundantly provided with small glands of two kind, excreting from the blood the perspiration and the sebaceous or greasy substance of the skin, which are therefore called sudoriferous and sebiperous glands.

The perspiration contains many regularly detached scales of the epidermis. Besides a small quantity of fat, several volatile organic acids, consisting only of carbon, hydrogen, and oxygen, are the principal constituents of the perspiration. The chemist calls these butyric, butyro acetic, and formic acids, and classes them in one group as being in their composition very similar to the fatty acids, to which butyric acid belongs; also with respect to their various properties. These acids occasion the sourness of the perspired fluid. Common salt, chloride of potassium, sulphates and phosphates of the alkalies, and traces of phosphates of lime and iron, are also dissolved in the perspiration.

---

[*] See *ante*, p. 315.

[†] It has been lately discovered, that an excess of fibrine, when taken as food, is always excreted from the body, by the rectum, in an unchanged state.—Ed.

To the perspiration may be added the tears. These are continually secreted in a very small quantity by a gland situated in the external corner of the eye, underneath the skin. From hence they flow over the surface of the eyeball to the internal corner, where they are reabsorbed by an aperture in each eyelid, leading by a minute canal into the nasal cavity, to be excreted with the nasal mucus.

The tears are a very diluted solution of common salt, mixed with some detached cellules from the external coating of the eyeball.

The sebaceous matter of the skin is also a mixture of detached epidermic cellules with some other substances, of which fat and some salts are the principal components. It has, however, a different composition in different parts of the skin. The ear-wax, for example, is remarkable for a bitter yellow substance, soluble in spirits of wine, and for a portion of gall-fat.

§ 30. *External Excretions.*—Just as a part of the intestinal mucus is voided as an excrementitious matter, so the mucus of the other parts of our body—of the nose, windpipe, lungs, urinary ducts, and the several organs principally of women—is to be considered an excrementitious substance.

As a considerable part of the mucus is represented by *horny substances* which coat the mucous membranes, with these excretions may be included those parts of the hair and nails which, being cut off and growing again—as if the younger parts pushed the older parts upwards—form a regular part of the expenditure of the body. It is the same with the epidermis, which is continually scaling off.

The organic origin of all these horny substances is to be derived from the albuminous compounds, which are, by their transformation into the former, separated from the blood; one part of a tissue is thus directly lost without having passed again through the blood from which it originated.

ON HUNGER AND THIRST.

§ 31. *Principle of Reparation.*—It has been mentioned, in a previous section, that one-third in weight of the food we take during twenty-four hours is lost with the urine, and another third with the air exhaled. Another third of the consumed aliments daily leaves our bodies in the form of excrements, perspiration, mucus, fat, tears, and detached horny matter.

It is evident that this does not mean an immediate excretion of alimentary principles as such; for, excepting the undissolved remains of food which the rectum expels with the excrements, there is no substance in our excretions which had not passed from the mouth through the blood to the tissues, and from these back again through the blood to the organs of excretion. Thus, for example, the carbonic acid and water which we exhale, have once been fat or albumen, and the urea has nourished the tissues in the form of an albuminous constituent of the blood, before the kidneys convey it as a useless sediment of the body to the expelling bladder.

This main result is not affected by the indirect mode of the excretion of our nutriment. The weight of a healthy grown-up person does not undergo any sensible alteration from one day to another; for as much as is subtracted from the body by excretion, is conveyed to it again by the food which is digested.

Thus experience teaches, when the total amount of excretion diminishes, the weight of food we take decreases also. If the proposition could also be transposed—if it were true that, with a diminished quantity of food, a proportionate diminution of the secretions succeeded, then we could learn the art of fasting, and the horse of the well-known tale would not have died the day before he promised to crown the hopes of his parsimonious master with the most brilliant realisation.

It is not, however, thus. Even when abstaining from all solid and liquid food, we exhale carbonic acid and water; the excretion of urine and excrements continues all the same, the hair and nails grow, and perspiration and mucus hourly subtract from the body its most essential constituents; and this abstinence, if continued, is only too soon followed by considerable diminution in the weight of our body.

Food only is able to obviate this decrease of weight; and as excretion takes place even if we take no food, it is less correct to say that we excrete again the aliments we have taken, than that the food restores what has been lost by the excretions. For carbonic acid, urea, salts, water; we take in exchange amylaceous and fatty matters, albumen, and inorganic substances. On this process of exchange, the metamorphosis of tissues hinges; the alimentary principles are, therefore, very often, and quite correctly, denominated the matters of reparation.

§ 32. *Effects of Inadequate Aliment.*—If the supply cease while the expenditure continues, the composition of the tissue is immediately changed; and the blood, which receives aliment not only for the tissues, but also for itself, fails in a few days, or at the longest, in a few weeks—for the oxygen we inhale wastes the blood when supplies are stopped. The constituents of the body continue, as before, to succumb to the influence of that mighty agent in the decomposition of organic matters.

The changes in composition produced in the blood and the tissues by a deficient supply, can only be distinctly observed after some time. Then we first of all notice the fat wasting away—a proof that the fats are more accessible to the action of oxygen than the albuminous substances. Carbon and hydrogen are the elements which combine with oxygen the most readily; and upon this depends their remarkable combustibility. The emaciation is, therefore, explained by the fact, that the fat substances surpass the albuminous in their quantity of carbon and hydrogen.

Next to the fats, those organs lose the most rapidly in weight which are remarkable for their great amount of albuminous substances. The muscles, the heart, the spleen, and the liver thus waste away.

From this speedy decomposition is excepted only one part of the human body, and that the part of which we should be least of all disposed to predicate a slow process of change; for, although the brain and the nerves consist almost exclusively of fat and albumen, two of the most mutable substances of our body, we know from investigation in cases of animals which have died of starvation, and of men who have succumbed to protracted diseases, that these organs have suffered the least loss of weight. The reason of this is an unresolved enigma. There is but one probable explanation for this strange circumstance—in the peculiar manner in which albumen and fat are combined in the brain and the nerves. If this combination, however, and its resistance to the influence of oxygen, cannot be sufficiently explained, we still find in this fact the best explanation of the late decay of the mental faculty, which we see so often flame up again with fallacious vivacity in the last moments of expiring life.

Slower than the fat and the muscles, but faster than the brain and the nerves, the bones, the cartilages, the skin, and the lungs waste away; including, in a word, all parts composed of gelatine, horn, and elastic fibres. These tissues owe their greater tenacity of existence to the difficulty with which they dissolve, which gives them greater power to resist the action of oxygen; for though the assertion of former chemists—that only dissolved bodies act upon each other—cannot be admitted without exceptions, yet there is scarcely any condition more favourable to chemical combination and decomposition than a state of solution.

§ 33. *Effects of Abstinence from Food.*—From a consideration of the intimate reciprocal action by which the blood is combined with the tissues, secretions, and excretions, the fact that, with a failing supply, the composition of the tissues still changes and the excretions continue, necessarily indicates an altered composition and diminished quantity of the blood. But while science endeavours to find the laws upon which this alteration in the composition of the blood is based, it has already ascertained a diminution of the colourless blood-globules in proportion to the coloured; and the decrease of the secretions after a protracted abstinence is an admitted fact. The activity of the glands of digestion, however, does not cease entirely; but the saliva, and the gastric and pancreatic juices, are decidedly diminished and altered; the saliva becomes viscid and saltish. Of the secretions, bile is present in the greatest proportion, though it also is diminished. This fact deserves so much the more attention, inasmuch as we have to consider the bile partly as a secretion and as an excretion.

It cannot surprise us that a diminution of the excretions should accompany the decay of the tissues, the impoverishment of the blood, and the impeded secretions. But although less and badly smelling air, scanty and stinking urine and perspiration, and a smaller quantity of excrements and mucus are voided, these excretions are just sufficiently abundant to prove clearly that they effect the decay of the tissues as a necessary consequence. In a smaller quantity of urine, in proportion to its contents of water, a greater quantity of urea is excreted, which explains the considerable loss of albumen in the tissues.

The proper-heat diminishes during fasting, and this completes the harmony existing between all these relative combinations; for when we exhale less carbonic acid, less carbon of the tissues is consumed; and by the smaller quantity of combustible substances which combine with oxygen, a decrease of the temperature produced in our bodies takes place.

A common tie unites matter, form, and function. The composition, the form, and the activity of the organs of our body form a chain, of which no link can be affected without a simultaneous alteration of the other two. There can likewise be no activity without continual transformation in the composition, without a perpetual becoming and ceasing to be.

During abstinence from solid and liquid food, as the composition is altered and the forms decay, the activity of all functions must necessarily deviate from that of the organs of a well-fed body. In the formation of the blood, the nutrition, the secretion and excretion, this deviation is easily to be understood, and has been, as far as necessary, examined in preceding paragraphs.

But the series of the altered functions is by no means thus closed. The muscle, lighter by having left its fat and albumen, appears a flabby flesh, which contracts slowly; the heart is inert; the number of the pulsations in a minute is considerably diminished; a sighing respiration takes place; frequent yawning, a hoarse voice, and languid movements, are all, more or less, direct consequences of the deficient nutrition of the muscles.

A bitter taste, often complained of by starving persons, comes from the bile, which is still pretty abundantly secreted, and passes from the intestines into the blood, by which it is carried to the nerves of the tongue. As the respiratory action is diminished, the combustion of that part of the bile transuding into the blood is less perfect than usual: so that a portion remains and acts upon the gustatory nerves.

In this condition, slight stimulants exercise a great effect. The light is painful, a slightly elevated sound is insupportable, and a touch excites peevishness. Perception is therefore distracted; and as memory also refuses its service, both sources of our faculty of judgment are exhausted; for what we have before met with, or now meet, induces the action of thought and judgment. But, in order to judge rightly, we must see clearly, hear distinctly, and feel without disturbance. During sleepless nights, the starving person is tormented by eagerness, the powerful lever of so many passions. He who grasps at carrion and corpses, at the flesh of his friends, or of his own body, shows a wilder longing than the imagination even of poets has ventured to conceive.

There is another instinct by which the vigour of the mind is vanquished in a more melancholy way. Hunger desolates head and heart. Though the craving for nutriment may be lessened to a surprising degree during mental exertion, there exists nothing more hostile to the cheerfulness of an active, thoughtful mind, than the deprivation of liquid and solid food. To the starving man, every pressure becomes an intolerable burden; for this reason, hunger has effected more revolutions than the ambition of disaffected subjects. It is not, then, the dictate of cupidity, or the claim of idleness, which prompts the belief in a natural human right to work and food—a motive to the force of which Christian charity itself must sooner or later give way.

All honour, indeed, to the charity which, in so many noble-minded people, anticipates and mitigates the sternness of law. We are, indeed, far from retaliating the contumacious censure with which the asserters of this right are often met by their opponents. It is the part of wisdom and comprehensive tolerance fairly to balance the merits of all opinions, and to do justice to their respective beneficial result. So much the more, however, do we consider it a duty to oppose the cogent power of convincing facts, to the rigorous sentence which makes a human right dependent upon a human grace.

Cold and rigid, the muscles quivering in the paralysed limbs; sighing, with troubled cloudy eyes, blunted sensation, and unsound judgment; the tortured wretch suffering the horrors of starvation struggles in agony, which often closes in a swoon; while sometimes a furious delirium will precede the final scene of death from exhaustion.

§ 34. *Effects of Hunger.*—We have thought it useful to describe the very extreme consequences of a deficient supply of nutriment, in order to explain by them the sensations which in general remind us to counteract the impoverishment of the blood, by a proper supply of food. The description of these sensations is the real science of hunger and thirst. For, if the blood be deficient either in its composition, in quantity, in its constituent parts, or in the rapidity with which it circulates through the organs of our body, the tissues must be nourished by other means; so likewise must the nerves, for their composition changes also with the combination of their mother-juices. But as the action, and therefore the sensation of a nerve is dependent on its composition, it follows that it must feel differently if deriving its nutriment from any other source.

If abstinence have lasted only a short time, all the phenomena occur which most people observe in themselves when awaking in the morning. The tongue is parched—*i.e.*, the coat of horny cellules lining the mucous membrane is thickened; and this condensation goes as far as the stomach. The saliva and mucus contain less water, and have often an unpleasant taste and a bad smell, as may be observed in fasting-people. Most persons, therefore, cannot eat anything in the morning until they have cleared their mouth and drunk some water. In feeble constitutions, and also in some strong ones, after a longer fast than usual, the quantity of blood present in the mucous membrane of the mouth and stomach, is perceived by a vague, unpleasant sensation in the mouth and throat, or a pressure, tension, and emptiness in the stomach; rumbling in the belly, which is hollow and drawn in. Yawning, a sensation of compression of the forehead even to headache and weakness, are the general indications of more constituents having been abstracted from the blood than is compatible with a sufficient nutrition of the nerves. Irritable persons become then so sensitive, that the least resistance, unexpectedly touching their bodies, or even an innocent word, is sufficient to put them out of humour. The total of all these phenomena, which are more or less conspicuous in different people, represents hunger.

If hunger remain for an unusually long time unallayed, the oppression of the stomach increases to pain and sickness. In autumn and winter the body becomes more sensible to cold; the general uneasiness disturbs the mental activity; unsteady thoughts are wasted in unquiet observation; and complete exhaustion is preceded by an excitement which only too often impels to unjustifiable acts.

§ 35. *Effects of Thirst.*—Many instances prove that hunger can be borne for several days before it causes death. If the fasting person drink water, this time is considerably prolonged. While, on an average, man cannot live longer than a fortnight altogether without food; there was, in 1831, an instance at Toulouse, of a convict who, preferring death by starvation to a public execution, survived for as many as sixty-three days on water alone.

Similar cases prove, that it is much more difficult to overcome thirst than hunger; and this is confirmed by daily experience. If it be alleged, on the other hand, that many people drink exceedingly seldom, and that females especially can do without drinking for many days together, neither must we forget that all food, even the driest, contains a great proportionate quantity of water.

Upon this reception of water into the system all depends. The blood and most of the tissues, with all secretions and excretions, contain an abundant quantity of water, as an indispensable condition of their right composition and proper action.

In the excretions from the skin and lungs, more than one-third of the weight of our food is daily lost in the form of water. To this a considerable quantity of water must be added besides, which is voided in the urine.

A deficient supply of water is, therefore, very soon felt; dry lips and cheeks, dryness of the tongue and throat, speedily betray the lack of that water of the mucus and saliva which ordinarily keeps the cavity of the mouth in a moist state. On the increase of thirst, the mucous membrane reddens and swells, and, after awhile, the inflamed tongue cleaves to the roof of the mouth, and the glowing breath escapes in sighs; the skin burns, because the perspiration continually diminishes; the urine becomes acid, as it contains the usual salts and less water; the slackened muscles move the limbs listlessly, and without power; mere talking or deglutition becomes an effort; groaning and quick respirations accelerate the pulse. In the action of the brain and organs of the senses, there is the same irritation as in hunger. Restlessness and despair torment with the continual representation of water and other beverages, which would allay his craving. All liquids—sea-water, tincture for the teeth, even his own urine—are swallowed, or attempted to be swallowed, by thirst-distracted man, with passionate eagerness. If no relief be given, a violent inflammation of the mouth and throat supervenes, with all the symptoms of an acute fever; sometimes the inflammation causes even gangrene of the throat, a quick, sighing respiration, and a pulse proportionally more rapid; a loose, lolling tongue, a whispering delirium and rage, ending in death, if the sufferer do not expire senseless in a swoon.

OF FOOD.—§ 36. *Definition of Alimentary Principles and Nutriment.*—From the blood are formed the tissues and the constituents of the secretions; to the blood the materials of the tissues return after having undergone a certain degree of decomposition, which renders them unfit for the peculiar functions of the different organs; and these products of decomposition are abstracted from the blood by the excretory glands, which expel them from the body.

The excretions diminish the weight of the body, and alter the nutrition of the tissues; their function depends upon their composition; and throughout a great division of the nerves of our bodies this function consists in sensation. The sensitive nerves are the media for the perception of all internal and external impressions. In the brain we become conscious of these impressions.

Hunger and thirst are the sensations which announce to the brain, through the medium of the nerves, the impoverishment of the blood. In popular language, every substance is called a nutriment which is able to quench hunger and thirst. The scientific definition of nutriment results from the cause of these sensations. Whatever substance possesses the power of restoring to the blood the essential constituents which it has lost, and begins the circulation from the blood through the tissues, may be considered a nutriment in the widest sense.

All the aliments which restore to the blood the compounds of chlorine, the salts, the fat, and the albumen, satisfy the sensation of hunger; that of thirst is quenched by the restoration to the blood of the deficient water.

§ 37. *Alimentary Principles.*—All nutriment is composed of certain *alimentary principles.* Under the latter term we comprehend all those compounds which are either identical with the essential constituents of the blood, or sufficiently similar to be transformed into them by digestion. Essential constituents of the blood are all those which do not originate from the regressive transformation of the tissues.

To this general definition we have to add, as a special one, the difference between alimentary principles and aliment. By ordinary dissolving media, like water, alcohol, and ether, simple constituents can be separated from the aliments, but not from the alimentary principles. These simpler constituents of the aliments, which cannot be separated by common dissolving media into any further parts, are the alimentary principles themselves.

Though the alimentary principles are often denominated the elementary constituents of the aliments, they are by no means to be confounded with the elements in a chemical sense. The latter cannot be decomposed into other substances manifesting, abstracted from form and colour, any essential differences; the alimentary principles can be decomposed, but only by agencies which act more powerfully than simple dissolving media, like water, alcohol, and ether.

No alimentary principle is composed of fewer than two elements; the simplest alimentary principles, like water and common salt, are combinations of two elements. A great many alimentary principles, as fat, sugar, and most of the vegetable acids, contain carbon, hydrogen, and oxygen; the inorganic salts consist of oxygen combined in the basis, and the acid with two different elements. All these alimentary principles are formed of three elements.

Four elements are found in the soaps which, in addition to the carbon, hydrogen, and oxygen of these fatty acids, contain a metal, forming with oxygen the basis alkali of the soap.

Finally, those organic alimentary principles, in which nitrogen and sulphur are associated with carbon, hydrogen, and oxygen, are composed of five elements; and some others, containing phosphorus, of six. To the former belongs gelatine; to the latter, albumen.

§ 38. *Digestive Principles.*—Before discussing the process of digestion, we classified the alimentary principles into inorganic, organic without nitrogen, and organic with nitrogen.

To the inorganic alimentary principles belong the compounds of chlorine, as common salt, and the combinations of inorganic acids and bases, which chemists, abandoning the ordinary use of language, designate by the name of salts.

The starchy matters and fatty substances, with by far the greater part of the acids of our aliments, are all alimentary principles without nitrogen.

Of the organic alimentary principles, the albuminous substances, the colouring matter of the blood, and the gelatine, all contain nitrogen.

The aliments which are composed of various alimentary principles cannot be classified, in a similar way, on any chemical basis into different groups; for the same alimentary principles appear in the most different aliments, and their distinction depends either upon the quantitative proportion of the corresponding constituents, or upon some freshly supervening substances; but there is so great a variety, both in the proportion in which the ordinary alimentary substances are combined in the aliments, and in the nature and qualities of the superadded substances, that the aliments classified with respect to their chemical properties could be united into very small groups only—a circumstance which would render difficult the review of the whole.

We have not, therefore, departed from the classification which has hitherto been popularly employed, but shall treat in succession on solid and liquid food, and or condiments. None of these sections need any further definition.

We must, however, guard against one error, not seldom met with. In believing that solid food only satisfies the hunger, while liquids only quench the thirst, we forget that there is only one alimentary principle—namely, water—that affects that condition of the blood which brings on thirst. But water is contained in all aliments in such abundance, that, on an average, it constitutes more than half of their weight. All beverages, on the other hand, contain also some other alimentary principles than water; for even in what we are accustomed to call pure water, there are always some of the compounds of chlorine and salts; while in milk, we have all classes of simple alimentary substances together, it being composed of water, compounds of chlorine, salts, caseine, fat, sugar, &c.

The condiments are also, in the restricted sense in which we shall employ the word, principally composed of alimentary principles; only a few of them contain substances which, although exciting the gustatory nerves, and stimulating the digestive organs to a greater activity, may not also be considered as restoring some of the losses of the body.

§ 39. As the alimentary principles are not found in nature in their simplest form, so also none of them is sufficient of itself to nourish the body. Not even a variety of these substances, if belonging only to one of the three groups before-mentioned, is able, if exclusively eaten, to maintain life: we may go further, and add that life cannot be sustained by two of these sections, if the third be lacking.

Not sugar, salts, nor albumen, if taken without any substances of the two other groups, are able to destroy the consequences which the change of matter effects, when the process of excretion goes on, without the accompanying one of nutrition.

Without phosphate of lime the bones cannot be formed, whatever quantity of albumen and fat we may consume; no muscular tissue could grow without albumen, however we might overload the stomach with sugar and salts; and, finally, without fat, no brain could be formed. But the bones, the brain, and the muscles are the most essential organs of the human body.

No element can be transformed into another: this is the whole solution of the secret. Phosphorus does not turn into oxygen, nor oxygen into carbon, nor carbon into nitrogen, nor nitrogen into sulphur: no power short of the miraculous is able to effect an exception from this rule. As something cannot be created from nothing, no power of the body is able to transform iron into hydrogen, or chlorine into calcium.

The organic alimentary principles, destitute of nitrogen, cannot be changed into those containing nitrogen, nor the nitrogenised organic substances into inorganic salts, containing any other elements than nitrogen, carbon, hydrogen, oxygen, sulphur, and phosphorus.

It might be supposed that albumen could be transformed into fat, because albumen, as well as fat, contains carbon, hydrogen, and oxygen; it could also be suggested that carbonates of alkalies and water, as containing carbon, hydrogen, and oxygen, could form sugar: but experience has shown that the animal body cannot accomplish the former transformation in a sufficient quantity, nor the latter at all.

Complete substitutes, therefore, for the nutriments which maintain the life constantly, can only be formed by a combination of all three groups of the alimentary principles.

§ 40. *Tests of Digestibility.*—The more easily these alimentary principles are dissolved in the digestive fluids, and changed into the constituents of the blood, the greater is their digestibility; for digestion consists not in the solution of bodies only, but also in their transformation into the essential constituents of the blood. Both conditions are of equal importance.

If two substances, therefore, are dissolved with equal ease, that will be the more digestible which has the greater similarity to some constituent of the blood. Stearine and margarine, for instance, are almost equally soluble in the digestive juices; but as margarine is present in the blood, and stearine is not, it follows that margarine surpasses stearine in digestibility.

But if the conformity of two alimentary principles with the constituents of the blood be equal, the more soluble is the more digestible. Soluble albumen and fibrine stand equally near to the blood, both being contained in it. As the soluble albumen, however, is more readily dissolved in the digestive juices than fibrine, the digestion of the latter is more difficult.

Hence it results, that the difficulty with which alimentary principles are dissolved, is, in many cases, compensated by their conformity with the ingredients of the blood. Although gum, for example, is much more easily dissolved than fat, the latter, if not taken in too great a quantity, is digested by a healthy stomach, under certain circumstances, more readily than gum; for gum is not contained in the blood, while fat belongs to its essential constituents. Gum has first to be transformed into sugar, then into lactic acid, and finally into butyric acid and some other fatty substances; while fat, on the other hand, as containing oleine and margarine, is represented in the blood itself. In the formation of fat from starch, the latter must first be changed into gum, then into sugar; the sugar into lactic acid, and this again into butyric acid. It hence appears, that of all these substances lactic acid is the most digestible, even if all were equally soluble in water; sugar would be next to it, then gum, and finally starch. Lactic acid and sugar are, besides, more soluble than gum, and gum than starch. The latter is, therefore, for two reasons, the least digestible of the above-mentioned alimentary principles. It follows, again, from the same law, that a substance which is both more easily dissolved in water than another, and more readily transformed into the constituents of the blood, greatly surpasses the latter in digestibility.

Of the aliments, those are the most digestible which contain the greatest number of alimentary principles easily soluble, and easily turned into the constituents of the blood.

§ 41. *Tests of Nutritiveness.*—The nutritiveness of any kind of solid or liquid food depends upon three circumstances: its digestibility, the quantity, and the proportions of the alimentary principles contained in it.

If an aliment contain many indigestible substances, which are voided again in an undissolved state with the excrements, it must lose as much of its nutritiveness; for only that which passes as an essential constituent into the blood, is to be considered as an alimentary principle. The more digestible an aliment is, therefore, other things being equal, the more nourishing it becomes.

In testing the value of a nutriment with respect to the alimentary principles contained in it, no regard is paid to the amount of water contained. Water is, in general, so easily to be procured, that we have not to take it into consideration, when judging of the value of solid or liquid food, with respect to its nutritious properties. In a dry arid desert, however, water would become the most important nutriment; and an aliment containing much water would be the most nutritious food. Where no deficiency in water exists, that aliment is the most nutritious which contains the greatest proportion of alimentary principles, and conveys, therefore, to the blood the greatest quantity of its essential constituents.

Besides the digestibility and the abundance of solid constituents, the combination of an aliment is also of the greatest importance. As the blood contains a greater proportion of albumen than of salts, and more salts than fat, the proportion of these alimentary principles will determine whether any particular food be nutritious or otherwise. Just as alimentary principles of equal solubility are the more digestible, the more completely they correspond with the several constituents of the blood; so an aliment is generally more nutritious, if the combination of its alimentary principles correspond more exactly with the composition of the blood. Thus, nutritious aliment is characterised by containing, of nitrogenised substances, more organic than inorganic, and of substances not nitrogenised, more inorganic than organic matter. Lean meat is the food which most completely answers these conditions.

Substances from each of the other groups, however, as we have just mentioned, are equally indispensable, though requisite in different quantities. Compounds of chlorine, salt, fat, and constituents of fat, are as absolutely necessary as albumen or gelatine. It always betokens a narrowness of view, therefore, to speak of any aliment as innutritious. It is true, potatoes are less nutritious than meat, because the latter is very similar to the blood; while potatoes contain very little albumen and a large proportion of starch: but in the unqualified assertion that potatoes do not nourish at all, we forget that starch is transformed into fat by the digestive process, and that this represents an essential constituent of the blood. Potatoes, combined with a certain proportion of white of egg, become as nourishing as milk or meat.

To distinguish, in one word, between digestibility and nutritiveness, we may say, that the former expresses the rapidity with which the alimentary principles of an aliment are transformed into constituents of the blood; the latter, the quantity of alimentary principles conveyed to the blood by solid or liquid food. Hence it follows, that we can speak of digestibility with respect to the alimentary principles as well as the compounded aliments, but of nutritiveness only with respect to the latter.

ON SOLID FOOD.—§ 42. *Meat and Eggs.*—In regarding the different kinds of food, from the whale-oil of the Greenlanders, and the bear's-grease which forms an article of diet in a Mogul tribe, up to the refined cookery of the wealthy in the more civilised countries of the globe, where, for instance, oysters and trepang (a small tubular animal belonging to the class of the Radiata) are favourite dainties, we soon find out that there exists no class of animals which does not furnish some contribution to the food of man. By all civilised nations, however, the flesh of herbivorous animals is preferred.

In this respect we may assert that the plants first prepare the food of man. It is an art in which they excel—that of preparing excellent meals from very simple materials. It is true that those plants which prepare the most nutritious food, take also up some compounded organic aliments; but it is also undeniable that plants can live exclusively on carbonic acid, ammonia, water, and some inorganic substances, and in every case derive from these simple alimentary principles the chief bulk of their body. The carbonic acid, the ammonia (a very simple combination of nitrogen with hydrogen),* and the water, are all three constituents of the air. "While the animal swallows bodies already formed," says Forster, who, before all others, deserves to be called the naturalist of the people, "these fine tubular and cellular formations eagerly take up the simplest elements from the air. Woven by sunshine and ethereal fire, such as formerly poets only dared to dream of, the soft green of the woods and fields smiles upon our sight; and, behold! in the infinitely delicate network of the blooms and ripening fruits, glows the sevenfold beam, and adorns the vegetable world with the manifold brilliancy of its hues!"

Animals living on plants not unnaturally convey the impression of a greater purity upon our fastidious senses, which are offended by the rancid smell of the carnivorous Mammalia, and by the oily flavour of the birds of prey. Hence our predilection for the herbivorous animals; and among these the Ruminants and the many-hoofed occupy the first place. Throughout the whole of Central Europe, no meat is consumed in greater abundance than beef and pork.

§ 43. *Constituents of Beef.*—The flesh of oxen, or beef, illustrates the composition of all other kinds of meat. We may take the composition of beef as the standard, with which, the varieties of the other most common animal aliments may be compared.

In beef, as in all aliments which, when taken to the exclusion of all other food, are able to maintain human life, the three groups of simple alimentary principles are represented. A combination of albuminous and fatty matters, of compounds of chlorine and of salts, abundantly diluted with water, is all that is necessary to sustain life.

The albuminous substances of beef are the fibrine of the muscles and albumen proper. The former constitutes the finest fibres of flesh; the latter is the essential body of the nutritious juice which occupies the space between the solid parts. The flesh owes its red colour to the blood which it contains in very numerous vessels; and this blood comprises albumen, globuline, fibrine, and traces of caseine; and in addition to these albuminous substances, some colouring matter containing iron.

The albuminous substances which animal food thus contains, are not the only supply it affords, to compensate for the albuminous matters of the blood lost with the excretions; for the finest muscular fibres are enclosed in the cellular or binding tissue which unites them into bundles. This tissue, when boiled, yields gelatine, which is soluble in water. In the body, gelatine is again transformed into albumen. Convalescents very often regain their strength by the almost exclusive use of jelly from bones; and gelatine is the only nitrogenised body contained in any large amount in this jelly. As the blood of man, however, does not contain gelatine, as a necessary condition of its regular combination, but albuminous matter, we must infer that the gelatine is transformed into albuminous compounds.

That the cellular tissue in the muscles is intermingled with elastic fibres, does not in any way affect the nutritious properties of animal food; for these elastic fibres are not dissolved in the digestive fluids. They constitute a part of those alimentary remnants which, united with certain excretory substances of the blood, compose the excrements.

Like gelatine, the horny cells lining the walls of the muscular blood-vessels are entitled to the name of constituents of albumen. They are, however, of small importance; for their quantity is so insignificant, that even if soluble in the alkaline secretions of some digestive glands, they are less digestive than the fibres yielding gelatine.

Kreatine, flesh-basis, and flesh-acid, are regular nitrogenised constituents of beef. Are they to be considered as alimentary principles? There is scarcely any doubt that they pass into the blood, and from the blood into the muscles. But is mercury a nutriment because it passes through the blood into the cellular tissue of the bones, and is found there in the form of small globules? Against this opinion the judgment of even the unprofessional reader protests. And the kreatine, the flesh-basis, and the flesh-acids, we cannot consider to be, strictly speaking, alimentary principles, as they belong to the regressive transformation, which process, by the action of oxygen, conveys all organic matters of our tissues to the excretory glands. The organic compounds without nitrogen, contained in beef, are much less various than the nitrogenised. The former consist of several fats, sugar, and lactic acid. We have often mentioned that the fat of the Ruminants owes its hardness to the stearine. This is associated with margarine and oleine; whilst the peculiar fat containing phosphorus, as well as the gall-fat of the nerves and the blood, scarcely deserve any consideration, on account of their small quantity.

Chloride of potassium, and phosphate of potash, are the peculiar inorganic substances of the flesh. They alone would be sufficient to distinguish the flesh from the blood. While the blood contains seventeen times more soda than potash, there is in the flesh of the ox about three times more potash than soda. Phosphates of soda, lime, magnesia, and oxide of iron are contained in beef, in somewhat considerable quantities; but there are only few traces of sulphates of the alkalies attributable to the blood of the muscles. The amount of water contained is so considerable, that, on an average, it amounts to more than three-quarters of the whole mass.

---

* See *ante*, p. 323.

§ 44. *Effects of Cooking.*—The foregoing description refers to the raw flesh. What becomes of this when boiled or roasted? If we put a piece of meat into boiling-water, and leave it long enough exposed to the boiling temperature, the soluble albuminous substances coagulate; the fibrine is transformed into two new compounds, each of which is richer in oxygen than the fibrine itself, and only one of which resembles fibrine in its difficulty of solution. The other, which may also be obtained from albumen, is easily dissolved in water.

The colouring matter of the blood turns brown from being decomposed at the boiling-point. By this process it also loses its solubility in water.

The cellular tissues dissolve, as by boiling they are transmuted into gelatine.

The fatty substances melt. Those of the inorganic compounds which are more easily soluble, are dissolved in the water. The same takes place with the sugar, the lactic acid, to which the flesh-juice owes its acidity, the kreatine, flesh-basis, and flesh-acid.

The albumen being coagulated by the boiling-water in the external parts of the meat, forms around the internal part a cover or outside, penetrable only with difficulty. A large proportion of the soluble alimentary principles is consequently retained, which the water would otherwise have abstracted from the meat. The heat, however, penetrates to the interior; each flesh-bundle gets surrounded, as it were, by a sheath of coagulated albumen. This protects the gelatine and the salts, the lactic acid and the kreatine, but, most of all, the real flesh-fibre, which, by the direct action of the boiling-water, would gradually become harder and more tenacious. Accordingly, the flesh yields only very little of its constituents to the water, by quick boiling, and preserves with the alimentary principles, not only its nutritiveness, but also its flavour.

If, therefore, the cook wish to prepare a juicy, savoury, and rich food, she puts the meat into the water raw when the latter is in a state of ebullition; but if a strong broth is to be prepared, she puts the meat into cold water, and heats it gradually. The soluble alimentary principles are, by this process, abstracted from the meat, and dissolved by the water before the albumen can coagulate. It is true, that when the solution boils, a quantity of small albuminous scales are formed, which are skimmed off with the colouring matter of the blood, which has now turned brown, and other adhering substances. But when the water boils, another part of the albumen is transformed into a combination containing more oxygen, and soluble in water. The same takes place with the fibrine of the muscles, which comes into direct contact with the boiling-water. Thus, a solution is formed consisting of transformed albuminous substances, kreatine, flesh-basis, and flesh-acids, gelatine and lactic acid, besides some salts; while small scales of albumen and melted fats—the well-known fat-bubbles—float on the liquid in an undissolved state. The broth thus prepared is savoury, but the meat all the poorer and tougher, in proportion as the water has been more slowly heated.

This explains why in Germany, in the households of the middle classes, where meat is put on the fire with cold water, boiled meat is seldom or never taken without broth; for the boiled meat, and its broth, contain the constituents of the raw meat. In other countries, the Netherlands for instance, boiled meat without broth is very common food. The Dutch cooks, therefore, put the meat which has not to furnish any soup, on the fire with boiling-water.

By roasting, as in the former case, a kind of sheath is formed around the meat. The albumen coagulates on the external surface, which becomes of a deep brown by the decomposition of the colouring matter; and afterwards by the formation of several empyreumatic-smelling substances. This surface retains the greater proportion of the soluble substances in the meat, from which a thick substantial juice oozes out in a proportionately scanty quantity; a part of the fatty substance is decomposed—stearic acid, for instance, being changed into margaric acid; and finally, an important substance is produced—namely, acetic acid, which originates in the action of dry heat used in roasting, and facilitates the solution of the albuminous matters.

Vinegar has the effect of rendering the meat more digestible, like common salt, by dissolving the albuminous substances, as has been mentioned in discussing the process of digestion. This is the explanation of an expression common in Germany—that vinegar makes the meat short; short meat being easy of digestion.

Large pieces of meat, which after boiling or roasting contain liquid blood in the interior, are, in Germany, considered not to be sufficiently done; whereas, in England, this is in many cases required as a proof of good cooking. What is the cause of the blood being thus retained? It is because the colouring matter of the blood is not decomposed, excepting where the temperature has been increased to more than 158° Fah. The internal parts which retain the crimson hue, have not attained this temperature.

§ 45. *Difference of Taste.*—Although the difference of taste in different kinds of meat would indicate material distinctions in their compositions, yet the ascertained differences are very trifling in the case of the flesh of the sheep and roe; these belong, like the ox, to the class of Ruminants, and correspond most exactly with beef in the alimentary principles which they contain. The fat of sheep, however, is generally harder—that is to say, richer in stearine; and the fat of the roe is more acid than that of beef.

Pork is richer in fat, but poorer in albuminous substances than beef, although even here the difference is not considerable.

All wild Mammalia are remarkable beyond our domesticated animals for the quantity of kreatine which they contain; the latter, however, surpass the former in their proportion of fat. The reason of this is obvious. Whilst, in the ox fattening for food, its even and quiet existence promotes the formation of fat, and moderates the tissue change—the roe, leading in the woods a free and active life, takes in a greater quantity of oxygen, which transforms the nitrogenised basis of the tissues into kreatine. It is the same with birds; their rapid flight, and their bones filled with air, augment their reception of oxygen. The higher temperature of the bird proves that it consumes oxygen faster than the reptiles crawling on the earth; even faster than the Mammalia, the only class of animals with which it shares the appellation of warm-blooded. Hence the more rapid decomposition of its albuminous matter, of which the proportion of soluble albumen is, besides, greater than in the other Mammalia; hence, also, the abundance of kreatine in the muscles of birds.

While between the Mammalia and birds, no great difference has been observed in the amount of water they contain, the three-quarters in weight of water contained in the flesh of warm-blooded animals, is increased to four-fifths and more in the flesh of the fishes. Little blood, and therefore mostly a white colour; much less muscular fibrine; a larger quantity of tissue yielding gelatine; and, above all, a fat containing phosphorus, which is not limited to the contents of the blood-vessels, are regular peculiarities in the flesh of fishes. And this phosphorous fat does not constitute the only difference in their properties; for the soluble albumen of the fish, which nearly corresponds in quantity with that of the flesh of birds, coagulates much more rapidly in a somewhat higher temperature, than the soluble albumen of the warm-blooded animals. The soluble albumen differs also from the latter by not containing any phosphorus.

§ 46. *Comparative Qualities of Flesh*—We have to take into consideration not alone the species of the animals whose muscles furnish our meat, but also numerous other circumstances affecting the flesh, before it appears on the table.

Thus the flesh of young animals is poorer in fibrine than that of the mature, but richer in soluble albumen, gelatinous fibres, and water: it is therefore more tender. This preponderance of gelatine explains why the broth of veal and lamb sooner coagulates than that of beef and mutton; for it is the gelatine diffused through the broth which converts the whole, when cool, into a jelly.

Is the difference in the taste of the flesh of different animals, so familiar to us in ordinary life, traceable to certain differences in the composition of their food? The taste of fieldfares, for instance, after eating juniper-berries, and that of some ducks and other aquatic birds which feed on snails, crabs, and fish, and whose flesh resembles train-oil, evidently settles this question in the affirmative. In Tahiti the swine were fed on fruits only; and while their fat had nothing of the rich taste of European pork, Forster compared their flesh to veal. Science, however, answers the question with special regard to the fats; by its exact comparisons, it correctly explains the every-day experience of domestic life. There can now be no longer any doubt that the substances with which we feed our oxen, swine, and fowls, and stuff our geese—namely, turnips, potatoes, sawdust, maize, rice, with several other seeds—are remarkable for abundantly containing the constituents of fat; for in these kinds of food, the substances contained in greatest quantities are starch and sugar, with other similar matters, which the animal body transforms into lactic and butyric acids, and some other fats. Game, again, owes its savoury taste in great part to its large proportion of kreatine. Fattening causes the quantity of kreatine to decrease. Partridges lose their taste if cooped-up and fed like domestic fowls, as is sometimes done in severe winters, to protect them from cold. Tame ducks, if left at liberty, become *lean*, but acquire the agreeable flavour of game.

Although it does not require a sentimental mind to regard the cramming of geese with a degree of aversion, yet man has not disdained much more cruel encroachments on animal life, with the intention of procuring a new titillation to the palate. Not only has he made capons and poulards of cocks and hens by mutilation, but he has mutilated several Mammalia, as well as carps, in the same manner. Chemical research has not yet discovered why the flesh should become by this process more tender and savoury; but the fact is undoubted. Cows grow fat more rapidly after the loss of their ovaries. The practice of baiting, carried on in former times, but at present only existing in the form of hunting, liquefies the fibrine, which is the least readily soluble alimentary principle of flesh, and renders the meat more tender.

§ 47. The intestines of some animals, the entrails in which sausages are made, the brain, the liver, the kidney, the spleen, and the sweet-bread, are very similar to flesh in the properties of their constituents; the differences being chiefly in their quantitative proportions. Liver, spleen, sweet-bread, brain, and kidneys, contain soluble albumen in remarkable abundance. In addition to this quantity of albumen, the sweet-bread contains much gelatinous tissue, and an extremely small proportion of fat; while in the brain and liver, a considerable quantity of phosphorus fat is intermingled with the ordinary alimentary principles.

In the bones, the nitrogenised alimentary principles are almost exclusively represented by the gelatinous tissues. Though there exists no doubt that gelatine is capable of being transformed into albumen, yet this transmutation takes place so slowly that the bones alone cannot yield a proper nutriment. Since gelatine, as such, is not present in the blood, it has therefore to be transformed into albumen in order to become one of its constituents; it is much more difficult of digestion than albumen, in spite of its facile solubility in the gastric juice. The bones are not deficient in fat and the more important salts; but as these pass only in part into the cakes made of the gelatine of bones for the preparation of broth, the use of these cakes as a principal supply of food is to be reprobated. In England, which excels all other countries in the preference of its people for a substantial nutriment, these cakes are prepared from the broth of meat inspissated by boiling to a jelly. Sometimes, indeed, bones and other parings may be used in addition; but fresh beef furnishes the essential constituent of the inspissated juice, which is poured into small cake-moulds. These cakes, when dissolved, closely correspond with real broth; and they therefore justly claim for themselves the name of portable soups. What in France is sold under the name of bouillon-cakes, is nothing but gelatine; a production difficult of digestion, only slightly nutritious, and therefore objectionable. No economy is so nearly related to extravagance, as that of preparing soups from such cakes in order to effect a saving in meat; for this broth does not repair the expenditure of the body; and while impoverishing the purse, fails to enrich the blood.

§ 48. *Eggs of Birds as Food.*—No other aliment unites so completely the advantages of meat, as the eggs of our domestic birds. The yolk and white consist chiefly of albuminous matters—the yolk, of caseine and albumen; the white, of soluble albumen, containing more sulphur than blood—and of an albuminous body containing a large quantity of sulphur, scantily soluble, and forming cellules in the shape of small membranes, which include the soluble albumen.

We have before explained why eggs coagulate when boiled. The heat of the boiling-water being communicated through the shell to the thick albumen solution, the albumen becomes hard.

The white of egg contains more water than the yolk; somewhat more than one-half of the latter, but only four-fifths of the former, consisting of water. The yolk is also, in a nearly similar proportion, richer than the white in fat and in albuminous substances. The yellow oil of the yolk contains a large quantity of oleine, with a little margarine, less phosphorous fat, and still less gall-fat.

What further does the egg require to represent a complete nutriment? Nothing but the salts and chlorine compounds of the blood; and all these are found in the inorganic constituents both of the white and yolk.

§ 49. *Animal Food Considered.*—"Flesh makes flesh." Thus says a popular proverb. We readily agree with this view, and that so much the more when we regard diet in its direct relation to our body, since the view is much more correct than if it had been said—"Flesh makes blood." It is not only the potash predominating in the flesh which distinguishes it from the blood, the latter containing soda in a greater proportion; for while in the blood more albumen than fibrine is to be found, the fibrine predominates over the albumen in the muscles. Flesh, therefore, is much more capable of repairing the waste of our muscles than blood.

Is this discordant with the fact, that all nutriments find their way to the tissues only through the blood? The chyle, originating from meat, is, like all the rest, mingled with the blood, to which it is conveyed through the thoracic duct. But as our flesh in great part consists, not by chance, but according to a necessary law of attraction, of chloride of potassium, phosphate of potash, and fibrine, an abundance of these constituents in the blood must be to the benefit of our muscles.

Under a predominant, and still more under an exclusive animal diet, the fibrine does, in fact, pass in greater quantity into the blood. The natural result of this is great vigour of muscle, as may be illustrated by the strong muscular structure and fiery movements of the Indian tribes, in North and South America, who snatch a livelihood from the chase. Has not breeding cattle the same influence upon the Calmucs and Tartars, the pastoral tribes of the Alps, and the mountaineers of the Scotch Highlands? Who does not know the superiority of an English labourer, who is strengthened by his roast beef, over an Italian lazarone, whose predominant vegetable diet explains in great measure his inclination to idleness? And, finally, the slighter strength of the Laplanders and Samoyedes, of the Greenlanders and Kamtschatdales, whose food consists almost wholly of fish, in which scarcely more than three-fourths of the fibrine found in the birds and animals is to be traced, is an additional proof of the truth of the sentence—"Flesh makes flesh."

The richer the meats are in soluble albumen, the poorer are they in fibrine and fat, the more easily digestible will they be, if other constituents do not neutralise this property. Thus the flesh of pigeons and fowls is more digestible than veal; veal more digestible than the muscles of oxen, sheep, and deer. Horse-flesh is, doubtless, very similar to the latter; and the Mongols and Patagonians, and even some Christian nations of Europe in times of famine, have proved its advantages as a nutriment; while recent investigations of the French physicians have scientifically established them. Unjustly, therefore, was the eating of horse-flesh declared by the holy Boniface to be a heathen indulgence of appetite, interdicted by Pope Gregory III. and other authorities. The quantity of fat places the muscles of swine and geese among the most heavily digestible meats; while, on the contrary, most of the different kinds of game owe their superiority to the small proportion of fat they possess, which distinguishes them from the meat of our high-fed domestic animals.

The flesh of fishes, according to their proportionately small quantity of fibrine and their abundance in soluble albumen, might be supposed easily digestible; but the quantity of phosphorous fat renders them difficult of solution in the digestive juices—a remark which is applicable, not only to fishes, but to the brain and liver of all vertebrate animals. Of the intestines, there is no aliment more easily digestible than the sweet-bread of calves, which is remarkable for its slight quantity of fat and fibrine, as well as for its abundance of soluble albumen.

On account of the formation of acetic acid in the external parts, and of the less complete coagulation of the interior, roast meat, which does not contain too much fat, is easier of digestion than boiled.

Soft-boiled eggs are, on the whole, dissolved in the stomach with greater facility than hard ones; but as dissolved albumen is coagulated by the acidity of the gastric juice, and is afterwards dissolved again, the process of boiling the eggs hard, if not carried to excess, does not materially interfere with their digestibility.

As all kinds of flesh contain a sufficient proportion of fat and salts to restore to the human body the inorganic constituents of the excretions and the transformed fats, that kind of flesh, however, which contains the albuminous matters in the greatest abundance is to be considered the most nutritious. Venison and beef are, therefore, more nutritious than veal, and veal more nutritious than fish. Pigeons and fowls, however, surpass beef in nutritiveness, being not inferior in their proportion of albuminous matters, but superior in digestibility. Pork, also, is less nutritious than beef, from the twofold reason of its possessing fewer albuminous compounds, and of being, on account of its preponderant quantity of fat, less digestible.

When fibrine is abundant in the blood, the heart, being a tissue of muscular fibres, is more fully nourished; the activity of the circulation is consequently increased. The excitation of this activity, observed after a copious meal of venison, is due not only to the abundance of albuminous matters contained in the venison, but also probably to its proportionately large quantity of kreatine.

The formation of blood and the nutrition are increased by animal diet, as all these facts prove. Shall we therefore be surprised to find that, after a hearty meal of meat and eggs, the secretions and excretions containing albuminous matters, or compounds derived from them, likewise increase in quantity, and especially in their proportion of nitrogenised matters? That the milk flows more copiously, and the quantity of urea and uric acid, in twenty-four hours, is considerably increased? Is it to be wondered at that the blood circulates more rapidly, that the muscles contract with greater vigour? Thus, it is true that an abundant formation of blood gives the first impulse to an active metamorphosis of tissue; thus it is true that all increased activity has to be referred to a corresponding supply of new material.

§ 50. *Bread and Cakes.*—All kinds of corn, including rice, maize, oats, barley, rye, and wheat, contain in their seeds a large quantity of undissolved vegetable albumen, combined with a little vegetable gelatine. The latter compound, belonging, like the former, to the albuminous matters, is a glutinous substance, which communicates its property to the whole combination; from this circumstance it is called gluten. In addition to the gluten, formerly erroneously supposed to be a simple body, most kinds of corn contain a small quantity of soluble vegetable albumen.

The constituents of fat are also abundantly represented in all kinds of flour, for all kinds of corn contain a quantity of starch so considerable, as by far to surpass their amount of albuminous substances. Besides the starch, a proportion of gum is always present. Formerly, also, sugar was supposed to exist in these seeds; recent investigations, however, have shown this supposition to be incorrect, as far, at least, as regards wheaten flour in a fresh condition.

A small proportion of ready-formed fat accompanies the constituents of fat; and, finally, all the inorganic constituents of the human body are present in the seeds of the cerealia—namely, soda and potash, magnesia and lime, iron and chlorine, fluorine, phosphoric and sulphuric acids. The phosphates of the alkalies and earths predominate amongst the salts; and magnesia amongst the earths.

§ 51. *Composition of the Cerealia.*—The difference in composition which exists amongst the seeds of the cerealia, is much greater than one would expect from the natural affinity of their parent plants.

Gluten and starch are the constituents of grain, in the proportion of which the greatest differences are found, the quantity of the one generally varying inversely as that of the other. Thus, wheat contains the greatest quantity of gluten and the smallest of starch; rye a medium proportion of both; while in rice and barley, in oats and maize, the largest proportion of starch and the smallest of gluten are to be found.

Potash considerably predominates over soda in the seeds of the cerealia; this has been established by the most recent completed investigations on wheat and barley, oats and rice.

Maize is remarkable for its considerable proportion of fattening matter. In the external covering of all kinds of grain, there are contained much more gluten and fat than in the interior. Peeled rice and pearled barley have, therefore, lost a great deal of their nutritiveness; and bread containing the bran is much more nourishing than that prepared from sifted flour; but, unfortunately, the former is rendered, by the hard cellular tissue which it contains, much more difficult of digestion than the latter, and excites an injurious irritation, causing diarrhœa in weak digestive organs. Sifted flour is, therefore, for general use, preferable to the unsifted.

If we consider that the breeding of cattle, and agriculture, are among the most ancient pursuits of mankind, we must not be astonished that, in the methods of increasing the produce of both, experience had anticipated science by some thousands of years. In many cases, therefore, nothing was left to the latter, but correctly to interpret the results of the former, and explain its principles. Often, too, the scientific explanation of a customary practice has proved the safeguard against those errors, which would have been sure to arise in reasoning from solitary instances experimentally established, without the sure ground of a general principle. If the agriculturist were but ready to acknowledge the services of the chemist, and the latter willing to cooperate with the former, then the power of mind and that of the purse, which have, in fact, but one common object in view, would not divide their forces; but to the obstinate pride of the theorist, who seeks to overthrow all that agricultural experience has established, there is only too often opposed, the equally obstinate narrow-mindedness of the agriculturist, who has no faith out of the circle of his experience, or beyond the limit of his fields; the one forgetting that old customs have been confirmed by new reasons, at least as often as they have been set aside.

This state of things is, however, happily disappearing: at least, in this country, agriculturists are now aware of the value of the chemical appliances to agriculture, and are not found to be backward in developing its resources. They are now aware, that what feeding accomplishes in the stable, manure effects in the field; and while with cattle an abundant formation of fat is principally sought, the chief endeavours of the agriculturist are directed to the production of gluten. The greater the amount of nitrogen incorporated into the soil by means of manure in the form of ammonia, the more considerable is the yield of gluten, which by means of the seeds of the cerealia renews the blood of man.

Besides manure, the temperature exercises a most important influence upon the quantity of gluten produced by the gramineous plants of the fields. In summer, and in warm climates, more gluten is formed than in the corn of winter and of the rough north.

§ 52. *Constituents of Bread.*—Although bread is made of different cereals in different countries—as of rice by the Hindoos, and of maize in Tyrol and at the Gold-coast—wheat and rye furnish the flour chiefly used in the preparation of bread in Europe.

Our ordinary bread is prepared with leaven, and is, therefore, called leavened or fermented bread. Leaven is nothing else than a part of the common dough preserved until the next baking, during which time it has become sour. By the process of fermentation in this preserved dough, lactic and acetic acids are formed. Yeast may be substituted for leaven with precisely the same effect. In both, an albuminous compound is the occasion of the sugar formed in the dough turning it into a vinous fermentation. By this process the sugar is decomposed into alcohol, which evaporates, and into carbonic acid, which, inclosed by the tough gluten, is retained in the bread.

Flour, the ferment water, and salt, form the dough. In this a part of the starch has already been transformed into sugar; and by the action of leaven or yeast, this sugar is transmuted into alcohol and carbonic acid. The carbonic acid, which is prevented from escaping by the tenacity of the gluten, produces the vesicles which give to the bread its ordinary lightness. By the process of baking, a portion of the starch in the external layer of the bread is transformed into gum and sugar. The soluble albumen coagulates the process; the alcohol evaporates.

By exposure to heat, this crust becomes brown; a compound of an agreeable bitter taste is thus formed, similar to that produced by the roasting of different other organic compounds. This peculiar bitter principle is called "roast-bitter," or "Assamar." Bread is so easily soluble in water, that it is liquefied even by the humidity of the air.

Good wheaten bread is white; the real brown bread, as, for example, the well-known Westphalia rye bread called "Pumpernickel," is from rye. As wheaten flour contains more gluten than rye flour, the same proportion is not found in white and brown bread; and as it is gluten which causes the sugar to undergo fermentation and retain the carbonic acid, the reason is apparent why rye bread, which contains a smaller proportion of gluten, is less spongy than wheaten bread. Stale bread is scarcely drier than fresh. In five days fresh bread loses one-hundredth only of its amount of water, and becomes stale even if it has cooled in an atmosphere saturated with moisture. But stale bread may be retransformed into fresh if put again into the oven, whereby a considerable amount of water is necessarily lost. Both high and low temperatures cause a change in the smallest particles, which has yet more closely to be investigated by science. It is, however, a fact, that stale bread is hard and firm, but not dry.

§ 53. *Nutritive Qualities of Bread.*—Bread is not, on the whole, so nutritious as meat, so far as the albuminous substances are concerned; for even the richest bread contains only about two-thirds of the quantity of albuminous matters present in beef.

The digestibility, moreover, of bread and flesh is not to be considered equal; for gluten is more difficult of solution by our digestive juices than the fibres of the muscles, and corresponds less intimately with the albuminous substances of the blood; therefore it is more slowly transformed into its constituents.

The starch, so abundant in bread, has to be transformed into fat. The inferior solubility peculiar to the ready-formed fat of the flesh is thus compensated.

Of the fat which the excretions subtract from the blood, bread is a much more productive source than meat; for more than one-third of wheaten bread consists of starch; while one-tenth in weight of gum, and a small quantity of sugar, is also contained in it. This predominance of the constituents of fat, explains why bread contains much more of solid substance than flesh. In the former, the proportion of water scarcely amounts to one-third of the whole.

This abundance of the constituents of fat does not at all correspond in proportion to the small quantity of fat to be found in the blood; and in comparing the nutritiveness of flesh with that of bread, we must, therefore, decide in favour of the former.

The nutritiveness of the different kinds of grain is dependent upon their comparative proportions of gluten; for in all of them the constituents of fat are present in abundance. Wheat, rye, oats, barley, rice, and maize, form a series, in which wheat takes the highest, and maize the lowest place with respect to nutritiveness. Thus in rice and maize there is scarcely to be found one-seventh of the amount of gluten contained in wheat. A corresponding proportion of nutritiveness consequently exists in the bread prepared of these different kinds of grain. Chemical knowledge thus justifies the old usage which prefers wheat and rye-bread to all other kinds of bread.

§ 54. *Indigestibility of Cakes.*—Like stewed hare, or any other composite preparation of meat, cakes belong more to a cookery-book than to a treatise on food. Eggs, fat, sugar, different condiments, almonds, dry or fresh fruit, are mixed with the dough of different kinds of flour; and all these constituents will be spoken of in their respective places. Why are cakes less conducive to health than bread? This question is so important to that large class of housewives who are proud of their pastries, that I will not pass it without a reply.

Sugar is the constituent considered, by most people, the most dangerous, while it is in reality the least so. If not added in too great a quantity to cakes and tarts, sugar is transformed into lactic acid, and assists the stomach in digesting. It is the fat, so abundantly mixed with many tarts in the form of butter, and as a constituent of the eggs and almonds, which renders many kinds of pastry so difficult of digestion. The more these fats are transformed by heat into the products of their respective decomposition, the more will this be the case. For this reason, macaroons, almond-tarts, or chocolate-cakes, containing the fat of cocoa, are more indigestible than other fruit-cakes and pastry which contain neither almonds nor cocoa.

The indigestibility of the latter, however, corresponds exactly to the quantity of butter and yolks of eggs used in their preparation; for in the yolk the fat of the eggs is principally to be found. Cakes, therefore, containing only a small proportion of butter and eggs, are the most innoxious.

The roast-bitter, produced by baking, in the crust of bread, originates in all farinaceous food in the same way. It is the substance which principally takes up water from the air, or the interior of the cakes, and causes the crust to be moist.

But why are cakes preserved in a moister condition, when kept in tin boxes secluded from the air? Because in a closed place the water of the cake evaporates less, and the cake therefore is less desiccated. The sugar, with which the surface is usually sprinkled, and the roast-bitter principle, attract the water from the interior of the cake; and after a time the sugar is found melted, and the crust humid.

§ 55. *Peas, Beans, and Lintels.*—Peas, beans, and lintels are comprised under the name of leguminous seeds. If we wished to divide all aliments into two principal groups, the former containing those of a higher nutritive quality, we should in this class the leguminous seeds together with meat and bread. For the legumin, which is a constituent of all leguminous seeds, is contained in peas, beans, and lentils, in so abundant a quantity, that this albuminous substance not seldom surpasses both the proportion of gluten in bread, and that of fibrine in meat. Legumin is soluble in water. Acetic acid precipitates a sediment in the solution, which does not dissolve again if a larger quantity of this acid be added. By mere boiling, the legumin does not coagulate; but this effect is produced on the soluble vegetable albumen, which, as in cereal grains, is also found in the leguminous seeds in a small proportionate quantity.

A considerable proportion of starch, accompanied by a good quantity of gum, and in the sugar-peas, for instance, by sugar also, takes the place of the constituents of fat, in the interior of the seeds of peas, beans, and lentils. The husk of these seeds, as well as the shell of those beans which are eaten whole, consist in great part of a substance which forms in all plants the young cellular walls, and is therefore called the cell principle, or cellulose. This belongs to the constituents of fat; it is identical in composition with starch, and like this is transformed into sugar by acids. But this process of transformation is so slow, that the cellulose, which does not dissolve in water, belongs to the alimentary substances, which are very difficult of digestion; so much the more so, as even the alkali of our saliva, bile, pancreatic and intestinal juices, is only able to dissolve a very small quantity of cellulose.

The ready-formed fat associated in the leguminous seeds with the constituents of fat, is present in so small a quantity, that, without their abundant proportion of starch and gum, the peas, beans, and lentils would not be able to restore the fat of the body, which, after being decomposed by combustion into carbonic acid and water, we constantly exhale.

All the compounds of chlorine and salts of the blood are to be found in the leguminous seeds; the most abundant salts of the blood, the phosphates of the alkalies and earths, existing there in the greatest abundance.

§ 56. *Alimentary Principles.*—Legumin owes its name to the circumstance of its representing the most important alimentary principle of the leguminous seeds; for it represents the albuminous substances in the peas, the beans, and the lentils, which contain only a small proportion of soluble albumen besides.

How is it that peas, beans, and lentils, become hard by boiling, as the legumin does not coagulate under the influence of boiling-water, and the proportion of the coagulating soluble albumen is so small! Because the chemist and the cook employ a water altogether different. The chemist operates only with water free from all dissolved substances. He first causes the rain or spring-water to evaporate by heat, and condenses again the vapour so formed in a low temperature; the water thus distilled containing none of those compounds of lime which are found in all the water used by the cook. But, in boiling, the lime unites with the legumin, and transforms it into a very hard substance; and as rain-water contains a smaller quantity of lime than spring-water, the peas remain softer in the former than in the latter.

By the process of boiling in rain-water, which contains but a small proportion of lime, a considerable part of the legumin is dissolved. It is better, therefore, both for the blood and the purse, to eat peas, beans, and lentils, not in a dry form, but prepared as soup. Just as boiled meat should be partaken together with its broth, in order to get the most digestible and nutritive part of the meat, so in pea and lentil soups, the fluid part is better than the undissolved portion. A great part, therefore, of the nutritious substance is thrown away if we only eat the peas which have been boiled in water, and throw the liquor away.

§ 57. *Digestibility of Leguminous Seeds.*—In respect of digestibility, the leguminous seeds, if taken without husks or skins, hold an intermediate place between meat and bread; for the fibrine and albumen have an advantage over legumin in their greater conformity with the constituents of the blood, while legumin surpasses the gluten of the bread in solubility.

But if water which contains much lime, as is often the case, renders the legumin hard, and if the seeds are rendered more difficult of solution by the presence of their husks, peas, beans, and lentils become dishes difficult of digestion, and occasion flatulence. This shows the advantage of preparing the soups of the leguminous seeds in rain-water, and straining them through a hair-sieve after the bursting of the husks by boiling. Peas, beans, and lentils, with their husks, require very vigorous organs to digest them.

But the leguminous seeds, though inferior to meat in digestibility, are superior in the abundance of solid constituents which they contain; for the proportion of water in peas, beans, and lentils, is scarcely one-sixth of their weight; and while the quantity of albuminous substances may surpass that contained in meat by one-half, the constituents of fat and the salts are also present in the leguminous seeds in a greater abundance.

Blood and flesh, and milk, are therefore abundantly formed by peas, beans, and lentils; and for this reason they are the comfort of poor people, to whom meat is so seldom and so sparingly allotted.

We have already mentioned the considerable proportion of phosphorus contained in legumin; but the brain cannot exist without the peculiar fat containing phosphorus, which owes its origin to the albumen and fibrine of the blood. Phosphorus cannot be formed from any other element. It necessarily follows, therefore, that meat, bread, and leguminous seeds are serviceable in supporting the nutrition to the brain; and that aliments like fish and eggs, which contain a ready-formed phosphuretted fat, will facilitate the conveyance of this peculiar constituent of the brain. The formation, and therefore the activity of the brain, also, is dependent on this fat containing phosphorus; and it has been said, as a mere pleasantry, that a sagacious man has much phosphorus in his brain. The chemical combination of an organ is as much impaired by containing too much of a constituent, as by possessing too little. There is no danger that the laws of regular attraction, upon which the nutrition of the tissues is dependent, should allow the excessive supply of a single constituent; but the function suffers if this constituent be present in too small a proportion. We cannot, therefore, presume an abundance of phosphorus in great thinkers; while yet it remains true, that with no phosphorus, there is no thought active in the brain.

§ 58. *Vegetables.*—Meat and vegetables are aliments so generally used together, as inevitably to suggest the presumption that one is complemented by the other; and on investigating the composition of the different kinds of vegetables, such as cabbage, cauliflower, salad, spinach, sorrel, and asparagus, nine-tenths of their weight will be found to consist of water, with scarcely half-a-hundredth part of soluble albumen. Although the proportion of the constituents of fat, especially of cellulose and gum, in addition to starch, wax, and the green nitrogenised matter of the plants, exceeds the albumen in quantity, yet it is evident, from the considerable abundance of water, that the constituents of fat form only a very small proportionate part of the above-mentioned vegetables.

But the leaves and young shoots which are used as dishes of vegetables, contain several organic acids; asparagus, for instance, with all the cabbage tribe, possesses acid of apples, or malic acid; the sorrel, oxalic acid; rhubarb contains both malic and oxalic acids. Malic acid consists of carbon, hydrogen, and a large proportion of oxygen; while oxalic acid, like carbonic acid, is composed of carbon and oxygen only, but with a smaller proportion of oxygen than is contained in carbonic acid. Both these vegetable acids have the power of keeping the soluble albumen of meat in a dissolved state. In asparagus there is associated with the malic acid another body, the asparagine, neither acid nor alkaline, but remarkable for its amount of nitrogen. Finally, the saurkrout, the dainty of a German citizen, and the relief of an English sailor, derives its name from a sourish taste occasioned by lactic acid, produced by the following process:—The cabbage, which is cut into slices and placed in a barrel, intermingled with a certain quantity of common salt, is pressed down, and in this state it undergoes fermentation; lactic acid, together with a small quantity of butyric acid, is thus produced.

The dissolving action of these acids—for they act also upon the fibrine of flesh—is assisted by their abundant proportion of compounds of chlorine and of salt. In cabbage and asparagus, lettuce and cabbage sprouts, potash considerably predominates; in spinach, soda and potash are nearly equal; while in rhubarb, a considerable amount of lime is contained. Cabbage sprouts are remarkable for their amounts of lime and magnesia; and in the stalks and leaves of lettuce, in asparagus and cauliflower, traces of manganese, a metal very similar to iron, have been found.

§ 59. *Digestibility of Vegetables.*—Are we, then, to express surprise that those vegetables should be praised, and put in comparison with meat, as aliments which dilute the blood, when we know that their solid substance often forms scarcely one-tenth in weight of the whole; and, moreover, that it contains more salts than albumen, without any undissolved albuminous substance at all, but merely a small proportion of organic acid? Whilst by themselves conveying very little nutriment to the blood, as may be seen in the feeble muscles of the inhabitants of the tropics, who live exclusively on herbs, vegetables are of service, first in the digestive canal, by dissolving the albuminous substances of the meat, and afterwards in the blood itself, by keeping the albumen and fibrine in a liquefied state, but not as nutritious food.

The cellulose, which in several kinds of cabbage, especially in the stem, is present in a greater abundance, belongs to an alimentary principle difficult of digestion; and this explains the flatulence which cabbages not unusually occasion in weak digestive organs. Of all other kinds of cabbage, the white cabbage used for saurkrout is remarkable for its amount of lactic acid, which renders it a readily digestible aliment. This useful vegetable is sometimes charged with indigestibility—a charge which should be brought against the pork and hard-boiled mashed peas so often taken with it.

If it be, therefore, apparent that as vegetables alone furnish a very insufficient compensation for the excreted substances, the fact that an exclusively vegetable diet affords but a defective nutrition to the tissue, is at once explained. Not only do the muscles become powerless, but a smaller quantity of nutriment is conveyed to the brain. Hence results an irresolute will, and a cowardly relinquishment of independence, as illustrated in the timid and slavish Hindoos, and other inhabitants of the tropics, who feed almost exclusively on vegetables.

Since, moreover, the alimentary principle of vegetables requires less oxygen than meat, bread, or the leguminous seeds, for the production of the same quantity of carbonic acid and water; while, at the same time, the amount of oxygen we inhale remains undiminished, it becomes evident why we exhale more carbonic acid while living on vegetables, than when supported by a more invigorating diet of meat, bread, and leguminous seeds. Precisely for this reason do we become satiated in a short time by an exclusively vegetable diet; for the blood and the tissues are only scantily supplied with albumen. But these tissues, containing a scanty amount of albumen, furnish fewer nitrogenised products of decomposition; and the excretion of urea and uric acid is, during the twenty-four hours, considerably diminished. The amount of urine, however, is increased by the salts and acids of the vegetables; and everybody knows how quickly the constituents of the asparagus, conveyed to the blood, and attracted therefrom by the kidneys, manifest themselves to the sense of smelling in the urine.

By substituting vegetables which are poor in albumen, for one part of the meat we take as a meal, the supply of albuminous bodies is diminished, and the digestion of what we have taken facilitated. Thus a combination is performed intermediate between meat and vegetables; the blood contains more water than the meat, more solid substance than the vegetables; and, by adding together the amount of albuminous substances in the meat and vegetables, and dividing the total into two equal parts, the average quantity of albumen in the composition may be found approximately corresponding with that in the blood. Thus the seeming chance becomes an approved law; and, instead of an arbitrary taste being left to dictate the choice of aliments, the necessity of attending to the law is apparent, clear light being thus thrown upon the connection between nutriment and blood; and the night in which the realms of knowledge were peopled with nebulous spectres and conjectural dreams, tending to show that all things existed for a settled purpose, is turned to day and conviction by the discoveries of science.

§ 60. *Potatoes and Edible Roots.*—Although in ordinary life we class the potato and other edible roots in the same category as the "vegetables," we must not forget that these roots and tubers considerably surpass the latter in the quantity of solid substances which they contain; on an average, the proportion of water they contain does not greatly exceed that of meat.

Are, then, potatoes and edible roots to be compared with meat in their nutritive qualities? Here it appears how important it is to compare the connection between the several groups of alimentary principles represented by the solid substances, with the composition of the blood, if we would accurately estimate their nutritive quality. By such comparison it will be found, that in potatoes, turnips, carrots, beetroot, parsnips, and Jerusalem artichokes, in leeks and celery, shallots, onions, and radishes, the constituents of fat surpass the albumen in precisely that proportion in which the latter ought to have exceeded the former, had these edible roots been intended of themselves to sustain the composition of the blood; thus the soluble albumen, which alone represents the albuminous substances in these roots, often constitutes less than the one-hundredth, and sometimes only the two-hundredth parts in weight; while the constituents of fat fluctuate between one-fourth and one-fifth.

In the several roots and tubers, the constituents of fat are very different in kind. Cellulose and gum are indeed found in all of them; but while the potato is remarkable for its amount of starch, we find in carrots, beetroot, and Jerusalem artichokes, an abundance of sugar also.

The roots just mentioned as abundant in sugar, and also turnips, contain a new compound of carbon, hydrogen, and oxygen; which contains more oxygen, in proportion to its hydrogen, than the constituents of fat. This substance, in the unripe fruit, thickens the walls of the cells, consisting of cellular tissue, and is denominated vegetable jelly or *pectose.* By boiling, it is transformed into a gelatinous substance called pectic acid, which might, therefore, be called gelatine acid. But since this gelatine acid is not transmuted into sugar, either by our digestive juices or by any artificial means, the vegetable jelly and the gelatine acid cannot be classed with the constituents of fat.

Fat is contained in potatoes and carrots in very small quantity; while in artichokes, besides fat, a trace of wax has also been found. Rush-nuts contain, with a great amount of starch, a considerable proportion of fatty oil.

The pungent taste of leeks and garlic, of radishes and horse-radish, of onions and parsley root, is produced by certain volatile oils; for these oils, if extracted from the roots, will be found to possess exactly the same peculiar pungent smell and acid taste as the roots themselves. The garlic oil, which exceeds all other oils in pungency of taste and smell, is composed of carbon, hydrogen, and sulphur, and is imperfectly soluble in water.

Organic acids, which were mentioned as characteristic of vegetables, are also to be found in these roots: thus the malic acid in potatoes and carrots; the citric acid, composed of the same ingredients as the former; and tartaric acid, containing a greater proportion of oxygen than the former, are found in the Jerusalem artichoke.

Citric acid has been observed in several roots, which are remarkable for the above-mentioned volatile oils.

Asparagine is found in potatoes, which also remind us of the composition of asparagus, by their containing malic acid.

While all the inorganic elements of our bodies, with the exception of fluorine, are found in the potato, it is characteristic of turnips that they contain no soda, and only very little iron. By way of compensation, they possess a large quantity of potash, which is also contained in the ashes of potatoes, in a greater proportion than all the other inorganic constituents put together.

§ 61. *Comparison of Roots and Vegetables.*—In comparing potatoes and other edible roots with esculent vegetables, we find the latter inferior in digestibility and nutritiveness to the former; for, in the roots, not only are the different constituents of fat—namely, starch, gum, and especially sugar—more readily soluble than the cellulose of the vegetables; but these constituents of fat and albumen, however small the proportion of the latter may be, are also much more abundantly present in roots than in leaves and stalks.

But if we contrast the roots with the group of the more nutritious aliments, as meat, cereal grains, and leguminous seeds, we find even the least substantial aliment of this group more nutritious than any edible roots. Rice and maize are not only richer in albuminous substances than roots, but exceed them nearly fourfold in the amount of starch which they contain.

The edible roots, as well as vegetables and fruit, belong, therefore, to the less nutritious aliments, and may be united into a second group, the first being formed of meat, bread, and leguminous seeds.

In this second group, potatoes and carrots, it is true, are distinguished from the other members by their superior nutritiveness, as well as by their digestibility. But, notwithstanding this, what must we think of the value of a nutriment in which the albumen and the constituents of fat are contained in an exactly inverse proportion to that which exists in the blood? It may, indeed, overload the blood and the tissues with fat; but inasmuch as it provides the blood only scantily with albumen, it conveys no fibrine, and, therefore, no strength to the muscles; nor can it furnish any albumen or phosphuretted fat to the brain. Now what would be the consequence if we were to accustom ourselves to eat such a quantity of potatoes as would suffice for providing the blood with the requisite proportion of albumen by their means alone? It is very obvious if, through this excessive supply, the process of digestion did not come to an entire stand-still, a superabundance of fat would be formed beyond the power of the oxygen to consume; and this fat would successively absorb from the albuminous substances a part of this vital element. A barrier would thus be raised against the endless change of matter in the tissues, against nutrition and regressive transformation; and only a portion of the material, and that the less important one, would take a part in that course of decay and reparation, by which the will and the energy, the movements and the thoughts, are brought to act.

It is this which so immensely aggravates the weight of poverty. The ill-satisfied want may be tolerated for a time; the strength of the arm may by strenuous efforts, and with the hope of obtaining better food, for a time uphold the fainting courage; but can a lazy potato-fed-blood confer on the muscle the power necessary for this labour; or on the brain the necessary vivifying impulses of hope?

§ 62. *Taste.*—It is not only the peculiar taste which is produced by the volatile oils existing, as above stated, in the several roots; that taste is but the first link to a long series of impressions effected by these oils upon the body. The different kinds of leeks, onions, and radishes, accelerate the pulse; the oil is conveyed to the nerves with the blood, and the irritability is increased; the smell of the oils is communicated to the breath; and, apart from the flatulent risings caused by the radish and horse-radish, it may be perceived immediately, from the exhaled air, that onions, leeks, or garlic, have been eaten. Through the action of these oils the kidneys abstract much water from the blood; for the diuretic effect of these roots is well known.

§ 63. *Fruit.*—Vying in scent and colour with the flowers of the fields, fragrant fruits decorate our orchards; and though the savoury mango, and other tropical fruits do not tempt the tongue in our climate, still the appliances of horticultural skill have given an exquisite delicacy to our apples and pears, and transplanted the cherry and peach from Asia Minor; while active commerce provides us with the orange, and the lemon, and pine-apple.

The nutritive and refreshing qualities of so many noble fruits have not escaped the researches of chemists. The cause, however, of so many subtle varieties of taste and odour has not yet received a satisfactory chemical elucidation. It is true we know the volatile oil which causes the peel of lemons and oranges to throw out afar their peculiar fragrance; it is true we know that some fine sorts of ether reside in raspberries and peaches, which are now abundantly produced by chemical means, and used for flavouring purposes. Yet if the causes of variety are to be as lucid to our mind as the variety itself is delightful to our palate, much remains to be investigated.

Cellulose, gum, and sugar—constituents of fat, therefore, both of difficult and of easy digestion—are to be found in all fruits, as in apples, in stone-fruit, in berries, in oranges, and in melons. These components are associated with but a small proportion of albumen; it is even smaller here than in vegetables, though here and there, as in apricots, it is greater. The proportion of water contained in fruits, is intermediate between that contained in edible roots and vegetables.

Fruit-marrow, or pectose, a substance we have already specified as found in several roots, is abundantly present in all unripe fruits. While the fruits are ripening, this is gradually transformed into the constituent of vegetable gelatine (*pectine*), which, by boiling, becomes gelatine acid.

Several peculiar colouring matters, together with wax, produce the brilliancy of colour in the peel of cherries and apples. Like a film, they cover the skin; a touch of the finger deprives the peach of that tender waxy bloom, which in fragrance surrounds the fruit with a virgin-like adornment.

Different acids, supported by several salts, cool and refresh our thirsty tongues; as, for instance, malic acid, present in almost every fruit, especially in apricots and peaches, in apples and pears, in gooseberries and currants; citric acid, present in lemons and raspberries, grapes and pine-apples; and tartaric acid, in grapes and figs. The skin of grapes derives its astringent taste from the tannic acid, which, in many other fruits, as in acorns, produces a taste entirely bitter.

Almonds and nuts, as well as the kernels of stone-fruit, contain an albuminous compound (emulsine), which we may call *ferment of almonds*. In a temperature somewhat raised, this ferment of almonds causes another nitrogenised substance, contained in bitter almonds and in kernels of peaches, and called the *almond-principle* (amygdaline), to undergo a fermentation, by which the volatile oil of bitter almonds and hydrocyanic acid are formed.

As chestnuts are distinguished by their amount of starch, so almonds and nuts are characterised by their abundance of an oil consisting of oleine and margarine. It is only from compliance with custom that we place almonds, nuts, and chestnuts in the group of fruits, as their very slight proportionate amount of water decidedly approximates them to the group of the more nutritive aliments.

§ 64. *Degrees of Acidity.*—Ripe and sweet, sour and unripe, are, in popular language, words of the same signification;—wrongly, if we ascribe the degree of acidity to the proportionate abundance of sourness; for in the ripe fruit, the proportion of acid is very often increased; but the sugar, which has augmented in a still greater proportion, moderates the sourness, which in the unripe fruit predominates over the sweet, though the quantity of acid is actually smaller.

In ripe fruit the acid is enveloped in the sugar, just as in stewed fruit it is by the jelly; for the vegetable jelly of the raw fruit deserves this name only when stewed. It is true, by this process, a new acid, the gelatinous or pectic acid, is formed. The latter, however, in the form of a mucous jelly, weakens the other acids. Stewed fruits and fruit-jelly, prepared with sugar, are therefore less injurious than raw fruits, so far as concerns the irritating power of the acids and salts; for the interior coating of the digestive tube is protected by the gelatinous acid.

Apples and berries, cherries and plums, apricots and peaches, melons and cucumbers, with all other similar fruits, dissolve the albuminous matters, and exercise a cooling influence upon the blood. While more nutritious than vegetables, and less so than potatoes, they have a great advantage over the latter in not over-loading the blood with fat. A thinner blood circulates with much vivacity through the vessels of the inhabitants of the South Seas; "these blessed countries," to use the words of Forster; "the cradle of the younger human race, where, not yet condemned to slavery, it enjoyed all the rights of free men, without being compelled to purchase at too high a price the happiness of existence in sweat and exhaustion."

ON LIQUID FOOD.—§ 65. *Water.*—If life consist in a metamorphosis of the tissue, fluids are an indispensable condition of life; for the combinations and decompositions in its substance, produced by the activities of our body, cannot take place without the agency of water. The simplest beverage is therefore, at the same time, the most necessary of all.

It is true, the same combination of hydrogen with oxygen, which constitutes the essential ingredient of all drinkable water, is contained in a small proportion even in the driest food; but neither meat nor bread, still less the leguminous seeds, are so abundant in water as to be capable of maintaining the proper composition of the blood. And who is not aware, from his own experience, that the most nutritious aliments are precisely those which most stimulate our thirst?

But it is impossible, in our climate, with our activity, with the vigour of our changing tissues, to live only on fruit and vegetables, meat and bread, and peas and beans. Our most important aliments must be intermingled with a food abounding in water, if the water, which is abstracted from the body through the skin and lungs, the intestines and kidneys, is to be restored by a process of uninterrupted attraction.

Our drinking-water is a nutriment which contains the greatest proportion of liquid; for is that not a nutriment which conveys to the blood the substance that renders possible the motion of all other combinations? Is not the water to be considered a restorative substance, inasmuch as the water, which constitutes three-fourths of the blood, is continually being withdrawn by all excretive organs, without exception?

And yet drinking-water is nutritious not alone because it contains water. The warmth of the earth indefatigably raises water into the air. From brooks, rivers, and seas, from plants also, and animals, there arise uninterruptedly, through the action of heat, vapours, which are condensed into clouds in the higher strata of the atmosphere. If that were true, which in a coward passion for repose has so often been imputed to nature, that its activity never deviates from the strictest method of quiet development; evaporating water, if falling down as rain, would provide us with water only. But the dashing of the sea, and the storms of the air surrounding the earth, the pressure of the atmosphere, and the power of fire, very often impel the vapour upwards with so furious a violence, that all substances dissolved in the water are carried with it. Hence, even the purest water falling down from the clouds, is impregnated with salts. Common salt and chloride of potassium, lime and magnesia combined with sulphuric and carbonic acids, magnesium with chlorine, even iron and manganese, have been found in rain-water; and however slight the proportionate amount of these fire-proof constituents may be, the regularity of their indications establishes the law.

In a greater abundance, however, than with these solid bodies, rain-water is impregnated with air. Oxygen and nitrogen, and the most important nutriments of the plants, carbonic acid and ammonia, are taken up by the falling rain watering the thirsty earth, and fertilising the fields; and even the lightning renders its assistance in enriching the verdant clothing of the ground. Its spark unites nitrogen and oxygen into nitric acid, and the thunder-shower supplies to the plant the nitrate of ammonia.

To ammonia especially, rain-water owes its softness; while lime renders the water, containing a greater proportion of salts, hard, as we have it in our wells and springs. The carbonic acid of the water dissolves the chalk of the earth, and the water itself dissolves the gypsum, or sulphate of lime, which forms the deposit when, in the process of boiling, a considerable quantity of water is evaporated. This is well known as occurring in kettles, boilers, &c.

The quality of spring-water is as various as the earth through which it oozes. Earths and alkalies, combined with chlorine or sulphuric acid, with carbonic or nitric acid, with iron and manganese, are contained in the water of wells and springs in the most varying proportions. One or the other of these substances is often absent. Phosphoric acid rarely, if ever, forms a constituent of water, notwithstanding the predominance of the lime-salts in wells and fountains.

That which causes the water of swamps and lakes, of rivers and seas, to be almost always unfit for drinking, is the admixture of putrefying organic substances, besides the common salt of the sea, which impart a putrid taste to it. Now it is the bottom of the sea, which, like a retort, sends the water up into the air; from which, as if distilled into rain, it streams down again in a potable condition: now it is the earth, forming, as it were, a strainer, through which the water, though not entirely purified, bubbles out of the wells. Even the skin of man possesses some of the properties of a filter. Cast upon a rock where not a drop of fresh water refreshes the languishing tongue, the shipwrecked man bathes in the sea in order to escape the most tormenting death from thirst; and from the sea-water itself, a refreshing moisture, with a smaller proportion of salt, penetrates the thirsty body.

§ 66. *Water Essential to Digestion.*—Since the last result of the whole process of digestion is a liquefaction of the alimentary principles, the formation of blood is impossible without water; but not only the formation, but the continual exercise also of the organs, depends upon their receiving a due amount of water. Without it, no digestion or formation of blood, no nutrition or excretion can exist. Even this statement, however, by no means exhausts the importance of water; for it is essential, not only as the medium for the movement of all dissolved substances, not only as the humidity necessary for the organs, of which the most active, the brain and the muscles, contain the greatest proportion of water; but the hydrogen and oxygen which we take in water, enter into the composition of many alimentary principles by being changed into the constituents of the blood. When starch or gum becomes sugar, the transmutation is effected by the absorption of water; for, with regard to their composition, a greater proportion only of water distinguishes sugar from starch; and separation of oxygen from sugar, causes the latter to be converted into fat.

No alimentary principle is so easily removed from the body as water, if taken in excess; for as no decomposition is required in order to its being attracted by the lungs, the kidneys, the skin, and the sudoriferous glands, it is not even necessary for this process that a greater proportion of oxygen be taken in. Water, taken in abundance, increases, at a low temperature, the activity of the kidneys; at a high one, the perspiration. He, therefore, who takes more water than necessary for nutrition and excretion, produces, in winter-time, a proportionately greater quantity of urine; in summer, an excessive perspiration.

§ 67. *Milk.*—A nutriment like milk, which during the whole period of life is of itself capable of sustaining the formation of blood, is, as it were, a ready answer of nature to the question—What alimentary principles are required for the formation of a complete nutrition? When treating on digestion, we took milk as the prototype of a perfect nutriment. It is at once a solid and a liquid food; a source of albumen and of fatty substances, of sugar and the salts—in one word, it is the most perfect of nutriments.

While more abundant in water than our blood, more abundant than bread and meat, milk possesses, in caseine, a representative of the albuminous substances, accompanied by the ready-formed fat of the butter, by a constituent of fat in the sugar of milk, and by the most important salts of the blood.

Contained in small cellules, which it dilates into glittering globules, the fat rises to the surface of the milk which stands undisturbed, forming the cream; while the lower, and far more abundant part, contains the chief quantity of the caseine, the milk of sugar, and the salts. More than one-third of these salts consists of phosphate of lime, associated with the phosphates of potash and magnesia, with some traces of oxide of iron, chloride of sodium, and a large proportion of chloride of potassium.

§ 68. *Qualities of Milk.*—Although the milk of goats and sheep may derive their peculiar smells from the uncombined state of one of the volatile fatty acids, which in the milk of the cow are united with glycerine into neutral fats, the more important difference between the milk of women and that of animals is exclusively dependent on the different proportion of caseine and sugar of milk, of butter and salts, to be found in these several sorts of milk. Thus, the quantity of caseine in human milk is only half as large as in that of the cow; and while, in the latter, butter and salts are likewise contained in greater proportion, human milk exceeds this in the amount of sugar of milk, by more than one-half. However slight the sweetening property of sugar of milk may be, if compared with cane-sugar, the babe does not fail to distinguish the milk of its mother, from that of the cow, by its sweeter taste. The peculiar butter-fat, or butyrine of the chemist, which, at ordinary temperatures, is more fluid than margarine or oleine, must be contained in the human milk in a greater abundance than in that of the cow, as the butter of the latter is of a firmer consistence.

Immediately after confinement, human milk contains a much greater proportion of solid substances, particularly of butter, than it does some days afterwards. After a striking diminution of these contents of the milk, which has already become remarkable the fourth day after confinement, the proportionate quantities of caseine and salts increase again. After weaning, the milk is again impoverished with equal rapidity.

§ 69. *Formation of Acids in Milk.*—By the influence of the caseine of the milk, its sugar is transformed into lactic acid, especially at a higher temperature, or in thunder-storms. As oxygen promotes the formation of lactic acid, boiling protects the milk for some time from turning sour—the oxygen which is contained in the milk being expelled at the boiling-point. The production of this acid takes place so much the more easily, inasmuch as lactic acid is identical with sugar of milk in its composition. The sour milk becomes thick from the caseine being coagulated by the lactic acid which has been formed; curdled milk is that in which caseine has been coagulated by the spontaneously transformed lactic acid. If from the curdled milk, the caseine, to which a great part of the butter adheres, be taken away, the whey remains, which is a solution of lactic acid, salts, and sugar, with a much smaller proportion of caseine and butter than is contained in pure milk.

In butter-milk the proportionate quantity of butter especially is diminished; for it is the remaining part of the cream from which, by the process of churning, the fats have been taken off. It always contains, however, some traces of butter, almost all the sugar of milk, the salts, and the caseine, very little of which passes into the butter.

§ 70. *Digestibility of Milk.*—It is natural to suppose that the food of the infant must be readily digestible and nutritious; and both suppositions are verified by experience: for while caseine belongs to the most soluble of albuminous bodies, the more soluble fats are represented in the butter. Next to cane-sugar, the sugar of milk is the most readily digestible of all constituents of fat, and its transformation into fat is facilitated by the butter and caseine associated with it. With the easy digestibility of the milk its nutritiveness is also proved; nor need we be astonished at the abundance of water in an aliment which, at the same time, furnishes the infant with solid and liquid food. And if the weight of the caseine scarcely amounts to one-sixth of that of albuminous bodies in beef, we must not forget that we commonly take the latter diluted—as in the form of soups, or associated with vegetables or edible roots; combinations by which the proportionate amount of albumen is considerably diminished. But the quantity of sugar of milk in the human milk is twice as great as that of caseine, and the butter is intermediate between both.

The milk of cows is often assimilated with difficulty by weak digestive organs, from the large proportion of butter it contains; but skimmed milk is in such cases usually readily digested, and this we find in a natural state in asses' milk. Poverty in fat, and abundance in sugar, make asses' milk an invaluable nutriment, maintaining and cheering the life of many invalids. Several excellent rules are drawn from nature, and none more so than is to be found in the food which nature supplies for the nourishment of the infant. We may consider the health of the child to be the surest and largest experience which enlightens us as to the right composition of solid and liquid food which man has to partake. This experience confirms the truth, that meat and bread cannot be taken without water; and that in the best nutriment of mankind, the albuminous and fatty matters, the constituents of fat, the compounds of chlorine, and the salts, must be represented without exception.

"Whether food has a yet higher influence," says Forster, in his dissertation on the utility of the bread-fruit tree—"whether mind and heart may directly or indirectly be tuned by it, will be left to our grandchildren for discussion. We only know that gentleness, love, and sensibility of heart, are the prominent traits of the people living on bread-fruit." And if we consider that, even now, the pastoral tribes are the gentlest, that the character of the beasts of prey is softened by getting accustomed to a mixed or a vegetable diet, why should it sound fabulous if we connect the noble tenderness of heart and pacific meekness of those tribes with the milk and the fruits upon which they live?*

§ 71. *Coffee, Tea, and Chocolate.*—The general opinion that coffee, tea, and chocolate, are beverages which, to a certain degree, may be substituted for each other, is based on a good chemical reason, for all three contain a nitrogenised basis, to which they owe some of their most important chemical properties. Tea and coffee even contain the self-same basis, denominated therefore, indiscriminately, thein or caffein. The basis of chocolate we will call cocoa-principle. The cocoa-principle, or theobromin, is richer in nitrogen than the thein, which very nearly corresponds in its composition with flesh-basis. In cold water, thein is only with difficulty dissolved, while of cocoa-principle but a small proportion is soluble even in hot water, in which the former readily dissolves.

While in tea the basis is combined with common tannic acid, in coffee it forms a salt with a peculiar tannic acid containing a greater proportion of nitrogen, which, together with tanno-caffeic acid, are united with potash into a so-called double salt. Tanno-caffeic acid, when roasted, develops the agreeable smell of coffee.

---

* Some curious researches have been made in reference to this by continental chemists; and it has been established as a fact, that diet has an essential connection with moral and mental development.—Ed

Not only the same basis, but also two similar organic acids—one contained in tea, the other in coffee—increase the conformity between the leaves of the former and the beans of the latter.

Legumin, cellulose, gum, sugar, citric acid, in addition to oleine and to the peculiar palm-fat, which derives its name from being found in the fruit of several species of palms, accompany the organic acids and the thein of the coffee-beans.

But the tea-leaves, apart from the basis and the acids, are composed of albumen, cellulose, gum, and wax, the green pigment of the plant, and the volatile oil of tea. This peculiar oil is the principal source of the aroma of tea, by which, in spite of the conformity between tea and coffee, it essentially differs from the latter.

The inorganic constituents of tea and coffee are, moreover, different. While in coffee, chlorine, phosphoric and sulphuric acids are combined with potash, lime, magnesia, and oxide of iron; tea contains another inorganic acid besides, consisting of manganese and a large proportion of oxygen.

In the kernels of cocoa, of which chocolate is prepared, there are to be found, besides the cocoa-principle, stearine and oleine, cellulose, gum, and starch, a red colouring matter, and a small proportion of water.

Chicory, so commonly used as a substitute or accompaniment of coffee, contains neither caffein nor any other peculiar constituent of the latter. No albuminous substance ever has, up to this time, been found in chicory. As albumen is not wholly wanting in any vegetable product, it must be present in chicory, though in a very small quantity. But the constituents of fat are represented in a larger proportion; for in addition to cellulose, sugar, and gum, it contains a pretty considerable quantity of a substance of the same composition as starch, which, by simply boiling in water, is transformed into sugar. Chloride of sodium, a compound of chlorine with ammonia (the so-called sal-ammoniac), sulphate and nitrate of potash, are its inorganic constituents.

As yet, therefore, no great importance as a nutriment can be attributed to chicory, nor any similarity with coffee. Unless a peculiar organic substance contained in it, but not yet exactly investigated, shall at a future time be proved to be peculiarly valuable, the infusion of chicory possesses no advantage over sugared water, to which a brown colour and bitter taste have been imparted; but we do not understand this bitter substance. Whilst, then, chicory cannot, on scientific grounds, be made out to be a true substitute for coffee, it has, on the other hand, been too partially investigated to justify an absolute condemnation.

§ 72. *Preparation of Teas.*—Roasted coffee differs from raw by its lighter weight and greater bulk. Several empyreumatic substances, produced by roasting, occasion the reddish or dark-brown colour; and the tanno-caffeic acid, altered by roasting, produces the aroma; the sugar loses a part of its amount of hydrogen and oxygen, and is thus decomposed into burnt sugar or caramel. In the infusion, the caffein and the acids, the gum and caramel, the melted fat and the salts, with legumin in a very slight proportion, are to be found.

Between green and black tea, erroneously so often supposed to be produced by different plants, a similar difference exists to that between raw and roasted coffee. The leaves are turned black by being dried at a higher temperature than that to which the green tea has been subjected. The latter is first brought into a withered condition by vapour, and then dried in iron kettles; while black tea is prepared by heating over an open fire. As heat exercises a decomposing action, black contains less tea-oil, less tannic acid, and less green colouring matter than green tea. By the process of drying, however, a dark product of decomposition is formed, few traces of which are found in green tea, but a considerable quantity in black. In China, tea is frequently coloured with curcume, and indigo or Prussian blue.

By the effect of the open fire, in black tea the albumen is more completely coagulated than in green; by this coagulation the tea-oil becomes disengaged. Partly from this cause the black tea has lost a greater proportion of its tea-oil than green; and for the same reason, tea possesses more flavour if infused with perfectly boiling-water, which coagulates all the soluble albumen, and therefore dissolves the tea-oil with greater ease. But the tannate of thein, also, is only sufficiently extracted by boiling-water: this compound is even separated at a low temperature; and hence the turbid appearance of a well-prepared infusion of tea when cooling, which everybody knows who has ever taken his tea out of a tumbler, as the Russians generally do. Thein and tea-oil, however, are the most important constituents of tea; boiling-water is therefore an indispensable condition, if we wish to partake really of tea, and not of a brown solution of gum. The tea-leaves have only to be infused with boiling-water, and after this the process of boiling must not be continued, or the tea-oil escapes, and the formation of a bitter solution of tannic acid takes place, a decoction which could as well be prepared from oak-apples. The first infusion contains four to six times more of the peculiar constituent of tea than the second.

Finally, the two principal kinds of chocolate are distinguished similarly to green and black tea. It is true, the cocoa seeds, of which chocolate is prepared, are always roasted. Besides the decomposed fat, an aromatic empyreumatic substance of dark colour is formed from the starch and gum; but the proportion of the latter substance is larger in the more strongly roasted, dark-brown Italian chocolate, than in the Spanish, which, being less roasted, holds more starch and butter of cocoa in an unaltered state. The colour of the Spanish chocolate is brown-red; its taste not so bitter and aromatic as the Italian.

§ 73. *Nutritive Qualities.*—From its very large proportion of albumen, chocolate is the most nutritious of these three beverages; but, at the same time, the most difficult of digestion from its quantity of fat. But as its aromatic substances strengthen the digestion, a cup of chocolate is an excellent restorative, and invigorating refreshment even for weak persons, provided their digestive organs are not too delicate. Cardinal Richelieu was indebted, in his later years, for his health and hilarity to chocolate.

Tea and coffee do not afford this advantage. Albumen in tea-leaves, and legumin in coffee-berries, are represented in very scanty proportions, and still more scantily in their infusions: for while in the former the albumen is coagulated by boiling-water, in the latter the legumin is prevented from being dissolved by the lime with which it is combined.

It is true that coffee and tea have been praised, even by chemists, as nutritious substances, at a time when "nitrogenised" and "nutritious" were considered identical terms. Since then, however, we have learned that, as restoratives for the body, not the elements but the alimentary principles are to be taken into account. The latter appellation cannot be ascribed to thein, which is excreted again as urea with surprising rapidity. To this swift transformation tea and coffee owe their diuretic action, which is considerably assisted by the warm water of the infusion; the kidneys attract the urea, with which the thein charges the blood.

Tea and coffee, though of themselves not difficult of digestion, tend to disturb the digestion of albuminous substances by precipitating them from their dissolved state. Milk, therefore, if mixed with tea or coffee, is more difficult of digestion than if taken alone; and coffee alone, without cream, promotes digestion after dinner, by increasing the secretion of the dissolving juices. No Italian takes cream with his coffee after dinner.

The volatile oil of coffee, and the empyreumatic and aromatic matters of chocolate, accelerate the circulation, which, on the other hand, is calmed by the tea-oil.

Tea and coffee excite the activity of the brain and the nerves. Tea increases the power of digesting the impressions we have received: "we become disposed for thoughtful meditation, and, in spite of the movements of thought, the attention can be more easily fixed upon a certain object; a sensation of comfort and cheerfulness ensues, and the creative activity of the brain is set in motion: through the greater collectedness and the more closely confined attention, the thoughts are not so apt to degenerate into desultoriness. Educated persons will assemble to tea for the purpose of investigating a certain subject by a regular conversation; and the higher spirits produced by the tea, tend to secure with more facility a successful result. If tea be taken in excess, an increased irritability of the nerves takes place, characterised by sleepiness, by a general feeling of restlessness, with trembling of the limbs. Spasmodic attacks even, in the cardiac region, may arise. The volatile oil of the tea produces heaviness in the head; and, in fact, a real tea-intoxication, first manifesting itself in dizziness, and finally in stupefaction, takes place. Green tea, which contains much more of the volatile oil than black, produces these obnoxious effects in a far higher degree than the latter."

While tea principally revives the faculty of judgment, and adds to this activity a sensation of cheerfulness; coffee acts also on the reasoning faculty, but communicates to the imagination a much higher degree of liveliness. Susceptibility to sensuous impressions is intensified by coffee; the faculty of observation is therefore increased, while that of judgment is sharpened, and the enlivened imagination causes the perceptions more quickly to adopt certain forms; an activity of thoughts and ideas is manifested; a mobility and ardour of wishes and ideals, which are more favourable to the shaping and combination of already premeditated ideas, than to a calm examination of newly originated thoughts.

"Coffee, taken in excess, causes sleeplessness and a state of excitement similar to intoxication, in which images, thoughts, and wishes rapidly succeed each other. A sensation of restlessness and heat ensues, together with anxiety and dizziness, trembling of the limbs, and a strong desire to go into the open air. Fresh air is commonly the best means of throwing off this condition, which, whilst it continues, exercises a really consuming power over man."

In Constantinople, the first coffee-houses used to be called schools of knowledge. Poets and philosophers assembled in these schools; their discussions and judgment alarmed even the ruling authorities; and the "schools of knowledge" were at last closed. In the seventeenth century, the coffee-houses in London had a similar fate; but the habit grew too strong for the state.

§ 74. *Wine, Beer, and Spirits.*—The immense variety of intoxicating liquors forms a striking illustration of the pains which men have always taken to excite the brain. Alcohol is the magic name with which the action of all these liquors is associated. Alcohol, a volatile substance, composed of carbon, hydrogen, and oxygen, may be produced from sugar; and thus, wherever the chemist finds an abundance of sugar, this discovery is ever closely followed by the proposition to transform the saccharine substance into alcohol. But long before the chemist could give his directions, palm-wine was in favour in Babylon; the Phœnicians and Greeks drank their wine, which their poets celebrated in songs. The Tartar sought intoxication in his kumiss, and Ossian praised the mead as "the power and glory of the shells"—the drinking-vessels of the Caledonians. In the juice of the palms and grapes, in milk and honey, in corn and potatoes, as well as in many fruits, this fermentable substance was found before the principle of fermentation and the nature of the process had even been divined.

Now we know that sugar is the fermentable substance, and that all intoxicating liquors must contain either sugar itself, or a constituent of sugar. When potatoes furnish alcohol, the starch has previously been converted into sugar; and before the kumiss is produced from milk, the sugar of milk has been changed into grape-sugar; for the latter only is directly fermentable. Starch and gum, cane-sugar and sugar of milk, are only indirectly so, being turned by the action of acids into grape-sugar. An albuminous body stimulates the fermentation: it is yeast. At a high temperature, sugar ferments under the influence of yeast. Air-bubbles rising in the juice, and a vinous smell, betoken that the effect of this agent has begun. The air is filled with carbonic acid, and the smell is occasioned by the spirit of wine, called by chemists alcohol, if free from water. The sugar is transformed into alcohol and carbonic acid, upon which the fermentation ceases. Diluted alcohol, or spirit of wine, is the intoxicating substance from which beer, wine, and brandy derive the name of spirituous beverages. Spirit of wine is contained in all fermented liquors. The proportionate quantity only is different; for while the lightest beer scarcely contains more than one-hundredth part, and the strong English ale scarcely more than eight-hundredths of alcohol, in wine its proportion rises to from seven to twenty-six per cent.; and in the strongest brandy this quantity is surpassed twofold. In the latter the alcohol of the fermented juice is concentrated. A high temperature evaporates the spirit of wine, which is collected in the vessel of a still. The name of brandy (burnt wine) attests the assistance of fire, by which it was carried over into the vessel.

First of all, therefore, beer, wine, and brandy are different in their respective strengths, which is due to their proportionate amount of alcohol. The several concomitants dissolved in spirit of wine explain the rest.

§ 75. *Alcohol in Wines and Beer.*—The weak alcoholic solution of beer contains nearly the same proportion of albumen as is found in fruits, some sugar and gum, malic acid from the hop, sometimes also some lactic and acetic acid, products of decomposition of the sugar and alcohol; and in addition to these a peculiar constituent of the hops, soluble in water, and consisting of carbon, hydrogen, and oxygen, which from its bitter taste is called the bitter principle of the hop (lupulin), together with some essential volatile oil of hops. The combinations of potash, lime, and magnesia, with sulphuric and phosphoric acids, are associated with carbonic acid, which is contained in the beer the more abundantly, as the quantity of sugar which had undergone fermentation was smaller when the beer was put into the barrel. A frothy beer is often prepared by a certain addition of sugar in bottling, and better still by adding sweet fruits—raisins for instance—in which both the ferment and the principle which promotes fermentation, sugar and yeast, are present. High-dried malt gives to the beer a more or less brown colour; hence the difference of colour between ale and porter.

In wine, more alcohol and less water than in beer, are combined with sugar and gum, with resin and colouring matter, acids and salts. Even the white wines contain a peculiar colouring matter, yellow-like oil, whitened by acids, browned by alkalies. The yellow tint of white wines, which after having been frozen have thawed again, is produced by the partial disengagement of the acid salts, which caused the lighter colour before the wine had frozen. The different kinds of grapes of a light or high yellow or copper colour, of a blue, red, or dark-brown tint, produce as many different colours in wine. The number of the peculiar colouring matters is probably smaller, as the acids and salts of the grapes alter the colour. By the action of acid salts, the blue colouring matter turns red. The particular colour distinguishing very old Rhine wines is occasioned by wax, which is united with the colouring matter.

The acids of the wine are the acids of the grape. Tartaric and malic acids—perhaps, too, citric acid—are sometimes accompanied by the tannic acid of the husk and by grape acid, being of the same composition as tartaric acid, with which it is associated in several kinds of grapes. As the fermentation has not ceased when the wine is put into the casks, all wines contain a certain proportion of carbonic acid; and the strong effervescence of sparkling champagne, depends upon the intentionally interrupted fermentation, which continues in the bottles.

The following are the salts contained in wine:—Cream of tartar, or acid tartrate of potash; tartrate of alumina, combined with tartrate of lime into a double salt; malate of lime; lime combined with phosphoric and carbonic acids, in addition to magnesia, iron, and manganese. In red wine there is a greater proportion of salts than in white; in both of them, the alcohol, augmented by the fermentation which still goes on in the casks, separates a part of the salts.

In all wines a peculiar ether is contained, upon which the odour generally depends. In this ether, the common chloric ether exists, in combination with a peculiar organic acid, which we may call the acid of wine-ether. The perfume, or "bouquet," is something different from the odour of wine produced by the wine-ether. This bouquet is extremely various. It distinguishes the Rhine wine, but in several wines it is not to be found at all. It is also produced by different kinds of ether, by ether combined with butyric, or valerianic, or acetic acid. The latter compound is said to be found in most of the Bordeaux wines or clarets. Like ether itself, which in its composition differs very little from alcohol, but surpasses the latter in volatility, the combinations of ether with organic acids are very volatile. Wine-ether and the bouquet are therefore recognised by smell.

The colouring matter and bouquet, the acids and salts, cause, by the difference of their composition, the variety of wines. The strength of wine depends upon its proportion of alcohol, and the sweetness of sack upon that of sugar. Spirits are obtained from corn and potatoes, from lees of wine and juniper-berries, from sugar and rice, from milk and fruits. The spirit of corn, or whisky, contains wine-ether and margaric-ether, oil of grain, and potato-spirit oil, which increases the pungent odour of spirits. Potato-spirit contains the same constituents, with the exception of oil of grain and margaric-ether. Brandy, or Cognac, is a mixture of water and alcohol with wine-ether and acetic-ether. The inferior sorts of Cognac contain also some potato-spirit oil. The fragrance of rum, which is prepared from the juice of the sugar-cane, is produced by a combination of butyric acid and ether. The molasses which remain after the preparation of sugar from the juice of the cane, yield the finest rum, called tafia, or ratafia. Arrack is obtained from rice; gin or Geneva from juniper-berries; kumiss (as already stated) from milk; and mead from honey.

§ 76. *Alcohol in Spirits.*—A good beer is as nutritious as fruit; the nutritious quality of wine is scarcely equal to that of sugared water; and spirits, in their proportionate amount of nutritious matter, do not even bear comparison with sugared water. Is it, therefore, a mere illusion that spirit compensates for the scanty food of the poor? And is the zeal, therefore, justifiable which attempts to check its use as an intoxicating poison—a destroyer of domestic peace and well-being? Such questions we often hear. Even medical men, occupied with the study of human physiology, have answered them in the affirmative: we shall reply to these questions by facts.

Alcohol, the essential constituent of spirits, and the most important substance in beer and wine, is not transformed into an essential constituent of the blood. It does not, therefore, effect any direct restitution, nor deserves the name of an alimentary principle. Still, it passes into the blood. By the oxygen we inhale, it is burnt in the blood into acetic acid and water, and finally into water and carbonic acid. But the oxygen, which decomposes the alcohol, is withdrawn from the albuminous and fatty substances of the blood. Alcohol, from its greater combustibility, protects these constituents of the blood from being burnt. And, if in addition to this, both special experiment and ordinary experience prove that alcoholic beverages diminish the quantity of carbonic acid we exhale—apparently from a great part of the inhaled oxygen combining with the hydrogen of the alcohol to produce water—there is a twofold argument for believing that alcohol moderates the combustion of the constituents of the blood, and therefore diminishes the first cause of the need of restitution.

He who possesses little, must spend little, if he wish to retain as much as another who unites abundance with liberality. Alcohol may be considered a savings-box of the tissues; but let the reader understand this expression rightly. He who eats little, and drinks a moderate quantity of spirit, retains as much in the blood and tissues as a person who eats proportionally more without drinking any beer, wine, or spirits. Hence it follows that it would be cruelty to deprive the working man, who earns his frugal meal by the sweat of his brow, of those means by which he is enabled to prolong the nourishment yielded by his scanty food. Or are we to abolish a custom which renders abuse possible, to degrade man by demanding of him to renounce an enjoyment, in order that he may not succumb to a bestial instinct? The monk who requires the vow of chastity, does not greater violence to the true nature of man, than the physician who would prohibit spirits because some men are drunkards. Goëthe has given to the new contemplation of the world the noble watchword—"*Memento vivere.*" He who preaches the renunciation of spirits, transfers us to the Christendom of the middle ages, which, by its motto of "*Memento mori,*" has stifled the fairest blossoms of humanity.

§ 77. *Fermented Liquors.*—Fermented liquors, taken in moderation, increase the secretion of the digestive juices, and promote the solution of the food. Taken in excess, they cause induration of the stomach; which destroys, together with the digestive powers, the formation of blood.

Beer, wine, and spirits accelerate the circulation, or, as people say, heat the blood. This acceleration is produced in a higher degree by wine than by beer—more by spirits than by wine; not merely because wine contains a greater proportion of alcohol than beer; and spirits still more than wine;—but in wine and spirits, the different kinds of ether, the oil of grain and the potato-spirit oil, all tend to quicken the circulation of the blood. The glowing cheeks and glistening eyes are produced by the capillaries of the cheeks and eyeballs being more filled, in consequence of the increased activity of the heart.

Together with the blood, the alcohol passes into the brain, which beyond all other organs is affected by its action. Spirituous liquors stimulate the imagination in particular. "In consequence of this faculty, the association of ideas is facilitated, and the memory sharpened. The susceptibility of the senses is also rendered more keen; the impressions are quickly and distinctly perceived. The judgment is formed with greater ease, as, from the lively idea and the excited memory, the facts from which it is derived are brought nearer together. Hence a frequent and surprising clearness and precision of judgment in matters not requiring a long and close examination. We speak foreign languages with more than usual adroitness. The facilitated movements of thought, the versatility of ideas, are associated with greater ease in the movement of all the voluntary muscles; the voice becomes fuller and stronger; the weariness and relaxation following the exertions of the body vanish. Thus arises a feeling of comfort and delight, of increased strength and freshly-armed courage, scaring away ill-humour, sorrow, and fear. The affairs of others find a greater sympathy and forbearance, which, in return, are likewise expected of those around us. We therefore talk with a greater self-confidence of ourselves; and not only of what has already been performed, but even future undertakings are spoken of with unreserved self-complacency.

"When wine or other spirituous liquors are taken in excess, hallucinations of the senses ensue; objects appear to the intoxicated person obliterated, blurred, or double; dark spots resembling flies and sparks appear before the eyes; there is ringing in the ears; he cannot hear distinctly his own voice nor the voice of others; crying instead of speaking, and involuntarily singing out of tune. At the same time the imagination produces uncertain, variegated, unsteady images, combined without regularity; the memory refuses its functions in the very act of speaking; the intoxicated man forgets what he intended to say, and thus the judgment is troubled and confused. Then follow the ebullitions of an unjust passion, and a sensibility to opposition, which is so much the oftener irritated as the disturbed action of the brain, over-loaded with alcohol, impairs the correctness of the judgment.

"Excessive indulgence in wine and all other spirituous liquors, causes sleep; if increased to a complete intoxication, the mental functions are disturbed to such a degree, that a condition of temporary insanity supervenes; the senses become blunted; the imagination produces the most various and irregular images, which the judgment is unable to examine, distinguish, or combine; all self-possession vanishes; at length even consciousness is lost, the intoxicated man becomes giddy, and finally falls into a profound slumber.

"But, before this, a sensation of lassitude and exhaustion arises; the muscles lose their elasticity; the features become flabby; the angles of the mouth are depressed; the pupils widen; and urine and excrements are involuntarily voided. The muscular coat of the stomach, urged at the same time by a pressure of the diaphragm and the abdominal muscles, often acts in an inverse direction; violent vomiting is a common phenomenon. Even the respiratory muscles are weakened, and often act irregularly, occasioning sighs or groans; the pulse becomes languid and slow. In addition to this, an increasing reluctance and uncertainty in all voluntary movements is observed; the tongue stammers, or speech entirely ceases; the head sinks, the arms hang down, the legs cross each other when walking; the drunken man staggers—his paces cannot maintain a steady direction—he totters and falls."*

We hasten from this disgusting picture, to describe, in the words of Hettner, the condition of a more moderate inebriation, intermediate between the former and perfect sobriety. "A beautiful, vigorous, full body," says Hettner, of an ancient work of art, "in the first freshness of a still juvenile manhood, with great, firm, swelling limbs; there he lies at his ease, partly leaning against a rock, his limbs partly outstretched. In this state of happy inebriation he has chosen this place of rest; now he has fallen asleep—arms and legs are hanging down; in his features are the indescribable expression of a half-intoxicated slumber. In a confused dream, the wakeful imagination is still dwelling with delight upon the past hours; but the weary, unnerved limbs cannot follow this sweet ecstasy. The eyes closed, the mouth widely open, this sleep is the state of that 'seedy' half-slumber, in which the internal heat and a thirst panting for water urge to awake; while the limbs, craving repose, desire to continue sleeping, and the mind is unconsciously apprehensive of the dreary, unrefreshed awakening."

ON CONDIMENTS.—§ 78. *Common Salt.*—When Cook and Forster, in 1772, visited the island of Otaheite, the natives were astonished, on account of the crew at dinner dipping every piece into "a white powder." At the same time they took their fishes and meat with a sauce of sea-water, containing common salt in abundance. It was a similar case to that of the Greeks and Romans, who were well acquainted with the alcohol in wine, but did not know the art of obtaining it pure and concentrated, by the process of distillation.

The addition of common salt to the food, whether in the form of sea-water, as a product from this, or of rock-salt, as dug from the mines, is usual everywhere. We must not wonder at this, seeing that common salt is contained in our blood in as great a proportion as it is scarce in the natural aliments; for in animal food the blood and cartilages are provided with the greatest proportion of common salt, and these are just the parts of flesh-meat which are taken in the smallest comparative quantity. In our vegetable food, potash so generally predominates over soda, that only a few plants of the sea-shore form an exception by their large proportionate amount of soda. Some vegetable aliments, turnips for instance, often contain no soda at all.

The addition, therefore, of common salt, consisting of chlorine and sodium, is usually an indispensable necessity; and as the vegetable aliments contain a smaller proportion of common salt than animal, the latter is generally mixed with less salt than the former. Hence, it becomes possible to some nations, as the Samoyedes, the Kamtschatdales, and some Indian tribes of North America, to eat meat or fish without any addition of salt. The greater the proportion of blood contained in meat, the more easily the addition of common salt may be dispensed with.

The common salt, however, of our kitchens is not a pure chloride of sodium. Rock-salt is generally the purest, as containing only some traces of chloride of potassium and chloride of magnesium, in addition to a somewhat greater proportion of sulphate of lime. But with bay-salt, a much greater proportion of chloride of magnesium and sulphate of lime, with a not inconsiderable quantity, besides, of sulphate of magnesia, or Epsom salts, are mixed. In common salt prepared from sea-water, chloride of potassium is entirely absent, or only small traces of it are found, which sometimes coexist with as small a proportion of iodine.

Common salt is as digestible as nutritious; for water dissolves it with great ease: and while no tissue of the human body can exist without common salt, the blood and the cartilages cannot keep up their regular composition without a considerable proportion of it.

If we also bear in mind that common salt promotes the digestion of the albuminous substances, and that the scantily soluble fats, when salted, become less difficult of digestion, the chloride of sodium appears to be the most important addition to food, rightfully meriting to stand at the head of the series of condiments. On account of its greater proportionate quantity of chloride of magnesium, sea-salt dissolves the albuminous substances more readily than rock-salt; for the temperature of the body is of itself sufficient to transform the chloride of magnesium into hydrochloric acid and magnesia; and every diluted mixture of hydrochloric acid and water is able to dissolve the albuminous substances.

Common salt is very useful for the preservation of aliments, by attracting their water, which more than any other constituent occasions putrefaction; yet it is important to know, that meat, by being salted, loses a part of its best alimentary principles. Together with the water of the flesh, albumen and kreatine, the lactic acid and the salts are extracted by the common salt. The brine thus formed is thrown away, and with it a part of the most soluble and most important substances of the flesh. This loss is somewhat compensated by the fibrine of salted meat being more soluble than fresh muscular fibres, as well as by the use of bread and vegetables containing chloride of potassium and phosphate of potash, which have been extracted from the meat, and substituted by the common salt.

By the excretions, common salt is abstracted from the blood. In the same proportion as the urine and the excrements, the mucus and the perspiration, the tears and the horny substances, have deprived the blood of common salt—the blood nourishing the nerves of the tongue is poorer in this salt. This is the reason why unsalted food tastes insipid. And even here the necessity of a law governs the seeming play of arbitrariness. It is the strictest consequence of cause and effect which unites the taste of the nutriment with the reception of the right alimentary principles. In former times, it was conceived to be a result of wise calculation, that just those aliments should have a better taste which contain the matters most requisite for the blood, and regarded as an inherent inclination in man to salt his aliments. "If it be considered more edifying," says Charles Snell, "to conceive of the Creator, so to speak, to be like a watchmaker who calculates exactly, than to regard Him as the organic, acting, productive reason of nature, we will not dispute any more." But then we renounce all certainty of knowledge; for it can scarcely be proved that it is part of the original tendency of our being to supply our blood with common salt; but the connection between differently mixed blood and differently feeling nerves, is perspicuous and evident.

---

* *Physiology of Food*—Moleschott.

§ 79. *Butter and Olive Oil.*—In milk left undisturbed for some time, cells containing butter rise to the surface. From the stratum thus produced, by beating or stirring at a higher temperature, butter is formed. The force of stirring, supported by a moderate heat, causes the cells in which the butter has been included to burst; the disengaged fat collects into flakes, conglomerating into larger masses.

This origin explains why butter cannot consist of pure fat; the proportion of the fat in it does not amount to more than from six-sevenths to four-fifths of the whole, one-seventh to one-fifth consisting of water combined with some caseine and sugar of milk. The fat of the butter, however, is for the greater part real butter-fat, or butyrine. By this name the chemist designates a fat peculiar to butter, which, for a long time, was supposed to be the only one present in it; but at the most, this amounts to but two-hundredths of its weight. Butyrine becomes liquid at a very low temperature. It consists of glycerine and butyric acid, which is volatile in a free state, and possesses strongly the characteristic odour of butter. Three fatty acids besides, all volatile in an uncombined state, are, like butyric acid, united with glycerine, and therefore without odour in the fresh butter—namely, the caseic, sudoric, and capric acids.

The other fats of butter are oleine and margarine. As oleine is more fluid than the oil of almonds, the solidity of butter depends exclusively upon the margarine. At a very low temperature the oleine coagulates, and accordingly produces the greater firmness of butter in winter; which is also partly to be explained by the fact, that in the latter, oleine and margarine are contained in the proportion of one to three; while in the butter made in summer, the inverse proportion exists. Margarine melts at the temperature of 118° Fah., and therefore winter butter also liquefies at a higher temperature. But while melted butter is cooling again, the liquid fats separate from the coagulating margarine, and hence the butter assumes a taste disagreeable to most persons. But much more so is the decomposition of real butyrine, and the other neutral fats composed of the volatile acids and of glycerine; for if butyric, caseic, sudoric, and capric acids become disengaged, the butter assumes an offensive, pungent odour, and an acid taste, liked only by the Icelanders. The butter is then called rancid.

This decomposition is produced by the caseine and the water of the butter. Common salt, intermingled with butter, has the advantage of attracting the water and causing the caseine to be ineffectual; while by the process of melting, the caseine is skimmed off from the surface of the butter as a gray scum, and the water evaporates. For preservation, therefore, butter is generally melted and salted.

Olive-oil is commonly used as a condiment with salad. It contains nearly three-fourths of oleine, and very little more than one-fourth of margarine. In the oil of almonds, the oleine is more than three-fourths, and the margarine rather less than a quarter, of the whole.

Although these oils do not afford any neutral fat with volatile acids, yet they have the property of becoming rancid like butter; for, by the process of decomposition, both caseic and capric acids are formed out of oleic acid. This transformation, however, caused by the influence of oxygen, takes place only very slowly in olive-oil, as consisting entirely of mere fat; and olive-oil, as well as the oil of almonds, may be preserved for a very long time without becoming in the least rancid.

§ 80. *Digestibility of the Fats.*—Only that small proportion of the fats which can be saponified by the alkali of the bile, the pancreatic and intestinal juices, is to be considered soluble in the digestive juices. By far the larger part is so finely subdivided by the pancreatic juice and the bile, as to be able to penetrate the walls of the lacteals and the veins. Moreover, with respect to this fact, the fats are to be considered as difficult of digestion; they are far inferior to the constituents of fat in the capability of being dissolved, but superior to them in the greater conformity with the actual constituents of the blood.

The observation, however, which was made a little time ago, that starch is much more easily transformed into fat if taken with some fat than if alone, proves butter, as well as olive-oil, to be particularly useful. In bread-and-butter, therefore, we have the satisfaction of discovering a fresh and striking illustration of the truth, that ancient experience often leaves to science nothing to do but to establish and explain its laws.

Quite unjustly, therefore, are butter and oil said, without qualification, to be difficult of digestion; and the poor man has adopted the best substitute when he tries to supply the want of butter by grease. Butter on bread is a necessity recognised by impartial science; salad without oil is digestible only by herbivorous animals.

§ 81. *Cheese.*—Cream, milk, skimmed milk, and whey furnish severally cream-cheese, rich, meagre, and green cheese. In its abundance of fat, cream-cheese is the richest: while green cheese, prepared from whey, which contains only a very small proportion of fat, is the poorest of all.

The principal constituent of cheese is the caseine of the milk; according to the means by which this caseine has been coagulated, whether by rennet or by the lactic acid formed in the milk itself, the cheese is called sweet or sour-milk cheese. The action of the rennet (*i.e.*, the stomach of calves) is aided by a warm temperature; a high temperature causes cheese to become hard, just as the abundance of fat makes cream-cheese soft.

In milk, the fat closely adheres to the caseine; in cheese, therefore, the proportion of fat exactly corresponds with the relative quantity of butter. In addition to butter, the salts of the milk, and a part of the sugar of milk, are to be found in cheese. In real cheese the caseine and the butter are partly decomposed. Of the caseine is formed a nitrogenised substance, the "leacin," which we will denominate "cheese-white," as it crystallises in glittering white threads, and as this word recalls the chemical technical expression. Besides this substance, an oily acid is developed, not very readily soluble in water, which corresponds with the peculiar acid of the root of valerian, not only by its penetrating odour, and its strong, pungent taste, but also in its composition and all other qualities; it is therefore called valerianic acid. Some butyric acid besides is formed of the caseine; and hence we find in cheese which is several months old, more butyric acid than in fresh.

But the greatest proportion of the butyric acid originates from the decomposing butyrine; and the same is the case with the caseic, sudoric, and capric acids, associated in cheese with the valerianic acid.

A part of the whey is very often retained in the cheese; the sugar of milk of the whey is decomposed into butyric and carbonic acids, and the latter causes the holes to be observed in the Swiss and American cheese.

The odour and taste of the cheese is produced by the fatty acids, as well as by the valerianic, which is similar to them. Common salt decisively checks the formation of these acids from caseine and butter. The taste of many Dutch cheeses is less aromatic, from their being mixed with an abundant proportion of common salt; and as the decomposition of caseine and butter increases with their age, the odour and taste of the cheese is much stronger the longer it has been kept.

Though butyric acid may originate from three different substances of the milk—namely, from butter, sugar, and caseine—yet the butter contributes by far the greatest proportion of volatile acids. A rich cheese, like that of Limburg, smells therefore much stronger than the poor Marzalino, or the still poorer green cheese.

§ 82. *Digestibility of Cheese.*—In speaking of the fat contained in confectionery, we have already remarked, that the digestion of it is the more difficult in proportion as it has been transformed by a high temperature into its products of decomposition. The abundance of these products of decomposition is the cause of the difficult digestion which characterises cheese itself. But cheese impels the digestive glands to a greater activity; a greater quantity of saliva and bile, of gastric and pancreatic juices, is secreted and carried into the digestive canal; and hence the cheese, notwithstanding its difficult solubility, may be considered, in a restricted degree, as promoting digestion. And not for this reason alone; for the caseine, while in a state of decomposition, promotes also the conversion of starch and sugar into lactic acid and fat. Like butter, cheese increases the digestibility of the bread; and dry bread is, therefore, less nutritious than bread with butter or cheese.

With regard to the inorganic alimentary principles, the cheese made from sweet milk is superior to that from sour: in the latter the earthy salts have been dissolved; while the phosphate of lime, contained in milk, is abundantly represented in the former. Only where the breeding of cattle flourishes, and milk is produced in abundance, cheese is prepared; where cheese is prepared, meat cannot be deficient; a rich blood produces, together with the vigour of the muscles, the noble mind and the ardent courage of liberty. This is the association of thoughts which made John von Müller say, that liberty thrives where cheese is prepared.

§ 83. *Vinegar.*—That which renders vinegar so favourite an addition to food is a peculiar acid, consisting of carbon, hydrogen, and oxygen, formed from alcohol by the absorption of an additional quantity of oxygen. From *acetum*, the Latin name of vinegar, this acid is called the acetic, and is to be obtained from all spirituous beverages. But as alcohol yields, in addition to the acetic acid, a quantity of water, both malt and wine-vinegar contain, in proportion to the acetic acid, more water than is to be found in either beer or wine, in proportion to the quantity of alcohol. Of wine or French vinegar, about one-twentieth in weight consists of pure acetic acid. In an inferior vinegar this acid does not even amount to more than one-fiftieth to one five-and-twentieth in weight.

Vinegar, therefore, is always a considerably diluted solution of acetic acid, containing in addition a small proportion of albumen and sugar, of gum, and of several other organic substances, especially of some colouring matters, which differ according to the liquor from which the vinegar has been prepared. Thus, in wine-vinegar there is some acid tartrate and sulphate of potash to be found; and in wine and fruit-vinegars, a proportion of tannic acid, to be attributed to the husks and skins of the fruits. Acetic-ether, as passing over into wine-vinegar from some kinds of wine, communicates a fine agreeable fragrance to the vinegar.

If the acetous fermentation has not entirely ceased, the vinegar still contains a small proportion of alcohol, which, by a further accession of oxygen, becomes decomposed into water and acetic acid.

In order to increase the sour taste of the vinegar, the admixture of one-thousandth part of sulphuric acid is permitted in England. If added in a larger quantity the sulphuric acid is injurious.

§ 84. *Dissolving Action of Vinegar.*—The vinegar assists digestion. With the exception of legumin it dissolves the albuminous substances, transforming, in a short time, even the gluten and the fibrine into a gelatinous mass. Hence, vinegar and butter are useful concomitants of fish; and vinegar promotes, as we have before mentioned, the digestion of meat.

As acids are capable of transforming cellulose and starch into sugar, the vinegar added to salad is likewise to be regarded as an admixture promoting digestion. Thus, in the majority of cases, the use of vinegar is a custom founded on good reasons. Only in soups of peas, beans, and lentils, vinegar is to be rejected, as by it, even if added in excess, the legumin is brought into an undissolved state.

The dissolving action of the vinegar upon the other albuminous substances goes even as far as to the blood. Beverages containing vinegar have a dissolving effect on blood, and are cooling; and in milk, the proportion of caseine-cells, containing the butter, decreases if the mother take much vinegar.

And because of this solution of the most important constituents of the blood, manifesting itself by a greater liquefaction, it would appear an unpardonable frivolity, or a lamentable ignorance, in young girls, to endeavour, from vanity, to produce by means of vinegar an artificial thinness; only too often, in attaining their aim, they incur dangerous and deeply-rooting diseases, which deprive them of their more beautiful maiden bloom.

§ 85. *Sugar.*—Sugar has a similar history to that of alcohol and common salt. As many fermented beverages were known before the art of distilling, and the salt taste of the sea-water before the art of inspissation by boiling or crystallising; so honey and sweet juices were familiarly known before the sugar, which produces their sweet taste, was extracted. It was not until the fifteenth century that the inspissation of the cane-sugar was learned; and it was much later before this process was carried to perfection.

Not only, moreover, has the method of preparing the sugar made great advance in later days, but also the knowledge of the sources whence it is derived. The temperate zone possesses in the red-beet a substitute for sugar-cane, though far inferior to it; and for the same purpose the sugar-maple is used in North America. Although the red-beet, the sugar-maple, and many other plants possess the same description of sugar as the cane itself, no other plant has been found equal to the sugar-cane; and the denomination of cane-sugar will maintain itself as descriptive of the sweetest kind of sugar. Cane-sugar is sweeter, and poorer in hydrogen and oxygen, than grape-sugar, which is distinguished from the former, and from sugar of milk, by its direct capability of fermenting. Acids, however, transform the sugar of milk, as well as cane-sugar, into sugar of grapes; and hence, the two former can indirectly be brought into a state of fermentation.

By boiling with lime, cane-sugar is purified; for the saccharine vegetable juice contains a portion of soluble albumen, which is coagulated by this process, and then skimmed off. A liquid is thus formed, containing uncrystallisable sugar, consisting, for the most part, of the brown syrup of commerce, called molasses or treacle. In addition to this liquid, crystals of sugar are obtained, which, while depositing themselves, become mixed with uncrystallisable sugar, and represent the brown, the raw-sugar, or Muscovado. In a purer state of its crystalline grains, the cane-sugar is called "loaf" or "lump-sugar;" while sugar-candy consists of regular and larger-sized crystals, formed by a slower process. A part of the lime enters into combination with the sugar; and the Muscovado, particularly, is mixed with some phosphate of lime, and a viscous substance, probably gum.

In honey we find grape-sugar, an uncrystallisable kind of sugar, and "mannite," or manna-sugar. The latter is distinguished from the other kinds of sugar by not being fermentable, and by containing a smaller proportion of oxygen than hydrogen; these two elements are present in the other sorts of sugar just in the same proportion as that in which they are contained in water. With these different kinds of sugar there is, in honey, some lactic acid most probably associated, which is formed by the decomposition of the grape-sugar, and some wax possessing a great similarity to the fatty substances.

§ 86. *Nutritive Qualities of Sugar.*—As by salts and acids, so likewise by sugar and honey, is the quantity of the digestive juices increased, and the digestion promoted. And the sugar, while being digested, enriches the gastric juice with a substance which assists in dissolving the aliments; for the sugar, on coming into contact with the saliva, has been partly converted into lactic acid, which acts upon the alimentary principles in the same manner as the hydrochloric acid of the gastric juice.

For this reason, sugar at once appears infinitely better than its reputation. Since the composition of the milk has been recognised, the sugar ought to have been acquitted of the bad repute which adhered to it for many centuries. A slander always leaves something behind; and even to the present time, the popular belief that sugar injures the teeth, is as widely spread as, on the counter-testimony of both experience and science, the opposite doctrine ought to be: for the teeth of the negroes in the West Indian colonies are of a bright white; and that which is thus proved by a whole community, remarkable for the abundance of sugar consumed among them, the example of many individuals nearer home amply confirms. Phosphate of lime is the chief constituent of the bones and teeth, but not before adult age; and an increase of the phosphate of lime is the essential characteristic of the development of the bones of children. Lactic acid dissolves the phosphate of lime of the food; and as sugar indirectly supports this solution, it facilitates the conveyance of the lime to the teeth. To this it must not be objected that sugar causes pain in a hollow tooth. Like sugar, a thousand other substances irritate the nerve; but who seriously believes that that is necessarily injurious to the healthy, which gives pain to the diseased?

The prohibition of sugar to children, therefore, is indefensible. Sugar is not dangerous to the teeth, but, on the contrary, assists in providing them with lime; it is useful to the stomach, if it do not, by being taken in excess, produce too great a quantity of lactic acid.

§ 87. *Spices.*—Under the name of spices we shall comprise mustard and carraway seeds, common and Spanish pepper, cinnamon and cloves, nutmegs and saffron. In addition to albumen and wax, cellulose and gum, starch and resins, acids and salts, which manifest unimportant differences with respect to their proportionate quantity and properties, all these spices contain a volatile oil of a pungent odour, and an acrid or aromatic taste.

It is only in the mustard, as we take it, that this oil is a product of fermentation. Just as the ferment of almonds (emulsine) transforms the principle of almonds (amygdaline) into volatile oil of bitter almonds, so a peculiar ferment of the black mustard decomposes a certain constituent of the latter, which is not to be found in the white mustard, into the volatile oil of mustard, which contains, besides carbon and hydrogen, a proportion of sulphur and nitrogen. Of a light yellow colour and a pungent odour, the oil of mustard is soluble only in a large proportionate quantity of water. To this oil the mustard owes its peculiar taste; the mother-body of the oil of mustard is of a bitter taste. The black mustard contains a portion of stearic acid and two other fatty acids; which last are likewise to be found in white mustard, but without stearic acid.

The oils of the different spices above enumerated are to be found, ready formed, in the vegetable substances; rather aromatic than acid, they consist partly of carbon and hydrogen, and partly of a combination of these two elements with oxygen. With fatty oils, the volatile are by no means to be confounded. The latter, though scantily soluble in water, are not entirely insoluble in it; cannot be saponified with alkalies; and are especially remarkable for their disposition to turn into resins by the absorption of oxygen. There exists no fat without oxygen; while several of the volatile oils contain nothing of this element.

Cloves are furnished with the greatest proportion of volatile oil; while its relative quantity in the more acrid nutmeg scarcely amounts to one-third; in the very acrid Spanish pepper not even to one-fourth; in the hot French cinnamon to one five-and-twentieth only of the proportion contained in cloves. Hence it follows, that in these spices, the degree of pungency of taste is dependent, not on the quantity of the volatile oil, but on its quality.

§ 88. *Heating Effects of Spices.*—In the first instance, it was, perhaps, only the pungent taste of the aromatic oils to which the heating effect of spices was ascribed; but the excitement and palpitation produced by their use, show that they accelerate the circulation. Not only, moreover, are the palate and stomach heated by direct irritation, but the cheeks also become tinged with a rosy glow under their influence.

These spices, by irritating the digestive glands, are also capable of promoting, to a certain degree, the solution of the aliments. Hence, the blood is not only provided with a heating oil, but also with an abundant supply of restorative substances; and the nutrition is increased at the same time.

Thus sleep also is prevented, and the passions are aroused. All nutriments causing sleeplessness irritate the brain, and accelerate the movements of thought. It is, therefore, not a mere fiction, that mustard for the moment quickens the action of the memory: just like the movement of the muscles, memory is an action of the brain; it is capable of being called into exercise like every other manifestation of bodily power. But the action, as an attribute of matter, is confounded with the instrument itself, if we say that mustard produces a good memory. It is true the instrument cannot exist without matter; moreover, it is not the bulk of the substance, but the celerity and force of its motion, which is to be considered the essence of increased action. The motion ceases with the matter which excites it. When, therefore, the volatile oil has disappeared from the blood, the excitement produced in the brain is over likewise; the mustard cannot, therefore, be an instrument of the memory. We repeat it—memory is a form in which the action of the brain manifests itself. But to call the brain an instrument of memory would lead to a greater confusion of terms, than if we were to denominate the muscle the instrument of speed. The brain thinks just as the muscle moves; sensation and will, recollection and judgment, are different forms of thinking, just as stretching and shrugging, trilling and grasping, are different forms of motion.

The spices cannot be called restoratives, as their most essential substance does not convey to the blood an essential constituent; they are stimulants; and whatever stimulates, renders over-excitement possible. An excess of stimulants, in the strictest sense, is therefore much more dangerous than a superabundance of nutriments. Sugar and common salt, butter and cheese, oil and vinegar, are far superior to the spices with regard to the service they afford to the body. When we consider the restless passion, the choler and insidious jealousy of those inhabitants of the tropics who take so great an abundance of spices with their food, we find it impossible to forgive the cruelty with which the Europeans of a former day sought to enrich their own part of the world with pepper and cinnamon, cloves and nutmegs. Had they never possessed any of these spices, the people of Europe would have one superfluous and often obnoxious addition to their food the less; and the Spaniards, Portuguese, and Dutch would be able to erase a bloody page from their history.

In the preceding pages, we have given so much of Professor Moleschott's remarks as exhibit the astonishing variety of combinations and their uses, of which oxygen, chlorine, fluorine, nitrogen, hydrogen, and carbon, are the subjects in the animal economy. Our readers will have learned how numerous are the changes of chemical compounds and products which a few elements are capable of producing; and how rapid and unceasing those changes occur in connection with vitality. In future pages we shall extend our observations to similar results observed in connection with vegetable chemistry; which, although having less direct connection with the chemical laws of our own existence, are only second to them in philosophical and practical interest. It would, however, be unjust were we to withhold that portion of the professor's paper which shows the application of the principles already laid down. It will assist to popularise the subject of chemistry with those of our readers who simply study the science as a branch of a literal education, or as a subject of general interest and importance. After introducing Dr. Moleschott's remarks on Diet, we shall then proceed to give the natural history of the remainder of the elements; the relationship of which generally exists in connection with the mineral kingdom, with the exception of instances referred to in our previous pages. Dr. Moleschott continues as follows:—

Of Diet.—§ 89. *Conditions and Definition of Diet.*—Real equality is shown in differences. We all are equal, only because even the slightest difference of circumstance produces a difference in the composition and functions of our bodies: another mode of life, another kind of food, another climate and soil, produce a different blood and brain. And, indeed, when from the icy north, up to the pure glowing sky of the tropics, so rich in flowers, we pursue the manifold gradations which act upon man by the boldness of contrast, as well as by the abundance of varying transitions—heat and cold—mountain and valley—sea and land—forest and steppes—animals and plants—we are no longer astonished that many refuse to recognise, in the changeful and multiform human species, the children of one ancestor, seeing that form and colour, as well as mind and morals, multiply distinctions in such prodigal abundance, as to render the very conception difficult.

Whatever, in their numberless shades of form and composition, the earth and the water produce, exercises its influence upon the food of man. We no longer fear to give offence by designating food itself as one of the most important sources of differences in our species;—so much the stronger emphasis, however, must we give to the assertion, that no influence exists, as an isolated one, in the history of our eternally progressing life.

Goëthe, with reference to the important axiom of Haman—that everything isolated is objectionable—says, in a manner at once so true and consolatory in all the incompleteness of human intelligence and expression—"In every communication of thought, if not a poetical one, there exists one great difficulty; for the word must detach itself, must become isolated, in order to say or to signify something. By speaking, man necessarily for the moment becomes one-sided; there exists no communication, no doctrine without separation." On the ground of this necessity, it is to be explained why we have left in the background the equally powerful influences of the air and the soil; of Nature as it surrounds us in the solitary forest, in the undulating mountain-region, in the wearisome monotony of vast plains, or in the awe-inspiring boundlessness of the tossing sea; why we have omitted to mention the intimate relation between plants and animals, the effect of the intercourse of man with man—now elevating, now degrading, often the source of the highest pleasures, but often, also, of the keenest wounds; why we have not specified the power of oral instruction, the magic of song—in order that we might speak with a greater emphasis of the far-reaching influence of food. Under the united influence of all these agencies, man becomes of necessity the being he is, comprehending the external world in just so many various aspects as the modes in which the latter acts upon him.

We have treated one part only of this series of food; but certainly not with the intention to remove a single link from the chain. The sea bordering the earth, and the earth the sea, both affect the condition of plants and animals; and these, again, occasion infinite diversities in the aliments of man, according to the climate. The effects produced by food upon man determine the commerce and the character of the people, as well as the individual. But commerce again alters man, man the food, and food the fields; everywhere action and reaction.

And to this reaction, the power of which is the surest and most concise expression of the heaven-storming reason of the race of Prometheus, man owes the pliability, so tenacious and yet so flexible, by which he becomes indigenous in every climate of the vast domain of nature. If he approach the north pole he contents himself with fish; while in the tropics he enjoys the fragrant fruit in addition to the savoury game; and if in the plains of North America, the huntsman lives on the flesh of the buffalo alone; while the New Hollanders, possessing on their vast island no edible fruit, not even the size of a cherry, take animal food exclusively: in the tropics, where meat taken in abundance is injurious to health, a vegetable diet prevails, to which, indeed, the inhabitants of Pegu and Malabar, from superstitious motives, restrict themselves.

Our blood is intermediate in its properties between that of the carnivorous and the herbivorous animals; but it is not in the blood that the difference begins, in the first instance, which distinguishes us from the animals that live on an exclusive diet. In our digestive organs themselves, a compromise has already been effected; and those differences present themselves, which are so sharply marked in the formation of these organs in the animals feeding exclusively on animal or vegetable food. If the herbivorous animal be enabled, by numerous and variously-formed teeth, to gnaw and grind, and by a long digestive canal and large salivary glands, to digest substances which could not be sufficiently comminuted by the less-developed and sharper teeth of the beast of prey, nor dissolved by their smaller salivary glands and shorter intestinal canal; in man we observe, in the structure of the teeth and of the jawbone, of the stomach and of the intestinal canal, of the salivary glands and the muscles of mastication, a proportion intermediate between the two.

Man, therefore, is able to digest both animal and vegetable food; and as there exist vegetable as well as animal aliments in which all three groups of the simple alimentary principles are to be found—as both bread and meat are able to convey to the blood its requisite elements—the native of Pegu gets accustomed to an exclusive vegetable diet, just as many North Americans live on animal food, and the Greenlanders almost entirely on fish.

Where both these products of nature—the gifts of the field and the gifts of the wood—exist in abundance, the taste selects from both sections some important representatives of nutriment; and if we denominate cattle and swine the domestic animals of man, corn and leguminous plants ought, with equal justice, to be designated his domestic fruits.

The more civilised that nations are, the more perfectly is the cultivation of domestic animals and fruits developed among them. Where agriculture as well as the breeding of cattle flourishes—or, to speak more correctly, where a thriving flock increases the fertility of the fields, and a productive agriculture the opulence of the stables—man takes for his nourishment meat and bread, milk and fruits. While digesting both with ease, the composition of his blood conforms to the digestion, just as digestion depends upon the structure of its organs; and if in man the digestion and formation of blood corresponds with his mixed food from plants and animals, will not a nutrition afforded by this mixed diet, just as it produces muscles and bones peculiar to man, develop also the brain, which, as really human, thinks and feels?

Equally remote from the savage hunting-tribes, kindred with that of beasts of prey; and the vegetable-eating Hindoos, with their greater mental indolence—not digesting in order to live, but living almost in order to digest—stands the cultivated European, who digests his mixed diet with ease, and from whose blood is evolved a brain, the action of which we admire in those forms where human beauty and wisdom are embodied.

This circulating mutual action, which on all sides unites man with nature, is continually recurring: the difference produced by the degrees of this mutual action causes the peculiarity of the individual. After a brief description of the change of matter in the tissues, as it generally takes place in the human species, we passed to the description, in general outlines, of the action of the several aliments. As sex and age, position and mode of life, habit and climate, exert various influences, we know but one-half of the science of food, so long as our acquaintance is limited to the metamorphosis of tissue in the species, and to the general action only of the aliment. The remaining half consists in describing the manner in which the tissue-change, as modified in the individual, determines the selection of the aliments. This selection constitutes diet; and hence there remains, in this book, for us the task of determining the diet in the principal circumstances of individual life.

§ 90. *Breakfast, Dinner, and Supper.*—Although during sleep the metamorphosis of tissue is less rapid, yet the eight or ten hours which commonly elapse between supper and breakfast, are sufficient to produce all those phenomena of sanguineous impoverishment comprised under the name of hunger. Hence, the meal breaking this state of fasting is called breakfast.

To the breakfast succeed the anxieties and labours of the day. Bread, therefore, or bread-and-butter, in the morning is a very proper food, as it is digested with sufficient ease, and yet so slowly as not too suddenly to overload the blood and brain with alimentary principles. Tea or coffee suitably prepares for the attention and exercise of judgment, and is more or less required by the labour of all classes. And from the consideration that tea more especially promotes the combination and the development of thought, while coffee excites the imagination likewise, a rational explanation is obtained for the fact, that in some countries, as for instance in Holland, those classes of society whose labour is chiefly that of the intellect, take tea for their breakfast, while those which employ both judgment and imagination take coffee.

§ 91. *Combination of Meat with Vegetables.*—Soup, vegetables, and meat, are the regular constituents of a European citizen's dinner. We have already explained how the daily taking of soup, together with the meat, is necessitated by the general custom of preparing soup from the same meat which is eaten when boiled. In the same section we showed the combination of meat with vegetables or edible roots to be a custom founded upon reason. Meat furnishes what is wanting in vegetables, and the vegetables dilute what meat contains in too great an abundance.

It is therefore an unfortunate custom, or a still more unfortunate necessity, that by so many poor families, potatoes, exclusively, should be eaten for dinner. When circumstances render it impossible to eat any meat with vegetables, the dinner ought to consist, as often as practicable, of leguminous seeds, the best of soups being from peas, beans, or lentils. Hence it follows again, that the distress of the poor might be essentially alleviated by the cultivation of the leguminous plants on so many acres of soil, where potatoes now grow or perish by a destructive disease.

In those families, however, which have meat on their table some days of the week at least, the meat ought on such occasions to be dished up together with potatoes or vegetables; while on the other days, the nutritious soups of peas, beans, or lentils, should be used. Such an alternation ought to be laid down as a general rule; for however correct the taste of certain housewives may be, in the selection of viands, it happens very often, in the more opulent households of the middle classes, that the meals are very improperly composed. How often does it occur that a meagre soup is followed by nothing but fish and potatoes! Or, how often is some kind of soup, together with a farinaceous dish, eaten without any addition of meat! Or a soup from some of the leguminous seeds is taken, and leguminous seeds or farinaceous dishes follow.

Whenever possible, meat ought not to be absent from the dinner-table; or if the less readily digestible and less nutritious fish be substituted, an easily digestible and substantial broth, or a nutritious soup of peas or lentils, ought to compensate for the defect. But if beans and farinaceous dishes, or soups of the leguminous seeds, constitute the whole meal, these most nutritious aliments will, by their difficulty of digestion, oppress the stomach, overload the blood, heat the head, and render it less fit for the ensuing work.

Pea-soup, therefore, with fish and potatoes, or fish followed by farinaceous dishes, or meat and vegetables, or broth, leguminous seeds and potatoes, or roast meat and salad, are suitable combinations for a good meal. In short, the more easily digestible albuminous substances ought always to predominate; and when aliments which are more difficult of digestion form the chief constituent of a meal—when peas, beans, or farinaceous dishes are taken—then soups containing vegetables or fruit, ought at least to be added, in order to promote digestion by their admixture of acids or salts.

But not alone are the right representation and combination of alimentary principles to be considered in our meals. Whatever impels our body to a new activity is a stimulant; and hence, in a wider sense, not only the heating spices, but solid and liquid food in general, are to be regarded as stimulants. It is characteristic of a stimulant, that its effect ceases when its use is repeated at too frequent intervals; and the slighter the irritation, the more readily will its effect become blunted, if the regularity of its influence render the peculiar effect less perceptible; a diminished susceptibility to the irritation, in consequence of repeated use, establishes the habit; while, with many kinds of solid and liquid food—for instance, with bread, meat, potatoes, water, milk—our insensibility to the stimulus does not attain a higher degree than that of becoming accustomed to it; and while even stronger stimulants, like tea and coffee, beer and wine, are overcome by habit; with other aliments, the insensibility overpowers the habit, and almost produces disgust.

While soup and meat, if taken day after day in the same form, at length become repugnant, it is equally impossible to eat every day the same kind of vegetables, the same farinaceous seeds; if carrots or saurkrout have to be partaken of even for two or three days in succession, the housewife may expect to meet with dissatisfied faces. This does not proceed perhaps from any bad state of the organs of taste; but taste is a very appropriate index of the irritation which the brain and nerves receive from the blood. We know accurately, that meat taken in abundance, conveys more fibrine to the blood, and the starchy aliments more sugar; and that the volatile oils of the superior kinds of fruit and of spices, the organic acids and the several combinations of the different salts of the vegetables, pass into the mother-juice of the tissues. And if in animals the monotonous manifestations of strength correspond with their uniform food; if even in plants the want of sensation harmonises with the simple composition of their not very numerous alimentary principles; must not the strictest logical sequence of cause and effect trace the agitated life of man, with his actions and passions, and all the numberless shades of sensation and thought, in great part to his variety of solid and liquid food and condiments? That there exists individualism in character, becomes possible only through the co-operation of the various aliments, together with the numberless moral and sensible influences which the surrounding material world exercises upon him.

And as the uniformity of the stimulant, even if repeated at longer intervals, is prejudicial to its effect, a regular arrangement of dishes, repeated certain days every week, is a custom not to be commended. If a stiff regularity only too clearly betray a commonplace narrowness of mind, such a regular repetition becomes a source of petty formalism; insensibly, but all the more dangerously, repressing the free movements of the mind. Whoever has watched himself with attention, will often enough have experienced how the refreshing and stimulating effect of a walk is evidently lost if taken for a long time daily at the same hour. It is the same with uniformity in viands; and while the ancient physicians used actually to assert it to be useful sometimes to throw the body out of order, in accordance with this doctrine it is perfectly true, that an inflexible regularity of life is by no means compatible with a genial freedom.

Not seldom do we hear the opinion advanced, that drinking during a meal is an obnoxious habit; but quite wrongfully; for the gastric juice may be diluted with a considerable quantity of water without losing its dissolving power in the slightest degree. Only a superabundance of water would diminish or arrest the peculiar action of the matters contained in the digestive fluids.

Large draughts of water, therefore, would be the most injurious with aliments difficult of digestion, like the fats; and hence, drinking of too much water after fat pork, for instance, is properly avoided; but, in countries where soup does not constitute a regular part of the meal, drinking water is positively to be recommended.

Beer and wine at dinner are also hurtful only if taken in excess; for, in the latter case, the alcohol coagulates the albuminous substances not only of the food, but also of the digestive fluids, and thus disturbs digestion. If taken in a moderate quantity, such beverages are calculated to cause the meal to hold out longer; for the fact that we are not so soon hungry again after taking a meal with wine, than if we have taken only water with it, is to be accounted for by the slower combustion of the constituents of our body, because the alcohol we have imbibed, takes possession of the inhaled oxygen. Hence, wine with a meal is extremely useful when a long journey, or work in hand, renders it impossible to take food again at the usual time; so much the more so, as such detention from food itself usually causes an acceleration of the metamorphosis of the tissues, which beer and wine efficiently obviate.

The general preference of warm food at dinner is based on rational grounds; for a low temperature coagulates gelatine, and the fats coagulate, which are much more readily digested in a liquid state. But when the food is much cooler than the liquids of the stomach and intestines—that is to say, much lower than 98° Fah.—it subtracts from the latter a part of their warmth, and the colder combination effects the solution less readily. Ice, therefore, as well as very cold water, are injurious, particularly if the nutriments contain a large proportion of fat or gelatine. As great changes of temperature in our body in general are not easily endured, a sudden transition from warm food to cold, or *vice versâ*, is injurious. By the sudden refrigeration of the heated cavity of the mouth, the enamel of the teeth is said sometimes to have actually cracked.

From the different hour at which the principal meal is taken by different individuals and classes, it sufficiently follows that no absolute rule can be given for it. This time is of little consequence to the classes having an occupation chiefly mental, and of none to those who do not work at all, provided, at least, they do not so utterly subvert the natural order of life, that night becomes day, and day night. Those classes, however, which are engaged in fatiguing, bodily exercise, expend, during the first six hours of the day, so great a quantity of material, that almost everywhere they observe the custom of taking at noon, or at least not much later, their largest portion of restoratives.

§ 92. *Suppers.*—The German custom of taking supper two or three hours, or even longer, before going to bed, has this great advantage—that digestion is almost at an end before going to sleep; for digestion disturbs sleep, and sleep digestion. Hence, supper should consist, as much as possible, of easily digestible aliments, as soups, salad with little meat, and not of fish or leguminous seeds. It is only when supper is taken very early, that the less digestible bread, or, still better, bread-and-butter, and meat, are proper food. When tea is taken in addition, those who are accustomed to perform close mental labour after supper, are agreeably excited. Intemperance is, most of all, to be avoided in the evening; for, apart from the sleep being disturbed by digestion as well as by hunger, an overloaded state of the blood is less easily adjusted during the night. In the night, less carbonic acid is exhaled, and the tissue-change in general retracted. Hence, an overladen state of the tissues, and especially of the brain, is very often manifested in the night by heavy dreams and nightmare, and in the morning by headache and a general state of ill-humour.

§ 93. *Diet of Childhood.*—In the form of a general proposition, and with application to special cases, we have repeatedly insisted upon the principle, that the amount of restoratives needed by the system, depends upon the extent of the expenditure. An abundant supply, accompanied by considerable expenditure, occasions an active metamorphosis of tissues.

Although the differences in human beings, as modified by age and sex, generally confirm this proposition, so that in a healthy man the activity of the tissue-change may be estimated by the quantity of the outgoings, still it is precisely here that we find, at the first glance, the most important exceptions. In the adult, the weight of the whole body remains from day to day the same, allowance being made for the augmentation or diminution most recently produced either on the one hand by a meal, or on the other by excretions of different kinds; for here, in general, the restoratives exactly repair the loss of the excretitious parts.

Not so with the child: for that the infant grows to a boy, the boy to a youth, is entirely and solely effected by the receipt surpassing the expenditure. The balance is not even in the exchange of the body. We have not to deal with a simple tissue-change. Growth consists in nothing else but in the proportion in which the formation of tissue exceeds the products of regressive transformation. The superior activity, however, of nutrition over excretion is the cause only of growth. The assimilation of the body in a greater proportion than it expends, is the condition without which it cannot grow. Strictly speaking, this greater appropriation of alimentary principles is growth itself. But its cause has to be more profoundly sought. The blood and the tissues of the infant are of a different composition from those of the adult. When treating of animal food, we mentioned that the muscles of young animals contain a greater proportion of albumen, but less of fibrine, than those of the full-grown. The real skin, in the adult consisting of fibres yielding gelatine, is formed in the infant from an albuminous substance, which, however, is not entirely absent from the skin of the adult. The bones of the infant yield gelatine of cartilages or "chondrogen;" and the organic basis is by degrees only changed into the tissue yielding gelatine of bones, or "collagen." Thus, while in youth, the solid parts contain a greater proportion of water, but less in weight of the formative substance deposited by the mother-juice; the tissues of the adult are, on the contrary, remarkable for their abundance of solid substance. As these solid substances are mostly heavier than water, their augmentation during the period of growth, explains the increase of the body in weight.

But if the body of the child have another composition than that of the youth, we must not be satisfied with the fact that the quantity by which the receipts surpass the expenditure, effects the growth. Tissues of a different composition likewise possess a different kind of attraction for the matters conveying the nutriment to the blood.

The muscles of the child attract fibrine from the blood, and their albuminous substances decompose into kreatine and urea; and the important consequence of their composition differing from the muscles of the adult is, that the fibrine attracted, surpasess in quantity the products of decomposition taken from them by the retransformative process. The same change takes place with the skin, as its albuminous substance is decomposed and lost with the urine and the exhaled air; while, with a superior attractive power, it forms from the blood, and assimilates the organic matter of its gelatinous fibres. But the remark is chiefly applicable to the bones; for just as these, more than any other tissue, cause the increase in weight of the whole body, so do they attract, in return for the wasting matter (known by yielding, when boiled, gelatine of cartilage instead of bone-gelatine), such an abundance of the true bone-constituents, that in a very short time their composition entirely changes. While gelatine of cartilage possesses a strong affinity for common salt, the tissue yielding bone-gelatine has the greatest tendency to combine with the phosphate and carbonate of lime. With the growing preponderance, therefore, of the bone-gelatine over the gelatine of cartilage, the lime-salts are continually increasing, and that during the whole life. The bones readily collect the lime-salts and the fluoride of calcium from the blood, a function shared in equal degree by the teeth only.

This strong attractive power, peculiar to the infant and child, is more than the condition—it is the real cause of its growth. It shows how the nutrition is in proportion to the excretions; a circumstance which we have before shown to be the condition of growth and increase of weight.

In the infant, therefore, change of matter only follows the same law observed in the adult. In both, the attractive power of the tissues towards the constituents of the blood induces nutrition. If, from the peculiarity of their composition, the tissues attract and detain a greater proportion of the blood than is lost by excretion, the blood, in order to maintain its composition, has to receive a larger quantity of the alimentary principle than would have been necessary if the activity of the nutrition had been simply equal to that of the excretion.

The direct expenditure of the blood upon the tissues, therefore, determines its supply; only the different composition confers upon the freshly-formed constituents of the tissues a greater constancy; and for this reason the body appropriates more than it eliminates.

This explains why children take proportionally more food, and especially why they take it oftener than adults, although the latter discharge a greater quantity of carbonic acid and urea than the former; and thus the regularity of the phenomena establishes the law—as it can be proved that the exception was only apparent. A law has its full validity only when the exception which withstands its authority merges in the law, as soon as the conditions of the seeming anomaly have been more exactly ascertained.

Philosophically, we come to the conclusion that the supply is regulated by the expenditure, and that in the infant, as in the adult, the exchange of the constituents of the blood is rightly denominated the change of matter. Practically, it results that the child's frequently recurring desire for food does not arise from mere *ennui* or restlessness, but from processes going on in the interior of the body. Hence the rule that the infant should not be trained by the power of habit to a diminished and less frequently manifested desire for food, but that its instinct ought to be satisfied; for such is the general and natural expression of a law regulating the peculiar change of matter, which causes the inclinations of the child to differ from those of the adult.

It is, therefore, quite proper that, at first, the mother should give the breast to the nursling as often as it awakes. Gradually the child desires milk less frequently; and in the distribution of the meals for her child, the wakeful eye of the loving parent may trust to her own observation. On an average, the child, after being suckled, can wait three to four hours until the next meal. Very healthy and strong children frequently sleep even for six or seven hours together, without being awakened by the want of food.

The child, after weaning, does not require any food at night; and the same rule holds good for boyhood. During healthy sleep, the change of matter in children is moderate. This explains why even those whose want of food is generally so great, can easily wait from supper to breakfast without eating anything; while, during the day, the desire of food has to be frequently satisfied. It is a very wholesome custom to give to children a slight repast between breakfast and dinner, and another between dinner and supper—nothing, indeed, tends better to temperate habits; for, in order to thrive, they have to convey to the blood the same quantity of nutriment, whether they take it at three or five times. In the latter case, the stomach is less gorged at any one time; digestion and the formation of blood go on with greater ease; and in the process of nutrition there is less danger that too great a quantity of nutriment should be conveyed to the tissues, which might have an injurious effect, especially upon the brain.

On the other hand, children are very materially injured by being gratified whenever their excitable palate asks for food or dainties; for, as the formation of all secretions requires due time, just as the development of the ovum, &c., and the accumulation of milk, are bound to certain periods, so the digestive fluids—the saliva, for instance, the gastric juice, the bile and pancreatic juice—are only secreted in a sufficient quantity for the usual meals. We must, therefore, allow the digestive glands the needful time to prepare and collect them, between one meal and another. If not, the requisite power of digestive action is deficient, just at the time when the most nutritious aliments, soup and meat, are taken. At table, if children complain of want of appetite, and if, accordingly, they do not eat, the blood becomes deficient in the best alimentary principles; if compelled to eat, on the other hand, imperfect digestion makes them languid and thin.

§ 94. *Milk as Food for Children.*—That milk is the most appropriate food for children is so generally recognised, that science has nothing to do but to confirm and interpret the fact.

Combining in a due proportion solid and liquid food, milk contains not only in the caseine an albuminous substance, which is transformed into albumen and fibrine, afterwards into gelatine, horn, and elastic fibre; but it has also, in its peculiar sugar, one of the most easily digestible constituents of fat; and in butter there are the ready-formed fats, which assist in forming the soft cushion of round limbs and full cheeks in children.

But it is the phosphate of lime, so abundantly contained in milk, which particularly constitutes this the most fitting nutriment of the babe. In milk, more than in any other food, the conditions are furnished for the conversion of the cartilages of the infant into bones. The phosphate of lime, so constantly associated with the caseine, is easily dissolved by the lactic acid, into which the sugar of the milk has been transformed by the bile; and thus the dissolved lime-salt passes from the digestive canal through the blood into the bones. The phosphate of potash performs the same office for the growing muscles.

In the milk of animals we find the same constituents as in human milk. Can, therefore, the latter be substituted for the former?

A direct comparison of the milk of the woman with that of the Mammalia, decides the question in the negative; that of woman contains a much smaller proportion of caseine, a smaller proportion of butter and of salts, but a greater quantity of sugar of milk and of water than is found in the milk of cows.

But whoever has attentively followed us in the description we have given of the change of matter, will not see anything fortuitous in this difference of composition. Here, as in many other cases, the manifold links are wanting, which enable us, step by step, to prove the differences of power to be nothing but differences of matter: occasionally we have a better knowledge of the matter than of the force, and sometimes the reverse. In a thousand instances, however, the power has been so distinctly proved to be a necessary quality of the matter, that, like all other qualities, it is an inseparable characteristic of the body, conditioned by the peculiar composition of its substance.

It is no empty prejudice to state, nay, it is a real belief in the general prevalence of a demonstrated natural law, that the nature of the mother is communicated by the milk to the child. And there is no thought more natural than the belief, that on the breast of its mother the infant may imbibe, together with the milk, her nobleness of mind, with the love which devotes that food to the most sacred purpose, and fastens still more strongly around the feeble child and the tender mother, the ties of their endeared relationship.

There are certain differences, though slight, between the milk of one woman and that of another; and as in successive months after confinement the milk alters in composition, the difference is so much the greater, as the children of the mother and those of the wet-nurse differ from each other in age. Since, in any case, the milk of the wet-nurse will be dissimilar to that of the mother, the closest possible conformity ought to be secured, where a wet-nurse is sought, between the age of the two children. Under any circumstances, however, the milk of a wet-nurse more resembles that of the mother than cows' milk; and therefore the milk of a wet-nurse is to be preferred to bottle-feeding. It is true that, in large towns, healthy wet-nurses are scarce; and still rarer, also, is that devoted love which nourishes a stranger's child as carefully as is desirable; for the effort is, indeed, not slight, by which a woman has to restrain her own will and inclination to such a degree, as to prevent indisposition of body or any bewildering passion from becoming hurtful to the babe; the easily excitable nature of the woman is often influenced to the great disadvantage of the child. Out of the manifold inconveniences arising from these circumstances, mixed food produces a more frequent uneasiness of body, than where uniformity of food is observed.

Hence, in many cases of difficulty, bottle-feeding will be preferable to the employment of a wet-nurse. By diluting cows' milk with one-third of water, and adding to five-and-twenty parts of milk about one part of sugar, a sufficient similarity with the milk of the mother is obtained. If asses' milk can be got, which is seldom the case on account of its high price, the dilution of the whole, and the increase of the proportionate amount of sugar, are very simply effected by mixing about two parts of asses' milk, which is remarkable for its abundance of water and sugar, with one part of cows' milk. As the milk in the first days after confinement contains more solid constituents than it does from about the fourth day afterwards, the cows' milk should for the first days be diluted with a smaller proportion of water; but after the fourth day, more than one-third of water is to be added to good cows' milk—a proportion which must gradually be diminished again, as the milk of the mother, after having become considerably thinner on the fourth or fifth day, increases again by degrees in the amount it contains of caseine and salts. Like all liquids of the body, the milk in the mother's breast has a temperature of 98° Fah. At this temperature, all aliments are most easily transformed by the digestive fluids. In bottle-feeding, therefore, the mixture employed ought always to be warmed as nearly as possible to 98°.

A long time before the period for weaning arrives, and earlier if the mother have not sufficient milk, more solid food may be gradually given. From rusks, fine wheaten flour, potato-starch, or arrowroot, first combined with water, milk, and sugar, and afterwards with broth of different kinds, a spoon-meat is prepared, usually much relished by infants. While in rusks and wheaten flour the albuminous substances themselves are present, in the mixture prepared of potato-starch or arrowroot, these are only contained in the milk, or in the juice of meat; for it is to be taken into consideration that arrowroot differs from potato-starch only in being composed of smaller granules, and by its forming with boiling-water a thinner paste. Arrowroot, in fact, is nothing but starch; but starch represents only the group of organic alimentary principles destitute of nitrogen; and among these the constituents of fat: now as the constituents of fat alone are not able to maintain life, arrowroot boiled with water only, cannot restore and supply the various essential constituents of the blood. With a paste of arrowroot and water, children may be fed to death, but they cannot be nourished; and many a child has succumbed to this diet, an unhappy victim of the lamentable error that the highly-commended arrowroot was of itself a complete nutriment.

Even after weaning, soft mixtures of a good bread, with milk and sugar, or with the juices of meat; also, the more readily-digestible roots and vegetables, together with soups prepared from the meat of young animals, may be considered the best food. After the teeth are cut, meat and bread, in their simple form, may also be given. Aliments difficult of digestion, fat meat, heavy bread, rich pastry, unripe wheaten grains, leguminous seeds, and heating condiments, are carefully to be avoided for children; and of beverages, water, milk, and a light beer only deserve commendation.

§ 95. *Diet of Youth, Maturity, and Old Age.*—While the boy is growing into the youth, the composition of his blood and tissues gradually approaches that of the mature body. As the muscles acquire more fibrine, the skin and bones become richer in gelatinous substances; in the bones and teeth, the lime-salts increasingly predominate over the common salt; and the whole activity of the change of matter is altered.

As at other times, so during this period, the expenditure of the body furnishes the best means of estimating the extent of these changes. The proportion of carbonic acid excreted by the lungs, and that of urea voided by the kidneys, increases up to maturity, attaining its height at about the thirtieth year; but at about the fortieth year, the activity of the tissue-change already begins to decrease, and the most important alterations gradually take place, of which those only of the tissues of the bones have been investigated with any degree of accuracy.

Of the solid parts, it is known in general, that in old age the proportions of water and fat decrease. Hence, the tissues of the eye become drier, and the light is less refracted through the crystalline lens, which becomes poorer in water; hence, also, the shrivelled hands and the wrinkled brow. That the hair is altered in its material composition is proved by its gray colour, the venerable decoration of old age; but of the bones, we know that they become more and more brittle, because, in proportion to their organic basis, the quantity of salts astonishingly increases, and it is particularly the phosphate of lime which more and more predominates; for although the salts, on the whole, increase so considerably, the carbonate of lime decreases relatively to the phosphate of lime; which latter, therefore, in a stricter sense, is so often denominated the bone earth.

Nor is the organ of thought without its share in alterations so important. In advanced age, the proportionate amount of fat in the brain diminishes; while, unlike all other organs, its amount of water augments.

Is it, therefore, to be wondered at, if the excretions undergo essential alterations? or, should the tissues, exposed to the same influences as before, although themselves differently composed, yield equal quantities of the same products of decomposition? We repeat, that in difference only lies the equality of men; only by the variety of circumstances, affecting both the matter and the force of our organs, can we be different; we are all equally dependent on air and soil, on men and animals, on plants and minerals; we could not have been primitively all equal, could we maintain equality under the different influences to which we are exposed: it is upon the difference of circumstances that our own differences are based.

Age is an essential element worthy of notice in this difference. The tissues have now another composition; in old age, less carbonic acid is breathed out, less urea formed. The drier tissues, containing a greater proportion of salts, undergo their normal transformations more slowly; the diminished decomposition proves a diminished activity; that renewal of matter, which is so abundantly induced by the decomposing action of oxygen, is gradually weakened; a smaller proportion is decomposed, and a still smaller portion formed.

Thus the susceptibility to all sensible and mental impressions gradually becomes enfeebled: that which formerly would have made a powerful impression, scarcely now leaves any trace in the form of memory. But a rich life lies behind the old man. Though now receiving less, the crown of a maturer experience adorns him. Ripe fruit which he has collected for himself and others, gladden the last years of his life, and increase the cordial and elevating sense of gratitude, with which we render homage to the venerableness of old age. "In the late evening of a much-agitated life," Alexander von Humboldt, whose very name illustrates the idea, lays before the world his Cosmos, "the idea of which, for almost half a century, had been floating in uncertain outlines before his mind;" and with it he enkindles the spirit of every one, whose view is not narrowed by those barriers which only too often separate all sublime enthusiasm regarding the universal, from the arid, and relatively sterile, assiduity which stolidly confines itself to mere details.

Not in every case, and not for very long together, can such a noble picture of man be exhibited. With the diminishing vigour of the change of matter, the torch of life gradually sinks. More and more slowly the matter moves from the digestive organs to the blood, from the blood to the brain and muscles. At length these activities wholly cease; for all that lives, bears in itself the germ of death. Those laws of gravitation which alter at every stage of life in a necessary succession, lead through growth to perfection, and from the blooming prime, by a regressive transformation, to decay. Not only do fat and water disappear, the bones also lose in circumference. While the latter become richer in lime, harder and more brittle, the wrinkling skin shrivels up, the cartilages ossify, and the watery brain loses more and more of its essential fat. Mentally, as the retrograde course continues in unbroken progress even to death, a kind of revolution is usually completed. The memory becomes dull, even for youthful recollections; and to the other infirmities of old age, a hebetation of the senses finally supervenes, which distorts the judgment, and destroys the memory. The old man who was before so venerable in his unbroken strength, bringing out the results of the experience of his former life, gradually becomes the image of a helpless child. Dissolution then becomes a blessing, and, with respectful awe, we drop the veil over that last proof of feebleness from which no mortal being can escape.

Matter, however, is immortal. Into the grave we let fall the noblest seed, with the certain knowledge that the transiency of one form "which has been bleached by the abundance of years," will yield to flowering and fragrant plants of the fields, to rise again, after numberless transformations, in fresh and youthful vigour, and still co-operate in the task, in which the spirit of all human works continues to live amongst us, visible to our senses. For the spirit is eternal, as manifesting itself in matter; while the terrestrial constantly changes, the earth and its inhabitants are as constantly renewed.

§ 96. *Requirements of Youth and Age.*—As growth continues during the time of youth, so the young not only require to satisfy their appetite oftener than adults, but need also a more nutritious diet. The attractive power towards the alimentary principles is greater, and the blood yields more to the tissues in spite of the excretions, subtracting altogether a smaller proportion from the body than in mature age. If the adult, therefore, require meat and bread, or leguminous seeds, to keep up the necessary strength for the tissue-change, this necessity is so much more peremptory with youth.

At the time of transition from boyhood to youth, care must be taken not to carry the nutritious diet to excess; for it is essentially characteristic of healthy development, that precipitance leads only to an unhealthy precocity in instincts, thoughts, and actions.

Granting him all adequate gratification, the growing youth should be provided with cooling aliments, fruits and vegetables, water and acidulated beverages; and if then his mind be sufficiently occupied, and he take abundant exercise in the open air, the tissue-change will harmoniously promote the proportionate development of every part, and youth will enjoy the pleasures of youth.

In mature age a fixed diet is the least needful; the full-grown man discharges as much carbonic acid and water, urea and uric acid, with other excretitious matters, as he takes up of food and inhaled oxygen. His wants he can measure by his appetite; the latter recurs less frequently, and is sooner satisfied than in youth. Every kind of excess, however, must be avoided; and this is infallibly secured by always leaving off before appetite has disappeared. Without this precaution excess is easily possible, because the limited size of our lungs, and the definite power of our movements, restrict the power of the change of matter. If man eat more than he excretes, the tissues become overloaded, which endangers their activity as much as the impoverishment of the blood and the consequent defective nutrition could do; fat is collected which the oxygen does not consume, and the albuminous substances, with the salts, assume a fixity which at once enfeebles the intellect, and destroys the pleasure of thinking; while it diminishes both the strength of the muscles and the inclination for movement. Thus do gluttons gradually grow lazy, impatient of thought, anxious only for repose, and unfitted, by their unwieldy frames, to embody the moral and intellectual greatness which characterises noble-minded men.

Apart from the mode of life and the degree of temperature of the surrounding air, the influence of which latter we shall afterwards describe more in detail, the peculiar constitution of the individual deserves a special consideration. It is true that here the grades of difference are as numerous as the population of the globe. The natural disposition, with a certain tendency to firmness in the functions of the brain, gradually produced by the school of life, form the character. The greater this firmness is, and the higher the courage with which it is displayed, the more naturally do we call the man a "character" in the good sense of the word; but, inasmuch as every individual holds a necessarily defined position in his relations to the external world, every one has more or less of distinctive character. On account of the innumerable degrees of transition, however, this rule can only be applied to the extreme representatives of one class or another.

The more vivacious the disposition, the more easily the man is excited by stimulants; the greater, also, will be the tissue-change. Generally speaking, such individuals will need food more frequently than those of a less excitable nature. With individuals of this habit, too nutritious or exciting food is to be avoided, because, as a stronger stimulant, it increases their nervous irritability. Vehement, passionate natures become still more ardent from partaking of game, heavy bread, leguminous seeds, or any considerable quantity of beer, wine, or spirits, coffee or tea. By these more stimulating aliments the circulation is accelerated; the tissues, especially the brain, are overladen with blood; and the skin, which in such persons is very easily filled with blood, turns red, especially in the cheeks. This heat is moderated by cooling aliments and beverages. Fruit and vegetables, therefore, with lemonade and similar drinks, are more advantageous for irritable constitutions than spirituous and aromatic beverages.

The latter are more appropriate to persons whose activity of the brain is disproportionately great; while their weak digestive organs, their slow formation of blood and nutrition, occasion a disposition to melancholy. Such persons require a stimulating diet. On account of their slow digestion, they have to select such nutritious aliments as are easily digestible; such, for instance, as the flesh of fowls and pigeons, veal, mutton, and veal-broth, in conjunction with a small quantity of light, well-baked bread, or of vegetables. As heating spices, wines taken in moderate quantity, as well as strong tea and coffee, accelerate digestion, and with this, indirectly, the tissue-change; they produce a greater uniformity in the functions of the different organs, and thus exercise a beneficial influence upon disposition and character.

And, finally, where a slow tissue-change characterises also the main parts of the nervous system, the brain, and spinal cord—where slight irritability is united with flabby muscles, a pale, flaccid, puffy skin, an inert digestion, and a deficient formation of blood, as in phlegmatic persons—a nutritious animal diet is to be combined with strong spices, strong beer, and wine. Vegetable aliments, especially roots containing much starch and sugar, must be avoided by all such; and for this reason, that in such persons there commonly exists already an excessive disposition to deposit fat, which, being itself the consequence of a less vigorous respiration, becomes a check to the tissue-change. The large quantity of fat withdraws from the other constituents of the blood, the oxygen necessary to transformation.

With the last-named characteristics, those of old age are chiefly to be classed; for here, also, the enfeebled activity of the digestive organs is the salient fact. If the diminished activity of the tissue-change be manifested by a languid appetite, it is so much the more necessary for the aged man to choose the most easily-digestible food. Lean meat, venison, strong broths, young vegetables, and roots, as carrots, containing abundant sugar, deserve the preference; while stimulating condiments, coffee, tea, a good old wine, a strong bitter beer, taken in small quantities, serviceably promote digestion.

§ 97. *Diet of Woman.*—The general laws of the change of matter are fulfilled in the case of women through another circle of developments than in man; for at the moment when sexual maturity begins to manifest itself, that continual augmentation in the exhaled carbonic acid, which in the female, as in the other sex, lasts as long as the child is growing into the maiden, ceases. Till the age of about forty-five years a uniformity is maintained, which yields to a slight increase only after that period; and in old age, as in males, gradually declines. At every age, however, the quantity, not only of the exhaled carbonic acid, but also of the urea daily voided, is much smaller in the female than in the male sex.

While woman, therefore, is remarkable for a less active tissue-change, a slighter muscular power, and a calm, contemplative activity of the brain, which is less easily aroused to greater exertion of thought, she is also less subject to wild passion: self-control appears to be the necessary consequence of material conditions; although the whole position of woman in life, and particularly the relation of the mother to her child, combine to ingrain these mental peculiarities into the true feminine nature. The material basis of the female body is the best proof that neither an arbitrary conventionalism, nor the unutterable longings of the youth indulging in sweet hopes, have evoked the attention and the cheerful support which everywhere men have devoted to the fairer sex. Although, in many uncivilised tribes, the strength which women gain from endurance encourages the men to burden them with correspondingly heavy work; still the woman enjoys everywhere the assistance which she necessarily wants. And when, with a higher civilisation, the consciousness of the dependence of woman increases, together with that of the dignity of motherhood, the superior power of man affords protection, his assistance becomes homage. The maiden's loveliness, added to the dignity of the wife and mother, helps to adorn the life of more rugged and ambitious man, her gentleness of manner producing that love of art which so often represents the wife in a noble ideal. This is the enjoyment which indemnifies the wife for great sacrifices: owing to a less direct contact with the rough storms of external life, she is able to cultivate a purer humanity, out of which the characteristic of womanhood is born.

The secluded life usually led by woman produces that perfect symmetry of nature—that fascinating serenity of manner, by which the matron is distinguished and adorned. But inasmuch as her life is less agitated, her manners more subdued, and her whole nature more accustomed to self-denial; so are the contrasts less marked between one woman and another. Their characteristics are less distinctive, and their peculiarities manifested in more delicate and minute distinctions—distinctions only to be accurately discriminated by the most acute observers. Even their features partake of this delicacy; and the painter finds it especially difficult to catch the more delicate peculiarities of expression in the female face, or infuse the characteristic expression into the less strongly-marked features. In woman only is found that charming harmony in which it is difficult to point out any salient part, because the equable and cultivated tone does not permit any particular point to be prominent. The least favourable aspect of this harmony lies in the greater monotony which distinguishes the sex from man. Of this peculiarity, the greater equability of the change of matter is at once the consequence and the cause. The variations in the quantity of the exhaled carbonic acid, so great in man, disappear almost entirely if we compare woman with woman. With the excretions, moreover, all the corporeal activities are moderated to a greater uniformity, as, on the other hand, the narrower sphere in which the life of the woman moves, reduces the change of matter also to a more equable course.

With this fact, the greater nervous irritability of the female sex in general is quite consistent, for the slighter vivacity of the change of matter produces a diminished demand for nutriment; but nutriment, as well as the mental impressions, belong to the stimulants, in the wider sense of the word. And the more sparingly the stimulants are used, the stronger in proportion is their effect, and the more quickly also does that effect again cease. As the change of matter specifically stamps its impression upon all the functions of the body, so most women are easily excited, but soon regain their self-command; in man, on the contrary, the stronger impression usually produces more lasting effect.

§ 98. *Appetite of Women.*—From this description of the change of matter in the female sex, it follows that the restorative substances are required in a smaller quantity than in man. It accords with a general result of experience, that a less nutritious diet, or nutritious food in smaller quantities, suffices to satisfy the want of women; it is, therefore, no prudish or dainty affectation, but a natural abstemiousness, which leads girls and women to partake sparingly of food.

On account of the greater irritability peculiar to women, they commonly have a disinclination to strong condiments and exciting beverages. To coffee and tea only do they accustom themselves, and that to such a degree, that they do not suffer any injurious effect from them. Both beverages are much relished, especially by aged women. In general, however, neither tea, coffee, wine, nor any of the heating condiments, are wholesome for the female sex; of these aliments, tea and coffee only ought to be taken, and that in great moderation, diluted with a large proportion of milk.

§ 99. *Diet of the Artisan.*—An active change of matter increases the muscular power; but, on the other hand, the exertions of the muscles augment the activity of the excretions. He who digs the soil with the spade, or wields the hammer, who breaks-in horses, or wanders in the open field—not only perspires more, but also breathes out a greater quantity of carbonic acid, and voids more urea, than the man who, by luxurious and indolent tranquillity, encourages the fat of his body, and an increase of the albuminous substances.

A real development of strength is inseparably bound up with an active change of matter. But change of matter consists of excretion and restitution; for he who exchanges, receives while he gives. The permanence of the substance does not contribute to the increase of activity. We have already several times expressly mentioned, that, though the presence of matter is the condition of all activity, yet the rapid movement of this matter only intensifies the manifestation of power. The limbs, therefore, if kept at rest, relax; and in return, the whole advantage of exercise consists in the excretion of the muscles being augmented by their exertion—the nutrition of the tissue being increased by that augmented excretion, and the appetite being roused, correspondently with the necessity of forming new blood occasioned by the accelerated excretion and nutrition. The rapid change of matter increases the power of the organs, just as the exertion of the limbs promotes the change of matter, and the increase of muscular power.

But to attain this, an abundant restitution is an indispensable condition. It is, therefore, equally consistent with economy as humanity, for those who employ labourers on heavy work, to satisfy the more frequent and strongly recurring appetite of their workmen; for it is only when the workman thrives, that the work can prosper. Insufficient food causes feebleness and inertness; and the master who scantily feeds his workmen, loses more in the decreased strength of their arms, than the aliments would cost him which would raise at once the value of their achievements, and the dignity of their nature.

By every one engaged in heavy bodily labour, a nutritious diet is required; and as, in a rapid change of matter, the digestion participates in the activity of the other functions, the appropriate aliments here are meat with bread, containing a large proportion of gluten and leguminous seeds; while the preferable meat is beef, containing a good quantity of fibrine: in a word, the most serviceable aliments here are those which are also the most difficult of digestion. And these more especially deserve preference, if circumstances or the kind of employment render it impossible immediately to satisfy the want of food recurring at short intervals; the aliments in this case are rendered more difficult of digestion, through their being more slowly transformed into the constituents of the blood and tissues; they also undergo less rapidly that decomposition which transmutes them into the excretitious substances. By this strong food, the labourer is enabled to resist the calls of hunger for a longer period; and this—in spite of the obstinate denial of mock-philosophers, who are deluded by their own luxurious life into a contrary belief—is the lurking enemy whose attacks continually irritate the anxious pater-familias among the poor. In these circumstances the leguminous seeds are an essential alleviation to sufferings arising from hunger.

Corporeal exertion increases not only the expenditure of carbonic acid and urea, the voidance of water as well as the excretion by the lungs and kidneys, but the expenditure by the skin and sudoriparous gland is also augmented. The loss of water, particularly, is increased by those actions which directly produce a more abundant evaporation from the mucous membrane of the tongue, throat, and lungs; as, for instance, by talking and reading, by singing and blowing. Hence, teachers and lecturers, singers and trumpeters, glass-blowers and public criers, are subject to extreme thirst; so also are all workmen who from their avocations are exposed to a high temperature, which stimulates the activity of the skin; and in a high degree augments the perspiration. This excites in glass-blowers the desire for drinking, and is the main cause of the often-returning thirst in smiths and iron-melters, sugar-boilers and cooks, bakers, and gardeners working in hot-houses. On the contrary, thirst is at a *minimum* in fishermen and sailors, who ordinarily live in a moist atmosphere, into which a smaller quantity of water escapes from the human skin and lungs. That sailors are partial to brandy and other spirits, arises from another cause; for, on the one hand, through the alcohol, which demands the inhaled oxygen for its own consumption, the food of these labourers, which may be limited to a scanty meal, enables them to hold out for a longer time; and, on the other, the fat, which the alcohol assists to preserve, frequently protects and comforts the mariner in the rough weather to which he is exposed.

A good beer partakes in all the advantage of the alcoholic beverages, and at the same time usefully quenches the thirst by its more abundant amount of water. Hence, this beverage is particularly adapted to satisfy the frequent thirst caused by bodily exertion; it is, therefore, a laudable custom to refresh artisans, who have to work hard, in the morning and afternoon with a glass of ale; this beverage, by its proportionate amount of albumen, which is equal to that of fruit, supplies even a direct substitute for food.

§ 100. *Diet of the Artist and Literary Man.*—If the brain, like any other part of the human body, be subject to the processes of tissue-change, it is evident that a greater activity of this main organ of the nervous system will augment the products of decomposition. Thus all the sensations and passions which increase the mental action—as hope and joy, anger and ambition, suspended expectance and happy love—excite the instinct for food. By vigorous exertions of the will, active imagination, sustained thought, the change of matter is likewise accelerated. It is true, this does not prevent one sensation from being able, as it were, to neutralise another. How often do we observe, that from joy or love, anger or suspense, a person cannot eat—or, in other words, the sensation of hunger is not perceived—while the intellectual power of the brain is over-exerted. But the desire for eating and drinking is only momentarily blunted; and after some time, hunger and thirst reassert their claims with a double force.

The far-spread error, that mental activity does not increase the consumption of matter, originates in our repugnance to admit the fact, so strongly forced upon our observation—that the power is inseparable from the matter; for how many, even of those who have exclusively devoted themselves to the observation of nature, frequently engage in vain speculations, about an essence of bodies, external to or hovering over them. And how few have a clear insight into the position which, since Spinosa, can no more be banished from science—that the total of all qualities makes the essence of a body. Only too often we may observe, that in an unguarded moment, intelligent men freely, and without prejudice, assert in some single instance the doctrine, that their mental actions are conditioned by the matter which by the nutriment is conveyed to the brain. But as soon as this seeming casualty is raised to a general law, they are terrified by their own significant presentiments, and fly from the clearness of conviction, in which only they could find satisfaction. This vague separation, however, of matter from power, which, pursued to the extreme, would lead us to ascribe an immaterial spirit to steel and amber, and other material substances, is not the only cause of the frequent, but false doctrine, that the matter is not wasted by the pictures of the imagination and combinations of thought. Commonly the artist or literary man is compared, not with persons who live quietly and in indolence as regards their thoughts and sensations, but with the corporally active artisans. In this case it is too readily forgotten, that while in the intelligent workman the brain is not inactive, the change of matter excited by mental exertion in most artists and literary men, is moderated by their sedentary lives; and yet an increase of the temperature of the body and of the desire for food does actually take place in consequence of mental effort. Artists and literary men, as well as the artisan, have to compensate, by a greater supply of nutriment, for the increased consumption, which transforms the essential constituents of their brain into the decomposed ingredients of their excretions. It is well known, that, notwithstanding their sedentary life, artists and literary men rarely suffer from corpulence; and no one expects to find that store of the more constant constituents of the tissues, so remarkable in good living and in active persons as characterising men of mental activity, excelling by their accomplishments in art or science. A large body and fleshy face may be suitable for monks and gluttons longing for repose, but it is not adapted for men of intellect. Abundance of fat in the blood of the brain paralyses thought, and hangs lead upon the wings of the imagination.

As a sedentary life renders digestion and the formation of blood difficult, and moderates the secretion preceding decomposition, which is increased by the activity of the brain, the artist and literary men have to choose, within the limits of a nutritious diet, the more easily digestible aliments. A well-baked bread and lean meat, combined with young vegetables, and such roots as are easy of digestion, and contain a considerable proportion of sugar, form a wholesome diet for thinkers and poets.

Well-seasoned aliments and stimulating beverages, if not taken in excess, are to be recommended to all men whose toil is principally mental, for a twofold reason. Spices, beer and wine, tea and coffee, if moderately taken, stimulate the different digestive glands to an abundant secretion, and therefore promote digestion, which, in a sedentary life, is so apt to become sluggish: this is one aspect of their usefulness. The other aspect bears directly on the brain: as the activity of this organ predominates in poets and thinkers, it requires a constantly-renewed stimulus; hence the heating spices, with wine, coffee, and tea, are appropriate and useful, imparting a bolder sweep to the mental activity, which creates images and combines thoughts into judgments. The oftener the stimulant is used, the greater is the quantity required on every subsequent occasion, in order to produce the same degree of excitation. This continually augmenting waste originates a habit, and impairs sensibility; for the frequent repetition of the excitement produces exhaustion, and the exhausted organ is only able to perform its peculiar function when the stimulant acts again; this would indicate that a frequent change in the mode of living is necessary. There are many literary men who cannot write successfully until they have increased the activity of their brain by tea and coffee, and in some rarer cases by wine. We say in rarer cases by wine; for while, from its action upon the judgment, tea is especially proper for the literary man; and while coffee, by animating simultaneously both the judgment and the imagination, belongs alike to the literary man and the artist; wine is the most appropriate beverage for the latter, who demands, above all, that his diet may stimulate the imagination, sharpen the senses and the memory, and facilitate the combination of ideas.

Provided only that a certain limit be observed, there results no disadvantage from the use of stimulants; but if they are taken to such a degree that exhaustion sinks into a complete numbness, the greatest quantity of the strongest stimulant becomes at length ineffective. When by habit, however, the stimulant has become a necessity, an enervating relaxation infallibly follows, as sometimes mournfully illustrated by less prudent literary men. The stimulant ceases to excite—the debilitated organs have already been indebted to it for all the activity it can give. In this case the victim continues to seek his refuge, until dangerous diseases of the stomach cripple the digestive powers; with the decay of the digestive organs the formation of blood and nutrition are disturbed; and with the digestion vanish clearness of thought, acuteness of the senses, and the elasticity of the muscles.

§ 101. *Diet in Summer and Winter.*—In considering the wide diversity between the modes of life of the inhabitants of the tropics and the temperate and frigid zones, we are induced to suppose that temperature must exercise an essential influence upon the change of matter. This supposition has become a certainty. It has long been known, that in a high temperature, the evaporation from the skin predominates; while in cold weather a greater proportion is excreted by the urine. This increase of urine, which in health is maintained during the whole winter, is accompanied by an abundant formation of urea. From these observations, it would appear that a higher temperature diminishes the quantity of carbonic acid exhaled in a certain time, and consequently that, by warmth, the two most important products of decomposition are diminished; it becomes indubitable that in summer the excretion is weakened, and in winter increased. To the excretions correspond the nutrition, the formation of blood, and the digestion; hence results the necessary conclusion, confirmed by daily experience, that in summer we digest a smaller quantity, and that more slowly.

The relaxation caused by frequent and abundant respiration renders digestion more inactive. Inasmuch as the formation of blood and the nutrition of the tissues progress more slowly in summer, we are then less fit for any kind of exertion than in winter; and since we observe this difference the most strikingly when a rapid change has produced a great alteration in our excretions, it is apparent why a walk or any violent movement so readily tires, when the rough, damp, and cold weather, amid which the winter so often takes its leave, has suddenly yielded to a sunny spring day. It is only when we have become gradually accustomed to the less active change of matter, that the expanding life of the vegetable world, awakening in the freshness of its verdure, delights us—that the alluring strains of the songsters of the grove exert their full influence upon our nature; but, with the retarded movements of the change, these impressions, effective as they are, invite us rather to tranquil enjoyment than to a vigorous activity. If the "*dolce far niente*" first exhibited itself under Italy's warm and serene sky, with us the sweet delight of calm sensations, the intensity of which is seldom disturbed by energy, is the privilege of spring: May is the month of love and enjoyment.

But if in autumn, when the oppressive summer days have passed, there suddenly appear much cooler but more genial weather, we feel impelled to a cheerful assiduity. The quicker movement of matter carries us along, as it were, with the flowing stream; and we often see achieved in a few days what had lain in our mind for weeks without our having been able to find the right disposition to attempt its accomplishment.

These differences, however, are most observable in labourers with the brain. Those who rely on their bodily exertions, and are never out of exercise, are as active in spring as at other times. And naturally so; for in the restless circle of cause and effect, which the change of matter embraces, they increase by their energy the movement of the matter. While the artisan continues, with an industrious hand, to labour for a living for himself and his family—while the farmer looks forward to the encouraging reward of his labour in a rich harvest, which he extorts from the soil by his activity, and for this shuns neither heat nor labour—the changing matter of his system remains equable and well balanced.

No influence, however, passes without some effect. While, therefore, in summer, as at other times, occupation and age, habitude and sex, unite with temperature in determining the choice of food, certain rules may be clearly established, if in this series of combined and mutually reactive influences we separately consider heat and cold.

In summer the desire for food is diminished, because the consumption of the tissues is less; a smaller quantity of nutritious food, or less nutritious but easily digestible aliments, are to be taken. The meat of young animals, young vegetables, edible roots containing abundant sugar, fruits and salad, are also much relished in summer. The predilection for cooling beverages at this season has a perfectly rational basis, as the heat frequently produces palpitation; while the less rapid decomposition of the tissues, which is peculiar to the warm season, retards the transformation of the blood. Cooling and diluting beverages containing vinegar, currant-juice, raspberry-vinegar, and water, operate against this retardation; but the palpitations are only increased by heating beverages and spices. An abundance of spirituous liquors is, therefore, doubly injurious in summer; for the alcohol deprives the constituents of the body of the inhaled oxygen which is necessary for this decomposition, and also for the animation of the corporeal functions. For this reason, in summer, the lighter sorts only of beer and wine, which contain a small proportion of alcohol, ought to be chosen. It is also important to be moderate in the use of heating spices, or to allow them only where a certain excitement of the digestive activity, within the limits of health, is wished for.

The greater expenditure which distinguishes the winter, necessarily requires greater supplies. In this season, therefore, the increased wants of the appetite have to be satisfied, and the more nutritious aliments, with those which are more difficult of digestion, are with good reason selected. The latter are easily mastered by the augmented digestive power; while the greater proportion of alimentary principles, contained in the former class, is gradually transformed into the constituents of the blood, and slowly conveyed into the circulation. Farinaceous food, containing a large proportion of gluten, dry leguminous seeds, and fatty pork, are in winter much more easily digested than in summer. In winter, the fat is much more easily burnt into carbonic acid and water, as is proved by the increase of the carbonic acid which we breathe out during that season. The oxygen which is taken in also acts more vigorously. Although the fats, on account of their abundantly proportionate amount of carbon and hydrogen, are easily combustible, yet they differ from the albuminous substances, as well as from the constituents of fat, in requiring a greater proportion of oxygen in order to be really burnt. In summer, therefore, and in hot climates, where the oxygen is less efficient, the fat of the food is digested with much greater difficulty; hence the preference given in the tropics to the constituents of fat over the fats themselves, is a circumstance arising from natural laws. So long back as the times of Herodotus, we know that in hot climates people lived chiefly upon a vegetable diet. The inhabitants of the islands of the Pacific Ocean very seldom eat fish of any kind, and pork and fowl only at festivals. The food of the negro is rice, millet-seeds, maize, and roots containing a great quantity of starch. The chief meal of all inhabitants of the tropics, consists of rice. Here we meet also with an illustration of the not unfrequent fact, that a custom, apparently traceable to superstition, is really founded on a deeper and more rational foundation; for inasmuch as at a high temperature fat is less easily decomposed through the diminished activity of our lungs, a correct interpretation of natural phenomena has led to the entire prohibition of pork during summer to the inhabitants of Southern Italy, and altogether to the Jews in Palestine. Obedience becomes superstition only when it continues to exist after the reason for the law has ceased.

If in summer everything must be avoided which absorbs the oxygen so necessary for the organic constituents of the body; so, on the other hand, aliments may be taken in winter, which moderate the decomposition of our tissues, produced by the oxygen; hence we can bear in the winter not only a richer diet than in summer, but those beverages are also relished which by their abundance of alcohol retard the consumption of the constituents of our body. It is inconceivable how physiologists can preach the renunciation of brandy, when we consider the simple fact, that the further north the greater its consumption. While the inhabitant of the south of Germany is satisfied with the proportion of alcohol which he takes in beer and wine; in Northern Germany, Holland, and England, brandy, gin, and other spirits are taken; but the Russians, Swedes, and Norwegians consume a still greater abundance of spirits. In a very instructive public lecture at Mayence, Von Kittlitz stated, that the Kamtschatdales, who are generally remarkable for their great respect of property, often steal brandy; but afterwards, with child-like simplicity, confess their theft, avowing that they could not do otherwise: they only steal what they consider a necessary of life. This regular increase in the consumption of alcohol, corresponding to the nature of the climate, cannot but suggest the existence of some valid reason for this popular custom, which has been completely confirmed by scientific investigation. The alcohol which has been taken, is a new source of the development of warmth, by which, on one hand, the food is more slowly consumed; and, on the other, the cushion of fat under the skin, which is a bad conductor of heat, and sufficiently protects the system against external cold, is kept from wasting. Travellers who have visited the Polar Seas, assert, that in such voyages Europeans could not exist without spirituous beverages. In low, cold, and damp countries, experience has always proved spirituous beverages, taken in moderate quantity, to be useful.[*]

It is true, science, as well as experience, warns against excess. When spirituous beverages have been taken in abundance, the venous and arterial blood have been found alike in composition; and in animals even fits of suffocation have been observed. It is apparent, that the oxygen which alcohol takes up in order to be transformed into acetic acid and water, and then into carbonic acid and water, is withheld from the constituents of the blood; while it is upon the combination of these matters with oxygen, one of the most important conditions on which a healthy change of matter depends, that the transmutation of the venous blood into the arterial takes place.

This circumstance ought always to be kept in mind; for then only do we restrain our fellow-creatures from intemperance, when we distinctly inform them that its injurious consequences are founded upon a necessary natural law, and one therefore infallible. A rational intelligence is the sole basis of all real morality. By total abstinence, and under the form of a solemn undertaking, we create slaves of an irrational promise, and treat men no better than animals, which we shut up in a stable that they may not stray too far away.

Inasmuch as man is formed by all the circumstances conjointly, the influence of which upon diet we have endeavoured to describe in this treatise, the rules given must be separately considered. The nature of man is the product, or rather the sum of all those effects of parentage and country, age and sex, position and habits, and even of the time of the day and year, which we have referred to. It is for the reader to determine the choice of food, according to the individual influences—bearing in mind that other circumstances to which we have not alluded still remain for consideration. These combinations of circumstances are nearly as numerous as the men themselves; and it must be left to the judgment of the individual to accommodate his diet to his own particular case.

All that we have written bears exclusively on man in a healthy state. "But in disease?" we hear you ask. It is just when the activity of the bodily functions deviates from the ordinary state of health, that the question of diet is the most important; and should not the book contain some instruction bearing upon this condition?

As truly as we are convinced of the usefulness to the people of a treatise on food for the healthy, so certainly do we know that we should only do mischief by giving here rules for the selection of food, of beverages and condiments, in disease. One point only is of the highest value in daily life; intemperance may become the source of the various diseases. This affirmation, in its widest sense, bears on the use of aliments of every description. And this general statement renders superfluous any attempt to explain why in autumn, for instance, the abuse of fruit will cause diarrhœa or dysentery; why meat immoderately taken may occasion the formation of calculus; why from an excessive use of spirits, gout or cancer of the stomach may originate. Such an attempt would be without any bearing in practical life, neither could it be justified on scientific grounds; for in the present state of our knowledge, it is absolutely impossible popularly to describe, with a proper chain of deduction, intemperance as cause, and the various diseases as effect. Such a description would require so thorough a scrutiny of each particular case, with so detailed a consideration of the condition of the body, that either superficiality would annihilate its value, or profundity destroy its clearness. The doctrine of the causes of disease, pre-supposes a thorough knowledge of disease itself; and this requires a considerable familiarity with all the more important laws of science.

If this be the case as regards the knowledge of disease, it is much more so with regard to diet when under its power. Only the man who has devoted his whole life, with all his powers of sense and thought, to the investigation of the condition of man in health and disease, can unite with the necessary knowledge the more subtilely discriminating judgment under such circumstances; and that only after the most accurate account of country and training, of climate and weather, of age and sex, of habits, occupation, and of parents. No one would require this if he consider that every action has its necessary consequences; that the widest experience only, purified by the clearest judgment, and after careful personal examination, is able to secure in the individual case the desired effect with any degree of certainty. Render, therefore, to the medical man that which is his, yet without neglecting, for the healthy state, the study of those rational rules of life which are given by science; for man is only obedient to such laws as he understands.

While solid and liquid food furnish the matter which is decomposed in our body and circulated through it, and by which we think and feel, nature and mankind exercise so continuous an influence on our senses, that the material of our body is never for a moment at rest. In never-ceasing motion, sensation and thought, will and action, are hurrying on; and if all this activity be only sustained by matter, all effects being but the result of the forces of matter acting upon matter, nevertheless the less material impressions of sound which elude our grasp, with those of light and colour which are altogether intangible, are no less important, and to many persons, indeed, much greater, than the alterations which food so infallibly produces in us. It becomes the wise man to recognise this dependence; and it is true piety heartily to feel this connection with the mighty Creator of all. Justly has Schleiermacher designated the sense of dependence in the individual, the true essence of all religion.

---

[*] It may be stated, however, that some Arctic voyagers have urged an abstinence from the use of spirituous liquors as being essential to health in high latitudes.—ED.

CHAPTER III.

SULPHUR—SELENIUM—PHOSPHORUS.

Sulphur, as an element, partakes to some extent of the characteristics of others we have already described. Like chlorine, iodine, &c., it has the power of uniting with other bodies, and of so forming compounds, which are termed *sulphides*. Its external appearance and general properties are exceedingly varied; generally speaking, it is sold in commerce in rolls, under the name of brimstone. It is found in a crystallised state; and the neighbourhood of volcanoes, such as Vesuvius, Etna, and Hecla, are the sources whence we derive our supply of this article. Sulphur, however, is very generally diffused throughout the animal, vegetable, and mineral kingdom. As we have already shown, it is a constituent of our bodies; in many vegetables it forms a component part; and in the mineral kingdom, we find it associated with iron and copper, in the form of pyrites, with lead as galena; and in combination with oxygen as sulphuric acid, it is exceedingly abundant throughout nature. Its symbol is S; the equivalent being 16.

Sulphur is readily melted and sublimed. At a moderate heat, a little beyond that of boiling water, it is converted into a fluid state. Beyond that temperature, it assumes a more solid state, and a darker colour; and in this form it is employed as a moulding substance, for the purpose of taking what are known as sulphur moulds. It is also much employed for the purpose of bleaching animal and vegetable substances. The following experiments will illustrate some of its qualities and applications.

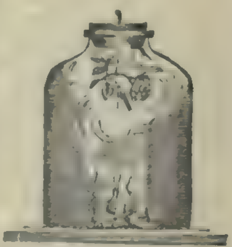
Experiment 54.—Place a little brimstone in a Florence flask, and apply a gentle heat to it by means of the spirit lamp. The sulphur will sublime, or rise to the top or cool side of the glass, in a yellow-coloured powder, formed of very minute crystals.

Experiment 55.—*To obtain Crystals of Sulphur.*—Melt some pieces of roll brimstone in an iron ladle, at a very gentle heat. When the whole is melted, remove the ladle from the fire, and allow it to cool until a crust is formed on the top. Make a hole in the crust, and let the melted sulphur inside run out. When cool, the mass in the ladle will present some beautiful crystals of a needle shape, if broken in half.

Experiment 56.—*To make Moulds from Coins.*—Melt some sulphur in a ladle, taking care not to overheat it. Pour this over any coin (except silver, which would be spoiled), first fixing the coin in a paper rim, such as a pill-box, to prevent the sulphur running away. The coin should be slightly oiled, to avoid the sulphur adhering to its surface.

Experiment 57.—*To Bleach by means of Sulphur.*—Wool, hair, straw, &c., may easily be bleached; and this plan is adopted by wool scourers, and straw bonnet manufacturers. Take a jar open at both ends, and in the upper part fix the article to be bleached by means of a string tied to a cork; as, for instance, a flower or a piece of straw bonnet, first moistened with water. Then place on a piece of hot iron a little sulphur, which must be set on fire, the jar being placed over the fumes. The jar should be slightly raised on one side, to allow a little air to pass in. In a short time the colour of the flower will be completely destroyed by the sulphurous acid thus formed. The arrangement is represented in Fig. 57.

Fig. 57.

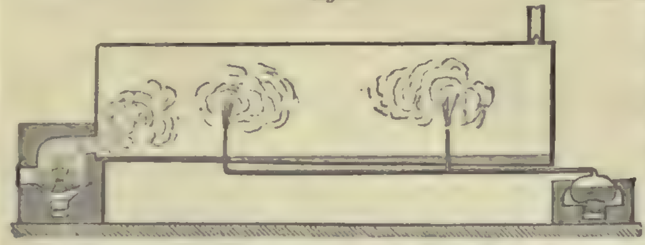


As an article of commerce, sulphur is largely imported for the manufacture of gunpowder, lucifer-matches, sulphuric acid, and as a medicinal agent. In its ordinary commercial condition, it contains numerous impurities, from which it is freed by sublimation or distillation, by means of which the non-volatilisable portion is retained, and the sulphur obtained as in Experiment 54.

Sulphurous acid is a compound containing one equivalent of sulphur united with two of oxygen. Symbol SO_2; equivalent = 32. It is at once produced when sulphur is ignited in the open air, and is the cause of the penetrating smell of the ordinary sulphur-match whilst burning. It may be produced as in Experiment 57; or, still better, by boiling sulphuric acid in a retort, with charcoal, mercury, &c., by means of which the acid is decomposed, forming an oxide of the substance, and setting sulphurous acid free. In this way sulphurous acid is produced in a gaseous form; and by extreme cold it may be obtained as a liquid, which, from its high volatility, produces great cold during evaporation. Sulphurous acid is readily absorbed by water; and, united with various bases, forms the substances called *sulphites*. It is owing to the production of sulphurous acid during the combustion of sulphur, that its bleaching powers are manifested, as shown in Experiment 57.

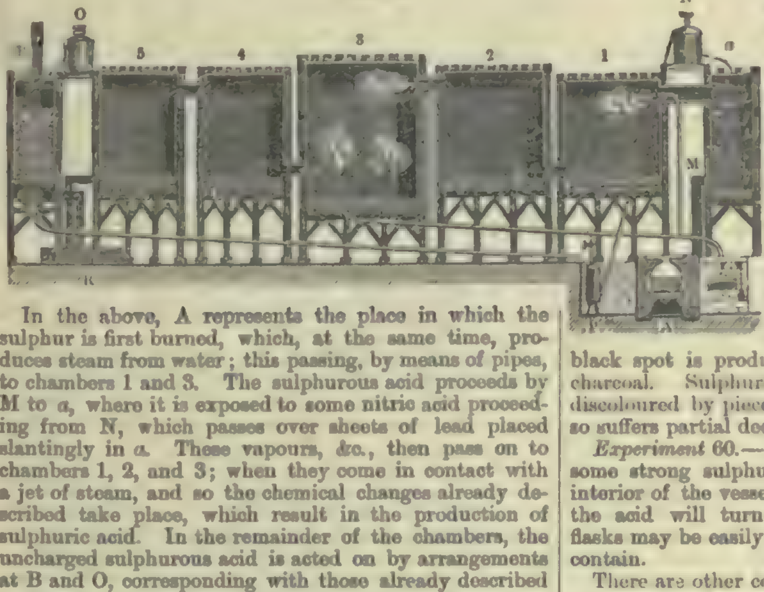
Sulphuric Acid is a liquid well known in the arts and commerce. It is a compound of one equivalent of sulphur with three of oxygen; and in the anhydrous or perfectly dry state, its symbol would be SO_3, and the equivalent = 40. In its ordinary condition, and at a specific gravity of 1·850, sulphuric acid is combined with one equivalent of water; hence its symbol will be SO_3, HO, and the equivalent 49. The manufacture of this acid has become of the highest importance in this country, as it is largely employed in producing the soda of commerce, and in bleaching and calico-printing. Its source is the combustion of sulphur, which may be in the ordinary state, or as produced from iron and copper pyrites. The latter source of the sulphur is much used in Glasgow, where the acid is produced in large quantities by Messrs. Tennant and other manufacturers. The process depends on the mutual action of sulphurous acid, the vapour of nitric acid, and the steam from water. The sulphurous acid, produced by the slow combustion of the sulphur, is allowed, together with the vapour of water, to meet that of nitric acid, produced from nitre in the usual manner, and being allowed to pass in at the same time. By these means the nitric acid is partly decomposed, and binoxide of nitrogen is produced. The latter gas seizes oxygen from the air, and so the sulphurous acid is gradually oxidised; and by its acquiring another equivalent of oxygen, sulphuric acid is produced. The process is carried on in large leaden chambers, at the bottom of which water is placed, which condenses the acid fumes. The dilute acid thus afforded is afterwards concentrated by boiling; and if required purer and freer from lead, it is subsequently distilled in platina stills, whence it issues as an oil-like fluid, having considerable gravity. From this appearance, sulphuric acid often is termed oil of vitriol.

Fig. 58.



Our diagram, Fig. 58, represents a section of a sulphuric acid chamber. On the left is the furnace supplying the vapours of sulphur and nitric acid; in the centre, we have the large leaden chambers in which the two vapours combine together with steam produced from a boiler, represented on the right of the diagram. In practice, a larger number of leaden chambers is employed; and the following engraving represents an arrangement often used on the large scale for the manufacture of sulphuric acid.

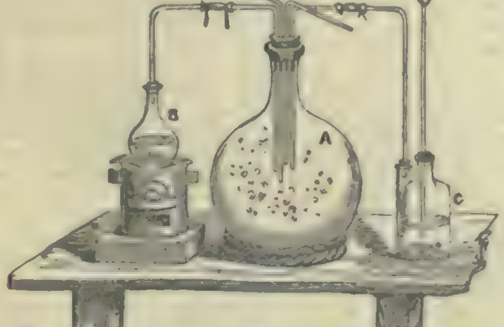
Fig. 59.



In the above, A represents the place in which the sulphur is first burned, which, at the same time, produces steam from water; this passing, by means of pipes, to chambers 1 and 3. The sulphurous acid proceeds by M to *a*, where it is exposed to some nitric acid proceeding from N, which passes over sheets of lead placed slantingly in *a*. These vapours, &c., then pass on to chambers 1, 2, and 3; when they come in contact with a jet of steam, and so the chemical changes already described take place, which result in the production of sulphuric acid. In the remainder of the chambers, the uncharged sulphurous acid is acted on by arrangements at B and O, corresponding with those already described at N and *a* at the right of the engraving. By such an arrangement all the materials are utilised; none are suffered to go to waste; and the manufacture of the acid goes on without intermission, so long as a supply of the materials is kept up.

The student may easily master the details of the process by means of the following plan:—Put some mercury

Fig. 60.



and a little sulphuric acid into a glass flask, and connect this, by means of a bent tube, with a larger flask, as seen in Fig. 60, in which A is the vessel receiving the vapours of sulphurous acid, produced by boiling the sulphuric acid and mercury in B. Pass some binoxide of nitrogen from another vessel, C, containing some copper filings and nitric acid, into the large flask, A, which should be moistened internally with water. As the sulphurous acid vapour comes in contact with the binoxide of nitrogen and air in vessel A, the decomposition, &c., already described, proceed just as they take place on the large scale in the leaden chambers, and sulphuric acid is accordingly produced. The preceding engraving illustrates this arrangement.

Sulphuric acid, in a concentrated state, is highly corrosive, acting with great vigour on all organised bodies, chiefly by the great attraction it has for water, which it will seize wherever it can be found. It unites readily with bases forming sulphates. It requires great heat to evaporate it; and the operation should only be conducted in platina vessels, on the large scale, because the vapour is disengaged so irregularly in glass vessels as to be almost explosive in its action. It may, however, be effected in small glass retorts, if a few pieces of platina foil be cast therein to facilitate the disengagement of the vapour. The following experiments will illustrate some of the properties of the acid.

Experiment 58.—Pour some strong sulphuric acid suddenly into a vessel containing an equal bulk of cold water. Great heat will be disengaged, which will sometimes rise so high as 300° Fah.

Experiment 59.—Into a strong solution of sugar pour some concentrated sulphuric acid, which will have so great an attraction for the water as to set free the charcoal of the sugar as a black spongy mass. In a similar manner, if the strong acid be dropped on wood, &c., a black spot is produced, owing to the liberation of its charcoal. Sulphuric acid of commerce is thus often discoloured by pieces of straw, &c., falling into it, and so suffers partial decomposition.

Experiment 60.—Into an oily Florence flask pour some strong sulphuric acid, and run it about over the interior of the vessel. The oil will be decomposed, and the acid will turn black. By these means Florence flasks may be easily cleansed from the oil they usually contain.

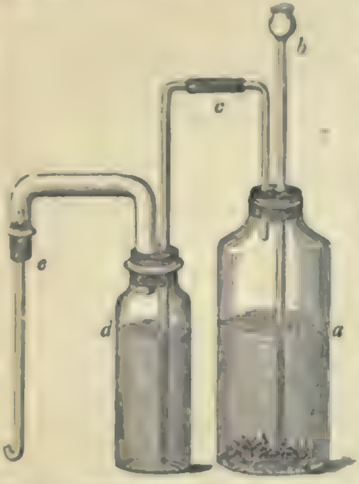
There are other combinations of sulphur with oxygen, which, with the exception of hyposulphurous acid, are of no importance. The only combination of this acid worthy of notice, is the hyposulphite of soda, which is so largely employed as a "fixing" agent in photography, and is produced by boiling soda with sulphur in excess.

Hydrosulphuric Acid.—This is generally termed, in chemical works, sulphuretted hydrogen; and it is a compound of one equivalent each of sulphur and hydrogen; symbol, HS; equivalent = 17. This gas is well known as being the cause of the offensive smell of house-drains, and arises therefrom, owing to the putrefactive decomposition of matter containing sulphur and hydrogen. It is a gaseous body, easily condensed by water, and is readily procured by pouring dilute hydrochloric acid on any metallic sulphide, such as the sulphide of iron or antimony. Its solution in water is much employed in the laboratory as a test for the presence of metals; and the following plan may be adopted for thus procuring it.

Into a glass jar fit a cork, through which pass two tubes, one of which should reach to the bottom of the vessel, whilst the other just passes within its neck. Attach this tube to another vessel, by means of india-rubber connections, so that it may be continued to the bottom of the second vessel: from this another pipe should pass to act as a safety-tube.

The arrangement is represented in the following engraving.

Fig. 61.



In the annexed figure, *a* represents the vessel in which the gas is manufactured; *b* is a funnel, by means of which more acid can be continually added to the sulphide; *c* is the pipe through which the gas passes to the vessel *d*, in which water is placed, which absorbs and forms a watery solution of the gas; *e* is a bent tube, which allows of the escape of uncondensible gas. We need scarcely remark, that the cork in each vessel should be air-tight in their necks, so as to prevent the escape of gas into the air. Instead of water, a solution of ammonia may be used in the vessel *d*, by which the hydrosulphate of ammonia is formed—a usefuland necessary test in the laboratory. Sulphuretted hydrogen gas is a deadly poison, and is partly the cause of many diseases common in badly-drained districts. It may be detected by means of lead in the form of a solution of the acetate. It is readily decomposed by chlorine; hence the use of chloride of lime in places wherever it abounds. The following experiments will impress these facts on the minds of our readers.

Experiment 61.—*To detect Sulphuretted Hydrogen.*—Dissolve a little sugar of lead in water; into this dip some white blotting-paper. On holding a strip of this paper in the jar of gas, or over a foul drain, it will turn black at once.

Experiment 62.—Into a jar of the gas introduce a little chlorine. The sulphur will be immediately separated, and all smell will vanish.

Experiment 63.—*Magic Writing.*—On a piece of paper write anything, using as ink a little solution of sugar of lead, and a quill pen. Let it dry, and the writing will be invisible. On moistening it with water, and holding it in a jar of sulphuretted hydrogen gas, or over a drain, the writing will at once be evident, and in black characters.

Sulphur unites with many substances, forming what are termed sulphides. Of these are the sulphide of antimony, iron and copper pyrites, the sulphide of lead, commonly called galena, &c. The combination of iron and sulphur is readily produced by holding a roll of brimstone against a red-hot iron rod, when the latter will fall down in globules of the sulphide of the metal. Many metallic ores, besides those we have named, contain the metal united with sulphur. The combination of sulphur and carbon, known as the bisulphide of carbon, will be further noticed as a solvent of phosphorus, when we describe that element.

SELENIUM.

We shall here call attention to an element which is rarely met with. It chiefly resembles sulphur in its relations: symbol, Se; equivalent, 39·5. With oxygen it forms selenic acid; and, combined with hydrogen, it affords seleniuretted hydrogen gas. It may be reckoned only as a chemical curiosity, for as yet it has had no application of any value whatever; and, indeed, its scarcity renders such, for the present, impossible.

PHOSPHORUS.

But a few years ago phosphorus was merely a chemical curiosity, or an object for the amusement of young persons, by its peculiar properties. It has, however, lately become an important article of commerce; and in the manufacture of lucifer-matches thousands of persons find employment.

Phosphorus is obtained chiefly from bones, which contain a large amount of phosphate of lime.* The bones are first calcined, and sulphuric acid added thereto. This decomposes the phosphate of lime. The liquid is evaporated to the consistence of a syrup, and mixed with charcoal. The mixture is then strongly heated in a retort, by which the phosphoric acid is decomposed, and the phosphorus distilled over as a wax-like substance. It is received in vessels containing cold water. Its symbol is P, and the equivalent 32.

At ordinary temperatures phosphorus undergoes a slow combustion if exposed to the air; and hence it should always be kept in bottles containing water, so that no part of the substance be above the surface of the liquid. We would impress this precaution strongly on our readers, as we have witnessed some serious results arising from its neglect: in one instance, an extensive laboratory was nearly destroyed by fire, through a stick of phosphorus having been left carelessly on a wooden table. It should never be cut except under water, nor touched by the finger, as the burn it produces is very serious, and difficult to cure. It takes fire at a temperature of about 150°. It has, however, the power of assuming what is termed an allotropic condition; for after having been heated till it obtain a red appearance, it loses its power of spontaneous inflammability, and becomes entirely changed in many of its properties. In this respect it much resembles sulphur, which has also the power of becoming allotropic. It combines with oxygen, hydrogen, &c., in a manner of which we shall presently speak. The following experiments will illustrate some of its ordinary properties.

Experiment 64.—Rub a small piece, by means of a pair of iron nippers, against a wall in a dark room; every mark will appear of a beautiful white light. This effect is called phosphorescence.

Experiment 65.—Boil a few small pieces of phosphorus in a flask, with some water; sparks will rise in all directions through the liquid; and if, at the conclusion of the experiment, you throw out the water into the open air on the ground, a splendid flash of light will be shown.

Experiment 66.—Into a test-tube pour half an ounce of olive oil, and add one small piece of phosphorus; heat *gently* over the spirit-lamp. A small quantity of the phosphorus will dissolve; and by rubbing the oil over the hands and face they will become quite luminous. This is a harmless experiment, and the oil can be easily removed by soap and water.

It is owing to the presence of phosphorus that many animal bodies afford a lambent light at ordinary temperatures. This is often noticed at sea, and during summer evenings: the wake of a steam-vessel, and the back-water cast from the paddles or screw, frequently present a most beautiful appearance, owing to the millions of small insects emitting a phosphorescent light. Crabs, lobsters, and other animal substances, the glow-worm, and fire-fly, owe their luminosity to the same cause. Oyster and other shells often afford a phosphorescent light after having been heated.

A very curious application of phosphorus may be made by its solution in the bisulphide of carbon, to which a little wax may be added. If the liquid so produced be poured upon paper, cloth, &c., after a short time such will burst into flame. Captain Norton has proposed to employ the liquid for the purposes of warfare. He encloses it in shells, which may be fired in the usual manner. On such coming in contact with the sails or hull of a ship, they will at once break, and, spreading the liquid on all sides, cause the destruction of the vessel. We cannot too strongly caution our readers as to the use of this liquid, as whatever combustible substance it touches it at once inflames. Even pouring water over it will not ensure subsequent safety.

---

* See *ante*, p. 360, *et seq.*

By means of a mixture of phosphorus, sulphur, and chlorate of potass, the ordinary lucifer-match is made, which, by mere friction, affords, as is well known, our chief source of artificial light and heat. The following experiment illustrates the production of light and heat beneath water, by those materials.

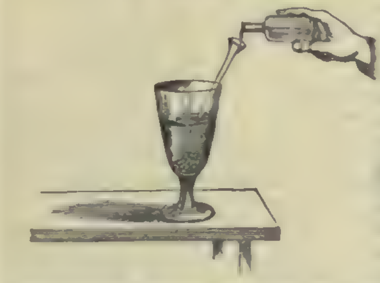


Fig. 62.

Experiment 67.—Into a wine-glass put a few grains of chlorate of potass; fill up with cold water, and then add a few pieces of phosphorus. Through a glass tube pour a little sulphuric acid; when this reaches the bottom of the glass, flame will burst out. This experiment requires caution, as sometimes the phosphorus flies out of the glass, and might injure the eye.

The most important combination of phosphorus with oxygen is that known as phosphoric acid: symbol, PO_5; equivalent, 72. This is produced by the combustion of phosphorus in oxygen gas, and is of great importance in animal economy. Combined with lime, it forms the phosphate of that substance which, as we have already shown, is an important constituent of the bones of animals. Phosphoric acid combines with other bases forming phosphates, such as those of soda, silver, &c. The phosphates of lime are found in the excrements and urine of animals; and to their presence in guano, together with nitrogen, the value of that substance as a manure is due. With three equivalents of oxygen, phosphorus forms phosphorous acid: symbol, PO_3; equivalent = 56. This is produced when phosphorus undergoes slow combustion in a limited amount of air.

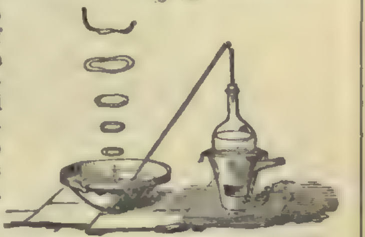
Phosphorus combines also with chlorine and iodine, forming definite compounds; which, however, do not possess any special interest.

Phosphoretted hydrogen gas is a compound of one equivalent of phosphorus to three of hydrogen: symbol, PH_3; equivalent = 35; and has the singular property of spontaneous combustion. It may be readily prepared from the phosphide of calcium, the latter being produced by heating together fresh-slaked lime with phosphorus, in a crucible or test-tube. If a piece of the phosphide be put into a little warm water, beautiful rings of smoke are formed, as represented in the annexed figure.

Fig. 63.

Phosphoretted hydrogen may also be produced by boiling a solution of potass and phosphorus together in a Florence flask, to which a bent tube is attached. The end of the tube should dip below the surface of water; and as the smoke arises therefrom in rings, it will catch fire. An arrangement suitable for this purpose is shown in the annexed engraving.

Fig. 64.



BORON.

Boron is an element of which little is known, in a free state. Its symbol is B; equivalent equals 10·9 Combined with oxygen, however, it assumes considerable commercial importance as boracic acid; its combination with soda forming the well-known borax. Boron is prepared by heating boracic with potassium in a test-tube, and, as such, is a green powder, which on combustion again produces boracic acid. This acid may also be procured by decomposing borax, by means of sulphuric acid, which unites with the soda, setting the boracic acid free. When this substance is dissolved in spirits of wine, it affords a green colour during combustion. Borax is largely employed by metallurgists and chemists as a flux, and is particularly useful in blow-pipe experiments. Boron unites with chlorine to form the chloride of boron, and, with fluorine, it forms the fluoride.

CHAPTER IV.

THE METALS PROPER, KALIGENEOUS, AND TERRIGENEOUS.

One of the most difficult subjects in chemical science is that of defining the exact character of a metal. So long as the number of metallic bodies was confined to those known by the ancients, no difficulty existed; for the properties of gold, silver, &c., are so distinct and marked as to leave no doubt respecting them. During the early part of this century, however, the discoveries of Sir Humphry Davy brought to light metals which differed entirely in their chief characters from those previously known. Thus, for instance, potassium and sodium have very low specific gravities compared with lead, iron, &c.; they have very little tenacity; cannot be drawn out into a wire, or beaten into sheets; and yet, from their various qualities, no doubt can be entertained as to their being properly termed metals. The same may be remarked in reference to calcium, magnesium, &c., which form the basis of the earths, called lime, magnesia, &c. In classifying bodies as metallic, we must have regard to general rather than special properties; and amongst the former we may notice the tendency which all metals have to combine with oxygen, chlorine, &c.; and of forming salts with oxygen and acids. Generally speaking, the metals are susceptible of receiving a high polish, which they retain in proportion as they have little affinity for the oxygen of air and water. Thus, platina, gold, and silver, will maintain a polish on the surface for almost any length of time; whilst iron, lead, and zinc soon become tarnished by oxidation. The tenacity of metals differs exceedingly; for whilst steel, gold, and silver may be drawn into wire finer than a human hair; lead, tin, &c., can scarcely be drawn out at all.

The uses of metals are so numerous and so well known that we need scarcely refer to them; but, perhaps, amongst all, iron is of the greatest value to mankind. Without it nearly every implement of manufacture would be wanting; and, strange to say, it is the most abundant metal. It is a constituent of our bodies, affording the colouring matter of our blood: it abounds in plants and minerals; and the colour of the earth and rocks is frequently due to its presence. Within the last few years a valuable addition has been made to our list of useful metals, in the production of aluminum, which is a constituent of common clay. For years its existence was recognised by chemists; but to M. St. Claire Deville, of Paris, and to the liberal patronage and aid of the Emperor of the French, we are indebted for the means of producing this metal in quantities. It is highly probable that other metals, such as calcium, magnesium, &c., which at the present time are mere chemical curiosities, will eventually, like aluminum, become of use in the arts and manufactures.

Considerable difficulty arises in properly classifying metals for the purposes of describing them in groups. This will be evident from the remarks we have already made on their individual properties. In the following pages we shall divide them into three classes; namely, metals proper, kaligeneous, and terrigeneous. Amongst the first are such as gold, platina, silver, &c.: in the second class we have potassium and sodium; and in the third, or those which as oxides produce the earths, we have barium, strontium, &c. Amongst these we shall include silicon, or silicium, which, although not properly a metal, will be more conveniently considered with the earths than apart by itself.

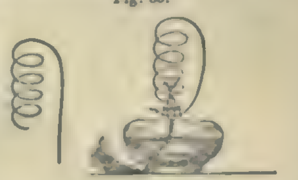
With respect to the oxides of metals, we may mention, that although, properly speaking, all the oxides may be considered to be earths, the latter term is confined to those oxides which produce the constituents of rocks, &c., in reference to mineralogical and geological doctrines. Thus, oxide of iron is a component part of nearly every earth, yet it is not reckoned of itself to be an earth. Such distinctions may be considered to be unnecessary, but yet they are required in the present state of scientific arrangement; because although we may properly hope for an extension of our knowledge in reference to the constitution of elementary bodies, we are compelled to follow the analogies which existing facts point out. The oxide of barium, or of calcium, is perfectly analogous to that of zinc or silver; yet we designate the latter as ores, whilst the two former are termed earths. Hence arises what we may term a conventionalism of science, in which its principles are recognised, but not absolutely insisted on. We admit the general laws, but also make exceptions as to their details. In this consists the humility of philosophy; for we must admit our ignorance, whilst we use the facts of which we are possessed. In the words of Newton, we pick up one pebble, whilst we reject that we previously gained, leaving the ocean of truth still unexplored before us. In the following pages we shall first treat on what are termed metals proper; we shall then describe those which by oxidation produce what are termed alkalies; and, lastly, we shall deal with the metals which, in combination with oxygen, afford us the well-known substances called earths, including, as we have already stated, the substance called silicon, and its oxide, silica, or flint.

PLATINA.

In many works on chemical and metallurgical science, the term "noble" is applied to platina, gold, and silver, from the fact that they are almost unalterable by any of the numerous agents which readily affect the appearances of other metals. Platina eminently sustains this character, inasmuch as it withstands the agency of heat, being nearly infusible; and none of the acids affect it, except aqua regia, which is employed as a solvent for it. Platina is, comparatively speaking, a rare metal, and is generally found in the form of small grains; and in this state occasionally contains iridium, osmium, &c. It is obtained pure by dissolving the native metal in aqua regia, and afterwards it is precipitated as a yellow powder, by means of chloride of potassium. It is then heated with carbonate of potash; the mass so obtained being again dissolved by means of aqua regia; and the platina is then thrown down by a solution of sal-ammoniac, which affords what is termed spongy platina, after being strongly heated. The powder is made into ingots, by being rammed into iron moulds, and heated in a wind-furnace. This process agglutinates the mass, which, when cool, is hammered. Platina has the property of welding at a white heat, like iron; and it may afterwards be rolled out into sheets, foil, &c., or drawn out into wire.

It resists the action of the most intense heat of our furnaces, being only melted by the oxy-hydrogen blow-pipe, or by means of voltaic electricity. It has a colour somewhat resembling, but darker than, silver, and is susceptible of a high polish, which it long retains. When obtained in a spongy state, as already mentioned, it has the power of igniting a mixture of oxygen and hydrogen gases, causing their combinations. For this purpose platina is used in the Dobereiner lamp, and occasionally in the laboratory. Employed in a similar manner with alcohol, it maintains a slow combustion, which results in the conversion of the spirit into acetic acid: even in the form of wire it may be made to maintain combustion without the aid of a wick; and is so used in lamps constructed to diffuse perfumes in an apartment. A piece of platina foil, twisted in the manner shown in the annexed engraving, and surrounding the wick of the spirit-lamp, will continue red-hot, if the wick be first ignited, and then gently extinguished by blowing on it.

Fig. 65.



The chemical symbol of platina is Pt; its equivalent 98·7; and its specific gravity varies from 21 to 22; that of water being 1.

In this country the uses of platina are almost exclusively confined to chemical vessels for laboratory purposes, and for the distillation of sulphuric acid. In Russia it is used as coin; and occasionally it is fashioned into snuff-boxes, &c. Spread in a state of fine powder on silver plate, it forms the negative plate of the Smee voltaic battery. Its solution in aqua regia is also employed by workers in silver, &c., to produce a dark bronze-like appearance. From the difficulty with which it is acted on by chemical agents, its combinations are not so numerous as those of some other metals. It combines with oxygen to form an oxide and binoxide. The protoxide is produced when a solution of potass is added to one of the bichloride of platina, and is a black powder, which is readily decomposed by heat. The binoxide is similarly produced from the bichloride.

The chief combinations of platina are the two chlorides. The bichloride is obtained by dissolving the pure metal in nitro-hydrochloric acid, when a deep yellow or orange-coloured liquid is produced; and the chloride may be obtained from this by heating the bichloride to a temperature of about 400° Fah. These two chlorides are readily distinguishable; the bichloride affording a yellow-coloured solution in water, whilst the chloride is insoluble. With ammonia, the bichloride of platina affords a double salt, which is obtained by the addition of a solution of sal-ammoniac to that of the metallic salt. This double salt is often produced in the course of organic analysis, and affords a ready means of estimating the amount of nitrogen present in the substance undergoing examination. For this purpose the ammonia is converted, by means of hydrochloric acid, into the hydrochlorate, which is subsequently precipitated, by means of the chloride of platina, as a yellow-coloured powder; and the constitution of the salt so produced, leaves the calculation of the ammonia an easy matter.

GOLD.

This metal is so well known, and so extensively employed for numerous purposes, that it requires but little description. It has a specific gravity of about 19·25; its symbol is Au; and its equivalent is 197. Like platina, gold undergoes no change with the most intense heat of our furnaces; it is simply melted, being quite unvolatilisable.

Although so precious a metal, it is widely diffused throughout nature, and is discovered in those rocks of which the mineral quartz is a component part. It is also found in grains or nuggets, of sizes varying from a grain to some hundred ounces in weight, in the beds of many rivers.

Generally speaking, it may be expected in any place where the primitive rocks abound, and in the granite, and allied formations; it has been discovered in many parts of Scotland, amongst which we may mention the Isle of Arran. In the south-west of England, as in Cornwall, gold has often been met with; but so far as our experience goes, at the present time there is no source in Great Britain which would repay the expense of obtaining the metal.

In Russia, Germany, Africa, and Peru, gold mines are worked to a profit; but we need scarcely state, that Australia and California are the chief places from which Europe obtains a supply of the metal.

The dust and nuggets picked up or mixed in the sand of auriferous rivers, require little more than melting before being introduced into commerce: when found attached to quartz, the stone is broken by means of powerful machinery; and the powder thus obtained is washed by an abundance of water until all the earthy particles are removed. This is sometimes done by means of a cradle, which being kept in continual motion, permits the earth to be washed away; whilst the heavy gold falls to the bottom, and is subsequently collected by the miners. In cases where the quantity of gold is comparatively small, the process of amalgamation is adopted; mercury is mixed with the golden sands, and it thus dissolves the gold, just as sugar would be dissolved by water; the gold and mercury, forming the amalgam, are put into a suitable vessel. Heat is employed, and the mercury distilling over, leaves the gold behind in an almost pure state: gold, thus procured, is generally cast into blocks called ingots, and is then ready for the various purposes to which we shall presently refer.

Gold may be distinguished from other metals by the following characteristics:—In its pure state it is easily cut by a knife; it is insoluble in almost every liquid, with the exception of nitro-hydrochloric acid: if it be thus dissolved, it affords a rich purple colour on a solution of tin being added thereto; and sulphate of iron throws the gold down, in the form of a dark-coloured powder, in the metallic state: it may be distinguished from brass by means of nitric acid, which dissolves the base metal, and leaves the gold untouched.

The uses to which gold is applied are very numerous; wherever magnificence, endurance, and costliness are involved, the metal is called on to take a part. Pure gold is never used for commercial purposes, being far too soft. In the current coin of the realm, it is alloyed in the proportion of twenty-two parts of gold to two of copper. By these means it acquires sufficient hardness to withstand the wear and tear to which it is exposed. It is alloyed in various proportions, for the manufacture of jewellery, watches, &c. Metals are readily gilded by being covered with an amalgam of gold; which is made by adding that metal to mercury. The latter is driven off by heat, leaving the gold as a thin coating. Gold is highly ductile and malleable; it may be beaten out into leaves which are so thin as to require between two and three hundred thousand of them to form a pile one inch thick. This is effected by beating the metal with heavy hammers, between skins of parchment. Gold may be drawn into wire as fine as a human hair.

Like platina, its combinations are few, owing to the weak affinity which subsists between it and chemical reagents. It forms two combinations with oxygen: the sub-oxide is obtained by precipitating the sub-chloride, by means of a solution of potash. Auric acid, or the peroxide, is a compound of gold and oxygen; and is obtained from the perchloride by digesting it with magnesia, and boiling the resulting mixture in nitric acid; which affords a yellow-coloured powder.

The most important compounds of gold are the chlorides and cyanides. The chloride is obtained by dissolving gold in nitro-hydrochloric acid; and the dichloride by heating the chloride so obtained to a temperature of 500° Fah. The cyanide is chiefly employed for the purposes of electrotyping; and for its description, manufacture, and uses, we refer our readers to the section on Electricity (article Metallurgy); in which a full account may be found.

A kind of fulminating gold—different to that which is sometimes termed the fulminate of gold—is produced by adding a solution of strong ammonia to one of the chloride, and by pouring more ammonia on the precipitate so produced. This powder explodes on being rubbed by a hard substance. The fulminates proper we shall describe hereafter. Besides the alloys with copper, which we have already mentioned, gold unites with silver, lead, &c., in various proportions. It may be obtained from such alloys by the process termed cupellation, which we have already described. The purple powder, produced by precipitating a solution of chloride of gold by means of the chloride of tin, is employed for the purpose of colouring china ware. It is termed in the arts, the "purple powder of Cassius."

As it is often desired to distinguish gold readily from the baser metals resembling it in colour, we may mention that this may be done by rubbing the suspected article on a rough hard stone, for which the "bloodstone" is usually employed. A very minute portion of the metal is thus removed to the stone; and, on the streak, a little nitric acid is to be dropped. If the metallic appearance be lost, it is evident that gold is not present, because that metal will not dissolve in nitric acid.

Steel articles may be easily gilded by dipping them into a liquid, made by adding ether to the solution of the chloride of gold. The ether takes up a portion of the metal, from which the steel article removes it to its own surface. Care should be taken that the metal does not touch the acid solution resting beneath the ether.

SILVER.

Silver, as we have previously remarked, belongs to a class of metals not readily acted on by ordinary reagents; but being more so than those we have already described, we have taken it last of the three. Its symbol is Ag; its equivalent 108·1; and its specific gravity = 10·5. It is found in a pure state in nature; and by a late discovery, which was accidentally made during an analysis of a sheet of copper, taken from the hull of a vessel which had been long at sea, it has been shown that the ocean contains many millions of tons of the metal. Silver is found in most of the lead ore of Great Britain, and is separated therefrom as much as possible, because even if not present in sufficient quantities to pay for extraction, it injures the lead by making that metal brittle. The chief sources of silver for commercial purposes, are Mexico, Chili, and Peru. It is sometimes found combined with other metals, and occasionally with sulphur. It is obtained from the ore by amalgamation, in a similar manner to that we have described in respect to gold.

Silver is easily distinguished from other metals. In a pure state it has a white colour, and is susceptible of a high polish; it, however, is readily acted on by air containing sulphur, and hence soon becomes tarnished in rooms wherein coal-gas is burned. It is readily soluble in nitric acid (*aqua fortis*); and if a solution of common salt be added thereto, a white curdy powder falls down, which turns to a dark colour on exposure to light.

It is readily separated from other metals by cupellation; and it forms alloys with copper, gold, silver, &c.; and an amalgam with mercury. The latter mixture is much employed for the purposes of plating, which, however, has been now almost entirely superseded by electro-plating processes, which we have fully described in the section on Electricity; article Metallurgy.

Our remarks in reference to the uses of gold are equally applicable to silver, which, to a considerable extent, possesses the same qualities. For the purposes of coin, silver is alloyed with copper; one pound of standard silver being coined into sixty-six shillings. It is largely employed for making various domestic utensils and ornaments.

It may be beaten into leaves of a thickness not exceeding $\frac{1}{100000}$th of an inch each. It is also easily drawn into fine wire; and in this state is, like gold, much used for embroidering drapery, &c. From being unacted upon by many chemical substances, it has been employed to line cylinders in which coffee is roasted, and also in vessels used in the manufacture of lemonade and soda-water.

Pure silver may be obtained by dissolving common silver coin in nitric acid. To this solution, common salt is to be added as long as the chloride falls down. The precipitate is then to be dried and mixed with carbonate of soda, and a small portion of powdered charcoal. It is then to be heated in a crucible, in a wind-furnace, by which the silver will be reduced from the chloride to a metallic state. Other methods for obtaining the same result in an economical manner, have already been referred to in the article on Electro-Metallurgy.

The salts, &c., of silver, are of considerable importance. In fact, at the present time, they have become an extensive article of commerce, for the purposes of photography. Their uses in this respect have already been fully described under the head of Photography, in the section on Light; to which we must direct our readers for information on that interesting application of optical and chemical science.

Silver combines with oxygen to form three oxides. The sub-oxide, $Ag_2 O$, is of little importance. The protoxide, $Ag O$, is the base of the salts of the metal, and is produced by adding a solution of potass or lime to the solution of the nitrate of silver; when a brown-coloured powder is produced. The peroxide, $Ag O_2$, is the result of electric action in bad-conducting solutions of the nitrate: its production often interferes with the regularity of electro-plating processes. The chloride, $Ag Cl$, has been frequently referred to in our previous pages; both under the head of Photography, and as an illustration of chemical changes. The cyanide of silver has also been fully described, as employed in electro-plating, and with respect to its constitution and manufacture. The iodide and bromide of silver have no interest except in connection with photography; and their uses and nature in that respect have been described in connection with that subject.

The nitrate of silver, as we have already remarked, is a substance of great importance. Besides its uses in photography, it is employed in medicine in a fused state, as the "lunar caustic" of the shops; and most kinds of ink, used for marking linen, have this salt as their basis. Nitrate of silver is produced by dissolving pure silver, by heat, in dilute nitric acid; from this solution it may be readily crystallised. Its solutions turn black on exposure to light, if they contain any animal matter; hence their employment as hair-dyes. The sulphate of silver is produced by boiling silver with strong sulphuric acid. The carbonate results from a mixture of carbonate of soda with nitrate of silver, both being in solution. The acetate may be similarly produced by substituting the acetate of soda. We have mentioned that polished silver readily tarnishes when exposed to the action of sulphur; hence plate, spoons, &c., soon lose their polish; and for a similar reason, silver spoons, if not gilded, become black on being used with eggs or mustard; each of which contains sulphur as one of their constituents.

Fulminating silver is a compound of the metal with nitrogen and hydrogen; and it is produced by adding alcohol to silver dissolved in strong nitric acid, when a powder is produced, which explodes violently on the slightest friction. We shall describe the process more fully when speaking of the fulminate of mercury. An explosive compound of silver is produced by adding liquid ammonia to the oxide of silver; forming what is termed the ammoniuretted oxide. This, however, is not a fulminate of the metal.

MERCURY.

THIS well-known metal forms an exception to the general rule that such bodies are solid, inasmuch, as at ordinary temperatures, it is in a fluid condition. In the Arctic regions, however, it is frequently observed in the solid state, owing to the abstraction of its latent heat by means of the intense cold prevalent in those latitudes. From the readiness with which this metal moves about, it has acquired the name of "quicksilver," by which it is generally known in the arts and in commerce. Its specific gravity is about 13·5; its symbol, Hg; and the equivalent = 100.

Our chief sources of mercury are South America and Spain, from which countries it is imported in wrought-iron bottles. It is obtained from its ores by the process of distillation, just as spirits or water are distilled over by the application of heat. The oxides of mercury are, in fact, readily decomposed by heat, the attraction between the metal and the oxygen being comparatively slight. It boils at a temperature of about 650° Fah, and its vapour has a highly expansive power. This circumstance affords a ready means of separating it from various impurities with which it is often contaminated. The mercury is introduced into a retort, and a moderate heat is applied. The quicksilver is by this plan volatilised, and condenses into small globules, which run into a receiver. The impurities, such as lead, tin, and bismuth, are left behind in the body of the retort, and are so separated from the mercury.

The uses of the metal are very numerous. In Brazil, California, Australia, and other countries in which gold-sands abound, mercury is used to dissolve out the fine grains, which are too small to be seen by the naked eye. The amalgam of the gold so formed is then introduced into a retort, and heat is applied. The mercury distils over, and leaves the gold pure. The metal silver is often separated from its ores by similar means, and the process is termed "amalgamation." There are many gold mines in several parts of the world, which would be utterly valueless but for this singular property of quicksilver.

We may here caution our readers to be careful lest any gold or silver ornament or coin should come in contact with the metal, for it soaks into them just as water enters the pores of loaf-sugar. They are thereby rendered very brittle; and if exposed to any mechanical action, are sure to break. In the case of mercury being absorbed by either of the metals named, the best plan is to place them on a piece of iron over a common fire, by which the mercury will be at once driven off, and the article restored to its old state.

Quicksilver is largely employed for "silvering" looking-glasses. A sheet of plate-glass, previously well cleaned, is placed on a board having a slight inclination. A piece of tin-foil is then pressed on to the face of the glass, and over this some quicksilver is spread by means of a hare's foot. A sheet of stout paper is then placed on the foil; and on this heavy weights are put for the purpose of driving off any superfluity of mercury. After a day or two's time the weights are removed, when it is found that the amalgam has adhered to the glass, and has so afforded it a reflecting surface.

As we have already mentioned, amalgams are formed by mixing mercury and other metals together. The amalgams of gold and silver are used for plating purposes. The metal to be plated is coated with the amalgam, and afterwards exposed to heat, by which the mercury is driven off, and the gold or silver left on the surface. This process is called water-gilding and plating. It has, however, gone much out of use since the introduction of the electrotype process. An amalgam of silver is employed by dentists for the purpose of filling hollow teeth.

The metal is also much used in making barometers and thermometers. It is of great value for the former purpose, owing to its fluidity and great specific gravity. Indeed, a column of mercury of a height of thirty inches, balances one of water thirty-two feet high. In thermometers, it shows the increase of temperature from very intense cold to its boiling point, by a gradual and almost regular expansion—more so, in fact, than any other liquid with which we are acquainted.

The combinations of mercury are both numerous and valuable, and of considerable use in the arts, medicine, and commerce. It forms two definite combinations with oxygen. The sub, or black oxide, is produced by adding a solution of potash or soda to those of the sub-nitrate or sub-chloride of the metal, and is so obtained as a dark-brown or black powder. The protoxide is produced by adding the solutions of the alkalies or alkaline earths to those of chloride of mercury, or corrosive sublimate, as it is frequently termed. It is of a red colour; and the oxygen may be separated from the metal by distillation, when the latter passes over in a free state. Mercury resembles the metals we have previously described in this respect. The protoxide may also be obtained by heating the nitrate. The sulphate is readily produced by boiling mercury with concentrated sulphuric acid; during which process large quantities of sulphurous acid, in a gaseous state, are evolved. Nitric acid dissolves mercury, by which the proto-nitrate is produced. On diluting the concentrated solution, a sub-nitrate falls down in the form of a white precipitate. The solution of the nitrate is often sold by unprincipled persons in the streets of our large towns, as a polishing liquid. If applied to a silver or copper surface, it at once produces a brilliant polish; but penetrating into the pores of those metals, and forming an amalgam, their tenacity is at once destroyed, and the article rendered useless.

The chlorides of mercury are of great importance as forming two well-known substances used in medicine. The sub-chloride is the well-known calomel. It is a white substance, and, when closely examined, has a crystalline structure. It may be produced by adding a solution of common salt to one of the sub-nitrate of mercury, or by rubbing together, in a mortar, metallic mercury, common salt, and corrosive sublimate. The product is then sublimed, and the sub-chloride, or calomel, is so obtained in a pure form. It is but sparingly soluble in water, and may be so distinguished from the other chloride. Corrosive sublimate is well known as a deadly poison to animals. In minute quantities, it is, however, employed in medicine; and both it and the sub-chloride have the property of producing a great flow of saliva, and for this purpose even moderate doses are sufficient. Corrosive sublimate is used as a preservative agent for both animal and vegetable substances. It may be prepared by burning mercury in a jar of chlorine gas, or by subliming common salt and the sulphate of mercury together. We may here remark, that in case of accidental poisoning, or of suicide, the best antidote which can be administered is the white of eggs, which, by coagulation with the salt, prevents any action on the intestines.

There are two iodides of mercury. The sub-iodide is a yellow powder, which may easily be procured by adding a little iodide of potassium in solution, to one of corrosive sublimate; if more iodide be added, then a red powder is produced, which is the proto-iodide: if, however, too much of the iodide solution be employed, the iodide of mercury will be dissolved, and the liquid will become transparent. We have frequently produced both iodides by placing iodine in powder on metallic mercury, and inserting the poles of a powerful voltaic battery in the metal: one is then to be withdrawn, so as to produce the disruptive discharge. A combination of the metal and the iodine will then take place, and the two iodides are produced. In many chemical works these iodides are respectively termed the proto, and biniodide. It has been proposed to use these substances as pigments; but they are liable to decomposition, and so defeat that purpose.

There are two sulphides of mercury. One, the sub-sulphide, is readily produced by passing sulphuretted hydrogen gas through a solution of the sub nitrate, by which a black powder is produced. The sulphide proper is well known in the substances termed cinnabar and vermilion; the latter of which has a beautiful red colour, and is much employed as a pigment. Cinnabar is a common ore of the metal. The sulphide, produced by passing sulphuretted hydrogen through the nitrate of mercury, is of a deep black colour; but on being heated, it becomes reddish brown; and the substance, if heated with a solution of sulphide of potassium, produces the pigment vermilion.

Mercury forms a compound with cyanogen as the cyanide of the metal, which is the usual source of cyanogen for experimental purposes. The cyanide may be procured by boiling a solution of prussiate of potash with sulphate of mercury, and subsequently evaporating the clear solution, when crystals of the white cyanide will be obtained.

One of the most interesting and useful compounds of the metal is that termed fulminating mercury, which is extensively employed in the manufacture of percussion-caps; an invention which has completely changed the construction of muskets, fowling-pieces, &c., and has made them infinitely more serviceable for the purpose they are intended for. In the old form of such guns, the powder was ignited by means of a flint and steel placed over the barrel, and the fracture of the flint rendered the musket useless. It was necessary to pour a little powder into the pan, which communicated, by means of a small hole, with the charge in the interior of the barrel; and it frequently happened that a gust of wind or a shower of rain rendered it impossible to ignite the charge. By means of the percussion-cap, the "nipple" is kept quite covered and protected, and, at the instant the hammer is allowed to fall, the powder in the cap explodes, and the charge is inflamed. The following method is that usually adopted in manufacturing the fulminating mercury, which is a combination of fulminic acid with the metal. Into a tall glass or porcelain vessel introduce one ounce of mercury, and on this pour gradually four ounces, by measure, of nitric acid, of a specific gravity of 1·45 to 1·50. Considerable heat will be evolved during the solution of the metal; and when all is dissolved, and the mixture still hot, it must be poured into six ounces of strong alcohol. As the mixture instantly froths up to a great degree, and abundance of vapour is given off, this should be done in a vessel of considerable height and capacity, to prevent the loss of its contents. A powder will soon be produced, which is the fulminate. This may be allowed to settle, and as much as possible of the clear liquid is then to be poured away. The vessel is to be filled up with cold water, and the contents are then to be gradually poured on to filtering-paper, on which the powder will be retained. This is to be well washed with cold water until all trace of acid is removed. The powder itself should always be kept wetted until required for use, as, if dry, the slightest friction would cause it to explode violently. It is best to remove the filtering-paper whilst wet, and to place it in a dish kept full of water; and when any portion of the fulminate is wanted, such should be removed in as small a quantity as possible, by means of a paper scoop, and allowed to dry by evaporation in the open air. We cannot too strongly caution our readers in respect to the manufacture of this dangerous compound. The quantities we have given are such as would be employed for making it on a large scale; but if the student desire to acquaint himself with the properties of fulminating mercury, he should use but a few grains of the metal, and the acid and alcohol in the relative proportions already indicated. To impress the necessity of caution, we may observe, that a few years ago, an able and experienced chemist, employed in manufacturing the article at the Apothecaries' Hall, London, was shattered to pieces, and the fragments of his body blown to an astonishing distance, by an explosion of but a moderate quantity of this dangerous substance. The tyro in chemical science should never attempt to make it at all. We have already named the fulminates of gold and silver, which are producible by a similar process to that just described.

Some of the salts of mercury are extensively used for the purpose of amalgamating the zinc plates of voltaic batteries; and for this purpose the nitrate is the most convenient. The same end is also obtained by brushing metallic mercury over the zinc, the latter being immersed in dilute sulphuric acid.

The detection of mercury, in a combined state, is generally very easy. The sulphate, nitrate, &c., readily part with the metal, if they are moistened with water, and placed on a sheet of zinc. A gold or copper wire is then made to touch the metal, the wire being passed through the moistened salt. The latter is at once decomposed; and metallic mercury, if present, will turn the end of the wire to a white colour. If a gold wire be employed, the mercury is at once removed by the heat of a spirit-lamp. Mercury has a peculiar effect on the human system; and persons employed in the mines, or in working with the metal, are generally afflicted with paralysis.

COPPER.

This metal was well known to the ancients, and is mentioned in the works of biblical and general history. Its specific gravity is 8·78; its symbol, Cu; and the equivalent = 31·7.

Copper is found in the rocky districts of most parts of the world, either in the metallic state or combined with sulphur and carbon. In some parts it is found in the metallic state in immense masses; a specimen weighing above one ton, and containing 95 per cent. of pure copper, may be seen in the Polytechnic Institution, Regent-street, London. When combined with sulphur, it is called *copper pyrites*; and as a carbonate, it forms that beautiful substance called *malachite*. The chief source of copper in this country is in the mines in Cornwall. Australia, New Zealand, America, Western Africa, Russia, and Sweden also produce it in large quantities. A very ingenious use of old iron pots and pans is effected in the water running from the copper mines. The old iron is collected in London, and shipped to Cornwall, and on being thrown into water containing copper in solution, the iron is dissolved, and the copper is thrown down in the state of a brown powder. It is afterwards melted and cast into bars. This plan is easily illustrated by dipping any iron article into a solution of blue vitriol (sulphate of copper), when the metal will be coated with copper, a portion of the iron having been dissolved away. When the ores of copper are employed, they are first roasted, to drive off the sulphur; and after smelting, tolerably pure copper is obtained, in quantities proportional to the richness of the ore.

In the metallic state, copper is recognised by its reddish-yellow colour. It can be highly polished, but soon tarnishes. It is soluble in many acids, and may be detected in solution, by the addition of a little smelling-salts (carbonate of ammonia), which produces a blue colour.

It is largely employed in a variety of ways. As a metal, it is fashioned into vessels for domestic use, which are, however, highly dangerous if they are not coated *completely* with tin, because a portion of the metal dissolves and forms a poisonous salt. In the manufacture of pickles and preserves, this often occurs; but copper may be detected by the means already named. In the absence of medical advice, abundance of sugar or the *unboiled* white of an egg may be taken as an antidote.

Alloyed with zinc, the well-known metal brass is produced. Bronze and gun-metal are a mixture of copper with about one-tenth of its weight of tin. Bell-metal is composed of four or five parts of copper to one of tin. An alloy of copper, instead of the metal itself, called Muntz's metal, is extensively employed for sheathing ships' bottoms.

The combinations of copper are numerous, and many of them are extensively employed in the arts and manufactures. It combines with oxygen in various proportions. Two equivalents of the metal with one of oxygen ($Cu_{,,}O$) produce the sub-oxide, which may be procured by heating the chloride with carbonate of soda in a crucible. The compound so produced by fusion, is then to be plunged in cold water, when the sub-oxide separates. It is chiefly used to colour glass, and a singular property exists in reference to it. If it be burned in at a comparatively low temperature, and for a short period, but a slight red tint is afforded. If the heat be increased, and the period of burning extended, the colour is deepened. In an instance which came under our notice some years ago, resulting from the destruction of the Glasgow Polytechnic by fire, a piece of cut-glass of about four cubic inches' capacity, which had previously been of but a light ruby tint, was converted into so dark a colour by the heat, that when chipped into the thinnest pieces, it appeared of the deepest ruby red.

The protoxide of copper ($Cu\,O$), which is extensively employed in organic analysis, may be readily obtained by heating strongly the nitrate in a crucible, when a black powder will be produced. Full directions for its use for that purpose will be subsequently given. A binoxide of copper, and an acid called cupric acid, have been discovered; but they are not of special chemical importance, except that the latter is somewhat analogous to the ferric acid, of which we shall speak hereafter.

There are two compounds of copper with chlorine—a sub and the proto-chloride. The latter may be procured by dissolving the oxide of copper in hydrochloric acid, when a pale-green solution is produced. This is often used as a sympathetic ink, and for the purpose of paintings, which, by being heated, change from a winterly to a summer-like appearance, by the production of the green colour which heat evolves. The sub-chloride may be prepared from the chloride, by heating the chloride with copper filings in a crucible.

The disulphide of copper is found naturally, and is one of the ores of copper, as we have already stated. It may be produced artificially, by heating sulphur and copper in a crucible. The ore is largely employed in Glasgow and other places, as a source of sulphur for the manufacture of sulphuric acid. The proto-sulphide is readily produced by passing sulphuretted hydrogen through a solution of a copper salt, when a black powder is thrown down. With cyanogen, copper forms the cyanide, which is chiefly used for the purposes of electrotyping.

The most important salt of copper is the sulphate, which may be obtained by boiling copper in sulphuric acid. It is a product of many copper mines; and when crystallised, affords large blue crystals, which are known in commerce as blue vitriol. This salt has become of great importance since the discovery of the electrotype process; and by means of this ingenious application of science, copies of expensive works of art, such as statues, engraved plates, &c., are easily obtained, at a trifling cost compared with that of the original.

The nitrate of copper is readily procured by dissolving the metal in nitric acid. Its chief use is that of affording the oxide of copper used in organic analysis, to which we have already referred.

The native carbonate of copper, called malachite, has been named previously. It is often fashioned into various ornamental articles, owing to the beautiful appearances which it presents. A compound of carbonic acid, copper, and water is readily produced on adding carbonate of soda to the sulphate of the metal, both being in solution, when a light-green powder is precipitated. Native carbonates are very common in the specimens of ores obtained from the copper mines.

On adding ammonia to a solution of a cupreous salt, a deep-blue colour is produced, which is a combination of the metal with the alkali, often termed by old writers the ammoniuret of copper.

One of the most valuable salts of the metal is the acetate, which is familiarly known as "verdigris," and extensively employed as a pigment. The pure acetate is readily obtained by dissolving oxide of copper in acetic acid. The ordinary commercial product is obtained by means of the waste of the vineyards and metallic copper, the external surface of the metal being converted into an impure acetate. This is removed, and the process is repeated until the plate is completely used up. "Scheele's green" is a compound of arsenic and copper, and is also used as a pigment.

IRON.

This metal is so well known, and used in such a variety of ways in civilised life, as to require no description on our part. It is universally distributed, and is one of the most abundant substances in nature. Its specific gravity is 7·5; symbol, Fe; and the equivalent = 28.

Its ores are chiefly the carbonate, oxide, and sulphide; the latter being a compound of the metal with sulphur, is called iron pyrites: this, with the copper pyrites, has been used by sulphuric acid-makers as a source of sulphur.*

The iron district of this country embraces a very extended area. In Scotland, a band of ironstone is found, which reaches from the German Ocean to the west coast; and the whole of the country from Ayr to Edinburgh is dotted with iron furnaces, producing thousands of tons of the metal annually.

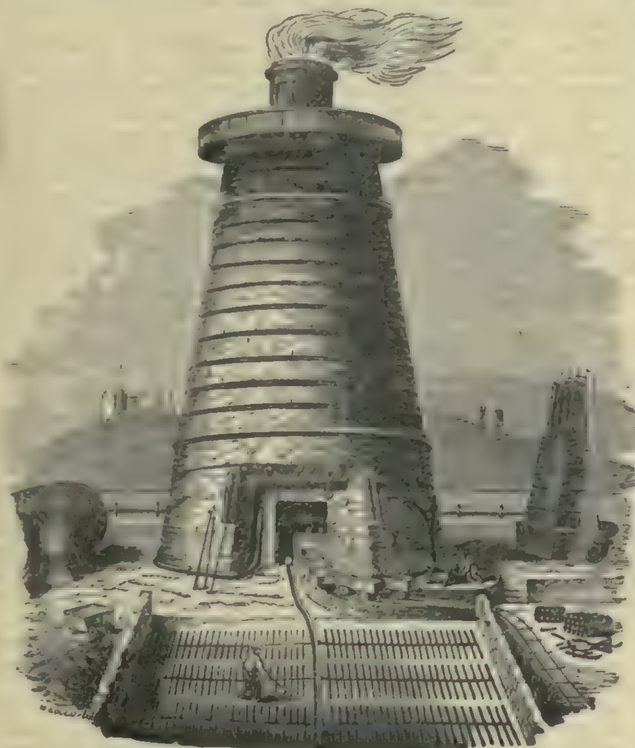
---

* See *ante*, p. 368.

In England, Staffordshire and the neighbouring counties produce immense quantities of the ore; and in most cases abundance of coal is obtained from mines or seams, above and below those of the mineral.

The ore, on being brought to the surface, is mixed with small coal and roasted for many hours; the mass is then broken up and taken to the smelting furnace, which is generally about thirty feet high; mixtures of the ore, coal, and limestone, which acts as a flux, are thrown into the top of the furnace, and an intense heat is maintained by means of powerful air-engines propelled by steam power. Every twelve hours the bottom of the furnace is tapped, and the melted metal is run into long furrows called "sows," adjacent to which are smaller ones called "pigs;" when cool these are sent to market as pig-iron. The following engraving represents the ordinary kind of smelting furnace.

Fig. 66.



But the metal in this form is very brittle, and would be almost useless unless further processes were brought to bear on it. Being broken up into small pieces, the pig-iron is then cast into a puddling furnace, in which it is continually stirred about by means of a rake. After a time it acquires a peculiar appearance, becomes soft and agglutinated, and is then removed to a block, on which it is hammered by steam hammers until all the impurities are driven out. It has now become fit for rolling, and is thus fashioned at a white heat into sheet, bar, or rod-iron.

Iron may be protected from rust by either tinning its surface or by covering it with a thin coating of zinc—a process which has been termed "galvanising." It may be drawn into very fine wire, being very tenacious. It has the singular property of welding; that is, two pieces at a red heat may be united together if well hammered. This property is only possessed by iron and platina.

Iron may be cast into moulds of any form, and thus castings of any size may be obtained. Cast-iron is of inferior strength to bar or rod-iron, owing to its containing several impurities. Mr. Bessemer has introduced an ingenious process for the purpose of making "wrought" iron from the ore. This he effects by driving air into the furnace whilst the iron is in a melted state. By these means its impurities are burnt away.

The most important combination of iron is that with carbon; and, as a late writer has remarked, most probably nitrogen is also present in minute quantities, inasmuch as a direct combination of carbon alone with iron does not afford a substance corresponding in all its properties with that known as steel. In many of their qualities cast-iron and steel are similar; but the latter has an elasticity, ductility, &c., which, as physical characteristics, constitute an enormous difference. Iron and steel may be easily distinguished by dropping on each a little nitric acid, when the pure iron will present only a white appearance, whilst the steel will afford a black mark, indicating the presence of carbon.

The qualities and value of wrought-iron and steel vary exceedingly, owing to the admixture of various substances, such as phosphorus, silica, &c. In England, the best is that produced in Staffordshire; but this is exceeded by that obtained from Sweden. Iron produced by the cold and hot blast also varies in its characteristics. By the latter mode, the iron has induced in it greater tenacity, the air being heated to a temperature of 600 to 700 degrees before it is admitted into the smelting furnace. Iron produced by charcoal is far better, in all respects, than that produced by coke or coal.

Of late years, the uses of iron and steel have been enormously extended. With respect to steel, we may remark, that steam-ships are now entirely constructed of it; even boilers and the masts of vessels have been made from it: some pieces of ordnance have been also manufactured from steel; and their extraordinary tenacity, we need not state, presents a great advantage.

Iron combines with oxygen in four proportions, the symbols and properties of which are as follows:—The protoxide ($Fe\ O$) is produced by adding a solution of potash to one of the protoxide of iron, when a green precipitate is produced. When this is boiled, a black powder is the result. The peroxide (Fe_2, O_3) is readily obtained by adding an alkaline solution to the nitrate of iron, and is a red-coloured substance. The presence of this in nature gives the rich red tint to the rocks of the old red sandstone, and is the cause of the colour of blood, &c. The black oxide (Fe_3, O_4) has, like the metal, decided magnetic properties: it is familiarly known in the scales so often seen when wrought-iron has been heated to redness, and is a common product of the blacksmith's shop. Ferric acid ($Fe\ O_3$) is the state in which iron is found combined with the largest proportion of oxygen.

Chlorine unites with iron in two proportions, forming a proto-chloride ($Fe\ Cl$) when iron is dissolved in hydrochloric acid; and a sesqui-chloride ($Fe_2.\ Cl_3$) when chlorine is passed over iron filings at a red heat. There exist two sulphides of iron. That which is best known constitutes the iron pyrites ($Fe\ S_2$), so common as an ore of the metal. The proto-sulphide is readily produced by bringing a roll of sulphur in contact with a bar of iron heated to redness. The metal will immediately be seen to melt away; and the dross which falls down, and which should be received in dry sand, forms the substance required.

Iron and sulphuric acid readily combine to form the sulphates, of which there are two; one being produced as a proto, and the other as a per-salt. The proto-sulphate is obtained by dissolving iron in dilute sulphuric acid: during the process, water is decomposed, and abundance of hydrogen is evolved. The proto is easily converted into the per-sulphate by exposure to the air, or by the addition of nitrous or nitric acid, when the oxide enters into the state of protoxide. Green copperas is a proto-sulphate of iron in an impure state. It abounds in many kinds of coal, &c., after exposure to the air, by which means the sulphide is gradually converted into the sulphate. In the Isle of Sheppy, at the mouth of the Thames, the process goes on at an enormous rate; for the soil abounds in nodules of iron pyrites, which are continually undergoing decomposition. Sulphate of iron is also found in many mineral springs; and frequently the oxygen it absorbs from the atmosphere, is the cause of the reddish-brown powder observed when such waters are allowed to remain still for a time. A solution of proto-sulphate of iron, from its great attraction for oxygen, is often employed with the nitric oxides, in the estimation of the presence of oxygen in air, &c. The proto and per-sulphates are largely used as fixing agents in photographic processes. The nitrate of iron is also similarly employed, and is produced when iron is dissolved in nitric acid.

Copperas (the proto-sulphate) is much employed as a dyeing agent for producing, with logwood, gall-nuts, sumach, &c., various shades of slate and black colours; and, for the same reason, it is used by calico-printers: but for these purposes the acetate is generally preferred, as it is more readily decomposed by the gallic acid found in the vegetable substances we have named. The acetate may be prepared by decomposing the sulphate by means of acetate of lead, when sulphate of lead is precipitated, and acetate of iron held in solution. Acetic acid and common vinegar, or sour beer, &c., may be left to digest on old iron hoops or other articles; which is, of course, a more economical, although slower, process for forming the acetate. These, and many other salts of iron, such as the citrate, succinate, &c., to which we might direct attention, are not, from their comparative rarity, of general importance. The citrate is employed in medicine, and the succinate as a chemical test.

The combination of iron with cyanogen, however, deserves by no means a passing notice, as the prussiate salts are extensively used as a dyeing agent, and are constantly employed in the laboratory as tests, &c. The cyanide of iron is obtained by adding cyanide of potassium to a solution of proto-sulphate of iron; and is, at first, a white powder. As, however, every salt of iron, unless in a peroxidised state, has a great attraction for oxygen; the cyanide, if exposed freely to the air, becomes of a blue colour. The most important cyanide of iron is that generally known by the term of yellow prussiate of potass. It consists of lemon-coloured crystals, of a regular form. This substance is produced on a large scale in this country for the use of dyes. Animal matter, such as hoofs, horns, old leather, blood, &c., is projected into a large iron pot heated red-hot, potash and old iron being also added; a general decomposition ensues; and when perfect fusion is effected, the mass is raked out, and, after being cooled, is dissolved in water, and, subsequently, crystallisation produces the yellow prussiate. During the process, a combination is effected between the carbon, nitrogen, iron, and potass. A new substance is thereby generated, termed ferro-cyanogen, which, with hydrogen, forms hydro-ferrocyanic acid; analogous, in some respects, to hydrocyanic acid. But the actual composition of the yellow prussiate is that of 1 equivalent of ferro-cyanogen; 2 equivalents of cyanide of potassium; and 3 of water: hence it is termed ferrocyanide of potassium.

Many years ago we had occasion to notice the accidental production of Prussian blue—which we shall presently describe—whilst visiting some gas-works. Now coal contains carbon, nitrogen, iron, &c.; and at the present time, the prussiate is produced by the union of these elements, in a similar way to that which we named as accidentally occurring; charcoal, air, oxide of iron, and carbonate of potash being heated together in suitable arrangements.

The yellow prussiate of potass is converted into the red, or ferri-cyanide—so called in contradistinction to the ferro-cyanide, which we have just described—by passing chlorine gas through an aqueous solution of the latter salt, by which means one equivalent of chloride of potassium is removed. It is chiefly used as a test for iron, giving a distinctive character as to the oxidation of the iron in the solution tested. The uses of the yellow and red prussiates, in this respect, will be considered under the head of Chemical Analysis.

By adding solutions of the yellow prussiate of potass to per-sulphate of iron, or to a solution of the proto-sulphate, to which nitric acid has been added, a rich, blue precipitate is produced, termed Prussian blue. It is the formation of this substance in woollen and cotton stuffs, by the successive use of the salts named, that such are dyed of a blue colour for many purposes, instead of by indigo. The colour is, however, turned green, and eventually destroyed by alkalies, and is therefore not of a permanent nature. Prussian blue is largely used as a pigment. If a solution of sulpho-cyanide of potass, produced by heating sulphur, carbonate, and prussiate of potash together to redness, and dissolving the fused mass in water when cold, be added to those of the salts of iron, a deep, blood-red colour is produced. It is highly possible that some such combination as this is the cause of the colour of our blood, as all the necessary elements are present in that fluid.

We have hitherto confined our attention exclusively to the chemical character of the metal iron and its salts. We must now speak of others, which are of considerable interest, before concluding these remarks. It is well-known that iron has the power of becoming attractive by the loadstone, and that steel is subject to the magnetic influence to such an extent, as to be able to retain all the characteristics of the magnetic force. This fact adds to the value of iron as a metal; for by means of it we are enabled to construct the mariner's compass, so essential to navigation in the present day. This subject has already been fully discussed, however, in the section on Magnetism; to which we must, therefore, refer our readers for information on the matter.

LEAD.

THIS metal is one which has long been employed for various uses by mankind, and, like those previously described, it was well-known to the ancients. Its specific gravity, on an average, is 11·45; its symbol, Pb; and its equivalent = 103·7.

Lead is almost always found in nature in combination with sulphur; in this state it is called galena; and it is very generally distributed over most parts of Great Britain, especially in Derbyshire, Yorkshire, and Northumberland. It is obtained by roasting the ore with coal, and subsequently smelting it: the metal is then run into long bars called "pigs," in which state it is sent into the market.

It has a bluish colour, and may be polished; but soon tarnishes, owing to the formation of an oxide on its surface; its presence in solution may be detected by sulphuretted hydrogen gas. This gas, which is the cause of the offensive smell of drains, immediately turns any solution of lead to a dark-brown colour; hence the reason that white paint is so often discoloured, containing as it does the carbonate of lead.

Lead is easily melted, bent, and rolled, and is therefore valuable in forming piping, cisterns, and other vessels. It, however, produces a deadly poison when in a state of solution (as the carbonate in water), which frequently occurs from the use of lead cisterns, &c., if the water in them be nearly pure. This, at first sight, would seem paradoxical, but is easily explained. At the part where the lead, water, and air are in contact, the carbonate of lead is formed. The carbonic acid, gradually absorbed by the water, facilitates the solution of the salt, and so impregnates the liquid with lead. Now this does not happen if the water be hard, because the sulphates contained therein form an insoluble coating of the sulphate of lead, which prevents further action on the metal. Considerable opposition on this account was made, a few years ago, to the introduction of the water of Loch Katrine into Glasgow, as it was considered that the exceedingly soft nature of the water, owing to its freedom from salts, would induce the solution of the lead in the cisterns and pipes of the city. Whilst we fully admit the prudence and good feeling of those who raised the objections, we are equally glad to find that the denizens of that city still flourish, and that the purity of the water-supply has not been attended by any untoward danger. Numerous instances, however, have occurred in which serious injury, and even fatal results, have arisen from the water supplied to houses and stables having become impregnated with lead; and there is no doubt that many families have been afflicted by disease arising from this effect, which has not been discovered at the time, but assigned to other sources for an origin.

The combinations of lead are of considerable importance. An oxide is at once produced when lead is heated to the melting point. Its surface gradually becomes coated with a varied-coloured powder, through the oxidation of the metal; and thus red lead—a pigment in so much use—is produced. The protoxide of lead may be obtained by heating the carbonate of the metal to redness. Massicot and litharge are oxides of lead; the latter being boiled with linseed oil, produces the drying-oil used by painters. When dilute nitric acid is made to act on the ordinary red lead, a portion only is dissolved, and a nitrate of lead is produced. There, however, remains an insoluble brown powder at the bottom of the vessel, which resists the action of the acid, and is the peroxide. The sulphate of lead may be produced by adding sulphate of soda to the acetate of the metal, both being in solution. It will fall down as a white powder. The same result is obtained by digesting galena (the sulphide) with nitric acid, by which the sulphur is oxidised, and the sulphate, together with some unchanged sulphur, are produced. The chloride is also a white powder, and may be obtained by adding hydrochloric acid to the acetate of the metal. The acetate, or sugar of lead, which is employed in medicine, and for other purposes, is a crystalline substance, procured by digesting litharge in vinegar. It has a remarkably sweet taste; and hence its name. A basic acetate of lead exists, containing less acetic acid, and more base than the former. The chromate of lead is produced on adding a solution of chromate of potass to one of acetate of lead, when a yellow powder is precipitated, forming the yellow chrome used by painters. The orange chrome is formed when the yellow is boiled with lime.

The most important salt of this metal is the carbonate commonly known as white lead, and extensively used for painting purposes. It is easily obtained by mixing solutions of carbonate of soda with the acetate of lead; but for commercial purposes, a more economical plan is pursued. Thin plates of lead are exposed to the action of the fumes of spent tan, by means of which both acetic and carbonic acids are afforded. Gradually, the external surface becomes coated with a white powder, which is the carbonate. As this is formed, it is scraped off; and the surface left is again exposed to undergo the same process, until the entire plate is destroyed. It is found in commerce, both in the dry state and ground with oil. This manufacture is peculiarly dangerous to the health of the work-persons; and females are generally employed, as being less liable to the evil effects than males. Of late years, a compound of zinc has been substituted, to some extent, for white lead in house-painting.

There are other combinations of lead, such as the iodide, cyanide, &c.; which, however, are of minor importance, and are little beyond the range of chemical curiosities. If the tartrate of lead, produced by adding cream of tartar to acetate of lead in solution, be dried and introduced into a tube, which must then be exposed to a red heat and sealed, a finely divided form of lead will be produced. If the tube be broken, and its contents shaken out, they will catch fire, affording what is called pyrophorus.

ZINC.

DURING the last few years, the metal zinc has been applied to so many useful purposes, as to have superseded lead to a very large extent. It is produced from two kinds of ores, known as calamine and blende; the former being a carbonate, and the latter a sulphide of the metal. As is usual with most metallic ores, those of zinc are first roasted. By this the oxide is produced; and the reduction of the metal is effected by heating with pulverised coke. Being volatile, it distils over from the crucible in which it is reduced; these being placed in a peculiarly constructed furnace. It is afterwards cast into flat plates, and sold in that form as "spelter," in commerce. If one of these plates be broken, a beautiful crystalline appearance is presented. The facets, however, soon become oxidised, and lose their brilliancy. Zinc can be readily rolled out into sheets; but for that purpose it must be heated to 300° Fah., because both above and below that temperature the metal is brittle, and may even be pulverised.

Zinc may be drawn into a wire, which, however, has no great amount of tenacity. It is manufactured into nails, and has been extensively employed for coating iron instead of tin. This process is termed, most erroneously, "galvanising," for no voltaic current has anything to do with the process. The effect of covering iron with zinc is simply that of enclosing a readily oxidisable metal within one having less attraction for oxygen, and thus of protecting the interior plate from the action of air and moisture. The tenacity of the iron plate is diminished; and nails over-"galvanised" become so rotten as to be easily broken by the fingers, even when they are of considerable substance.—Whilst referring to the properties of lead, and its application to domestic purposes, we stated that considerable danger exists when it is employed to line water-cisterns for domestic use. Of late, zinc has been advantageously employed for that purpose. Its surface only becomes superficially coated with oxide, which is insoluble in water, in all ordinary cases; and hence no danger can arise from its use. Zinc is largely employed in the construction of voltaic batteries; and was most ingeniously proposed to be attached to the copper sheathing of vessels, so as to prevent the corrosive action of sea-water on them. The plan failed through a secondary result taking place; for shells of molluscs, &c., attached themselves to the copper, and so impeded the speed of the vessel.

Zinc, in combination with copper, produces brass: it forms alloys with other metals; and so its uses have been greatly extended.

Zinc, like iron, is a very combustible metal; for in the form of thin shavings it will burn with ease, affording a beautiful blue flame. If zinc be melted in a ladle, and, when red-hot, a portion be cast into the fire, the same result will be produced. A ladle may be filled with melted zinc, and small portions of nitre or chlorate of potass being cast on the surface, a splendid combustion results. A jet of oxygen directed on shavings of zinc which have been previously ignited, affords a beautiful spectacle. The combustion of zinc, as poles of the voltaic battery, produces a blue light fringed with red.

From the above experiments a white powder is always produced, which is the oxide of the metal. A hydrate of the oxide is obtained by adding a solution of potass to one of sulphate of zinc. The oxide has been extensively employed as a substitute for white lead; and it is to this substance we referred in our remarks on the carbonate of lead.

Chloride of zinc is obtained by dissolving the metal in hydrochloric acid. This compound has been recommended as an excellent disinfectant; and its value in this respect has been well tested by the medical boards of health throughout the kingdom. A small quantity of the solution is to be sprinkled over any offensive object; or in applying it in hospitals, &c., towels wetted with it may be hung in different parts of the wards or rooms. A remarkable instance of its efficacy came under our notice some years ago (1849). A metal manufacturer in the neighbourhood of London, employing a large number of hands, was in the habit of using chloride of zinc for soldering purposes; and considerable quantities of the waste material were allowed to run down a sewer. All his workmen escaped attacks of cholera, which was then prevalent to an alarming extent; as did the inhabitants, whose drains were connected with the sewer. About the same period, we observed a similar result from chloride of lime; the waste liquor, to the amount of hundreds of gallons, daily passing down a drain in the centre of a street situate in Lock's Fields, Walworth. Although on all sides deaths were occurring hourly from cholera, yet the whole of the inhabitants of the street escaped; as did the workmen in the adjacent factory.

The sulphide of zinc, or zinc blende, to which we have already alluded as an ore of the metal, may be obtained by heating the oxide with sulphur in an iron ladle. It has no specific uses as an artificial production.

The sulphate of zinc is readily procured by dissolving the metal in dilute sulphuric acid; and this is often done to procure hydrogen gas, which is afforded in abundance. It is largely produced by the use of Smee's batteries employed for electro-plating. A dilute solution, say twenty-grains, to a pint of distilled water, forms an excellent eye-wash. As an application in cases of burns and scalds, and in other cases, it may be used in place of "Goulard water," which is a weak solution of acetate of lead. The equivalent of zinc is 32·6; its symbol, Zn; and its specific gravity averages about 7·0.

TIN.

TIN has long been known as a metal capable of a variety of uses; and the British tin mines are spoken of by both Greek and Roman writers. The sources of this metal are the mines in Cornwall and Devonshire, in England; but considerable quantities are imported from Malacca. It has a whitish colour; produces a peculiar smell when rubbed, and a crackling noise on being bent. Alloyed with lead, it forms pewter, solder, &c.; with copper it affords bronze, gun and bell-metal, and bearings for shafting, &c. It is also largely employed for tinning iron and copper vessels for domestic use; preserving the former from oxidation, and preventing the poisonous effects of the latter through its protecting coat. Tin also forms a constituent of the material used in the manufacture of specula, for reflecting telescopes. Its equivalent is 59; the symbol, Sn; and its specific gravity, 7·25.

Tin combines with oxygen in two proportions. The protoxide is obtained by adding alkaline solutions to the proto-chloride, when a white powder is precipitated, which is a hydrate. The binoxide, or, as it is termed, stannic acid, is produced when tin is digested with nitric acid. It behaves as an acid, by forming salts with alkalies.

Sulphur and tin unite to form the sulphide and bisulphide. The latter may be produced by passing sulphuretted hydrogen through the per-chloride. Mosaic gold is a sulphide of tin, and is produced by heating an amalgam of tin with sulphur and sal ammoniac. The most important combinations of this metal are the chlorides, which are largely used in the arts. The proto-chloride is produced by dissolving tin in hydrochloric acid. This liquor is used as a mordaunt with vegetable colours, such as Sapan, Brazil wood, &c., in dyeing woollen and other yarns. The "purple of Cassius," which we have named in connection with gold, is produced by adding together the chlorides of the two metals; both being in solution. The per-chloride is produced when powdered tin is combined with chlorine gas, which should be passed over the metal in a porcelain tube. The product is a liquid which used to be known by the name of the fuming liquid of Libavius.

NICKEL.

NICKEL is chiefly known as a constituent of German silver, and is, comparatively speaking, a new metal. It has a greyish white colour; and, like iron, possesses magnetic properties. Its equivalent is 29·5; symbol, Ni; and it has a specific gravity of 8·7. It derives its name from the German term given to its ore. It is obtained from its combinations with arsenic, either by the moist or dry way. By dissolving the ore in nitric and sulphuric acids, the arsenic and nickel are separated; and by means of carbonate of potash, a double salt of nickel and potash is produced. From this the oxalate is procured, which affords nickel on being reduced by heat. The protoxide of nickel is obtained by adding an alkaline solution to the sulphate, and heating the precipitate, which is a hydrated oxide. The sulphate of nickel and other salts have a rich green colour. They have, however, no special application. We have already remarked that nickel forms a chief constituent of German silver, in which it is united with zinc and copper. The proportions of these metals vary according to the views or requirements of the manufacturer. Its use in connection with electro-metallurgy has already been fully dealt with, under that head, in the section on Electricity.

It is somewhat remarkable that nickel is generally found associated with iron in meteoric stones. The two metals have many qualities resembling each other. As we have seen, they are both subject to magnetic action; their equivalents and specific gravity do not greatly vary; and the colour and characteristics of several of their combinations are occasionally almost identical in some respects.

BISMUTH.

THIS metal is found in Cornwall, Germany, and other countries in Europe. It has a white crystalline appearance: it is obtained from an ore containing sulphur and arsenic; and is occasionally met with in an impure metallic state. It is distilled from its ores in iron tubes; and forms beautiful crystals on being melted and cooled. Its symbol is Bi; its equivalent, 213; and its specific gravity, 9·8. Alloyed with tin, it affords a material which has sonorous properties. Eight parts of bismuth, five of lead, and three of tin, form an alloy which fuses at a temperature a little less than that of boiling-water; and two parts of bismuth, one of lead, and one of tin, fuse at a temperature of 200°. For the amusement of young persons, such alloys are occasionally made into the form of spoons, which at once melt on being immersed in hot tea. It forms several oxides; the ter-oxide, $Bi\ O_3$, prepared from the ter-nitrate, $Bi\ O_3,\ 3NO_5$, is a yellow-coloured powder, which is used in the porcelain manufacture. The nitrates are the chief salts of the metal; and the one to which we have referred is prepared by digesting the metal with nitric acid, diluted with an equal quantity of water. The sub, or basic nitrate, forms the "pearl powder," used by ladies as a cosmetic; and is employed in medicine as an astringent and tonic. Bismuth, as a metal, is rarely used in the arts or manufactures. It is employed in constructing thermo-electric piles in combination with antimony.

ANTIMONY.

ANTIMONY, so valuable as a material in printing-types, and as a medicinal agent, is obtained both in a native state, and in combination with sulphur, as a ter-sulphide. Its ores are obtained from Singapore and Borneo. It is also found at Linz, in Germany. The sulphide is heated with charcoal, when it fuses: the mass so obtained is reduced to a coarse powder, and roasted with charcoal moistened with a solution of carbonate of soda. The mixture is then raised to a red heat, by which the metal is afforded in a tolerably pure state. It is very brittle and crystalline; has a bluish-white colour; and volatilises at a high temperature. It has the singular property of expanding as it cools. The latter circumstance renders it of great value for casting types, as the moulds in which they are formed are thereby more accurately filled, and the casting becomes more perfect. Its other alloys are also valuable. It forms a constituent of Britannia-metal; specula, for reflecting telescopes; bell-metal; and, associated with bismuth, it has the singular property of affording a current of electricity on the application of heat in the form of the thermo-electric pile. (See Bismuth). Its symbol is Sb; its equivalent = 129·; and the specific gravity, 6·8. Oxide of antimony is prepared by mixing the chloride with a hot solution of carbonate of soda, by which a grey powder is produced. This oxide, combined with tartaric acid and potash, forms the "tartar emetic," used as a medicinal agent. Antimonious acid, $Sb\ O_4$, is a constituent of James' powder, a well-known substance, employed in medicine. Antimonic acid, $Sb\ O_5$, is produced by acting on the metal by means of strong nitric acid; and forms salts with bases. Sulphur and antimony, united as sulphides, differ in appearance, in the native condition, from those prepared artificially. The natural sulphide is a dense black powder; and is much used by firework-makers to give coloured flames. Its peculiarity in this respect may be noticed by burning the following composition:—Nitre, four parts; sulphur, two parts; sulphide of antimony, one part.

Each ingredient is to be separately pounded, and the whole is then to be intimately mixed in a mortar. During combustion, the above produces an intense light, and is used for the manufacture of Bengal lights and sea-signals. We have frequently employed it for the purpose of taking photographs at night. The artificial sulphide has a rich red colour, and may be prepared by passing sulphuretted hydrogen through a solution of tartar emetic.

Kermes' mineral is produced by boiling the sulphide with potash or its carbonate, and has a reddish-brown colour. A sulphide of antimony, containing five equivalents of sulphur to one of the metal, is produced by passing sulphuretted hydrogen through a solution of the perchloride in hydrochloric acid, when it falls as a yellow powder.

If a little powdered antimony be heated and dropped into a jar of chlorine gas, it will take fire, producing a chloride of the metal. If the black sulphide be boiled with hydrochloric acid, the terchloride is formed ($Sb\ Cl_3$), which has been called the "butter of antimony." This, with olive oil, is used as a bronzing composition.

Antimony, like arsenic, has the singular property of combining with hydrogen, forming what is called antimoniuretted hydrogen. This may be procured by passing hydrogen through any solution of the metal. If a cold plate be held against the flame of this compound, metallic antimony will be deposited, which will not volatilise on the application of heat—a point of importance as distinguishing it from arseniuretted hydrogen, of which we shall have to speak hereafter.

ARSENIC.

The ores of this metal are very widely diffused in combination with those of other metals; and one of its oxides is the well-known poison, commonly called white arsenic. The importance of the subject of poisoning by this substance, will require, on our part, a somewhat extended notice of this element and its compounds; and we shall enter into a general description of the various methods which have been proposed for their detection.

The metal itself is obtainable from any of its combinations by first applying heat—say to the arseniurets of iron, copper, &c. White arsenic, or arsenious acid, sublimes; and if this be heated with charcoal in a test-tube, the metal can be readily procured as a crystalline substance having a metallic lustre. Its equivalent is 75; symbol, As; and the specific gravity about 6. When heated and in process of volatilisation, arsenic affords a smell resembling that of onions. We may here warn our readers to be exceedingly cautious with respect to inhaling the vapour, as it produces extreme inconvenience by acting on the membranes of the eyes and nose, even in minute quantities, and may prove highly dangerous if incautiously inhaled.

Arsenious acid is the most important combination of the metal. It contains one equivalent of arsenic to three of oxygen; and, as we have stated, is the poison known by the name of white arsenic. It is surprising that so deadly a poison should be so extensively employed. It has been stated, on good authority, that the inhabitants of some parts of Germany are accustomed to eat arsenious acid, and that it has the effect of making them plump in body, and sustains their power of ascending steep places, so far as the act of breathing is concerned. It has also been remarked, that so long as the habit is maintained, no inconvenience of any kind is produced; but if it be left off, then all the symptoms of arsenical poisoning present themselves. White arsenic is often given to horses, and produces a sleekness of skin not obtainable by any other means. As a sheep-wash, and to steep wheat, it is often employed; and it is no uncommon matter to find farmers purchasing the article extensively on market-days, for the purposes we have named. We need feel surprise, not that cases of arsenical poisoning so rarely occur, but rather that they are not more frequent, when we take into account the character of the individuals with whom it is entrusted. Arsenic with copper forms a pigment largely used for the purpose of printing a rich green colour on paper-hangings. This fact, in the opinion of many, has given rise to instances of poisoning in households, owing to the arsenical powder being brushed off from the walls, and being inhaled afterwards. Such an occurrence *may* take place, undoubtedly, in extraordinary circumstances; but we are strongly inclined to the opinion, that an accident only, and not a constant tendency, must exist to produce harm from such a source. Ladies' dresses have often their green tint heightened by means of Scheele's green; and persons employed in making such, and in the manufacture of wax and other artificial flowers, suffer seriously from the inhalation of arsenical powder thus used in their business. It is much to be regretted, that the personal charms of the *belle* must be enhanced by her poorer sisters paying the cost with the sacrifice of their health, and, possibly, their lives.

In the early attempts to manufacture candles from stearine, considerable difficulty was experienced in the tendency towards crystallising, which that substance always exhibited whilst cooling. White arsenic was used for the purpose of preventing this, and it was successful; but great danger arose to persons sitting in rooms wherein such candles were burned. Hence the use of arsenic was given up, and, by mechanical means, the difficulties we have named have been overcome. Another source of danger to a family, is the use of arsenic (by which term we shall in future call the arsenious acid, for the sake of simplicity) as a poison for rats and mice. To the ordinary observer, little difference exists between flour and that substance; and to prevent the danger arising from this source, an act of parliament has been passed, in which it is insisted that the white arsenic shall not be sold in its ordinary state, but mixed with other substances to give it a distinctive character. Another and extraordinary use of this poison is that of a cosmetic. For this purpose, a little of the white arsenic is put into the water in which the person is washing, and the face and hands are bathed with the solution. Independent of the certainty that the dissolved matter will be absorbed by the pores of the skin, small particles are likely to be introduced into the mouth, nose, and eyes; the least inconvenience from which would be that of causing inflammation of the membranes. But as the pores of the skin communicate with the blood-vessels, the poison is gradually absorbed by the system, and the consequences of its use soon become apparent by symptoms of arsenical poisoning, which supervene.

We may suggest a very simple way by means of which arsenic may readily be distinguished from any other substance usually found in our houses. Let a small pinch of the suspected powder be placed at the end of a penknife, and introduced into the flame of a candle. If it be white arsenic, it will soon pass off as vapour; or a small portion may be placed on some red-hot coal, when, if arsenic be present, it will volatilise, affording a smell exactly like that of onions.

We shall now proceed to familiarise the minds of our readers with the modes which may be adopted to detect the presence of arsenic—commencing with some comparatively rough experiments, and then giving those refined methods which the analytical chemist adopts in cases which form the subject of judicial investigation. If the student proceed successively with each, he may soon acquire skill in the detection of the poison.

(*a*.) Introduce a few grains of white arsenic into a test-tube, and apply the heat of a spirit-lamp to the powder. It will volatilise and condense on the cool part of the tube as a white crystalline substance.

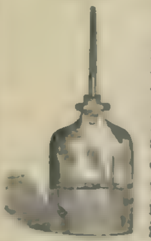
(*b*.) Mix a little white arsenic with some powdered charcoal, and apply heat as before. The oxide will be reduced, and *metallic* arsenic will be produced in dark metallic crystals.

(*c*.) Apply heat to these crystals, when they will immediately volatilise, recondensing in some cooler part of the tube.

The foregoing experiments will illustrate the characteristics of arsenic and arsenious acid, and the method by means of which the metal may be reduced.

Arsenic has, like antimony, the power of combining with hydrogen, and of forming what is termed arseniuretted hydrogen. This fact has been taken advantage of by Mr. Marsh, to afford a most ingenious and effective means for discovering the presence of arsenic in minute quantities. The best mode of illustrating this is as follows:—

Fig. 67.



Into the bottle represented in the following figure, introduce some water, zinc-shavings, and a little sulphuric acid; just as is done in making hydrogen gas. Refit the tube and cork; and after having allowed the mixture of air and hydrogen to escape, so as to prevent any danger of explosion, ignite the gas, and hold against the flame a white porcelain plate. If the zinc and acid be pure, nothing will be deposited on the plate except a little water. Dissolve a small portion of arsenious acid in hydrochloric acid, heating the mixture. When the solution is effected, pour a few drops into the bottle producing hydrogen, and instantly replace the tube. After a few seconds, apply a light to the jet; when it will be noticed that the flame has a blue colour; and if a cold plate be now held against it, crystals of arsenious acid will be at once produced; in the centre of which will be a black mark. Instead of the plate, let the flame play inside of a glass-tube. The arsenious acid and arsenic in a metallic state will both be deposited. These may then be again volatilised in the manner already referred to in experiments *a* and *c*, above. We need scarcely state, that in accurate analysis, it is of the utmost importance that all the materials employed should be pure. Zinc and sulphuric acid frequently contain arsenic; hence, if the commercial articles be used, they may possibly afford arsenic, which would render all results obtained valueless. This precaution, the experienced chemist, of course, always attends to; and is at all times scrupulously careful as to the purity of his tests.

If a piece of clean copper be dipped into the hot solution of arsenious acid just mentioned, and boiled therein, the copper will become coated, arsenic being reduced on its surface. The copper slip may then be removed; and after being washed in water and dried, the arsenic may be sublimed from its surface, if it be introduced into a test-tube, and heated by means of a spirit-lamp. This plan is Reinsch's test; but unless quite pure copper be employed, the results are vitiated and valueless; for copper frequently contains a portion of arsenic, obtained from its ores. In a late case of suspected poisoning, the accidental discovery of the impurity of the copper, after the analysis had been effected, alone saved the condemnation and execution of the suspected individual.

Arsenic in solution may also be detected by liquid tests. That of nitrate of silver with ammonia, when the alkali is not in excess, affords a yellow precipitate; of sulphate of copper and ammonia, a rich green one; and a stream of sulphuretted hydrogen produces a yellow sulphide. These tests, however, are never relied on in accurate investigations.

The foregoing remarks and experiments will give our readers a general idea of the various methods employed to detect arsenic. We shall now direct attention to the usual *modus operandi* in post-mortem investigations, when death has been suspected to have arisen from the use or administration of arsenic as a poison.

Arsenic is generally taken in comparatively small quantities—*i. e.*, of a few grains only. It is not very soluble in water of the temperature of the stomach; but it must be borne in mind that the acids in the stomach greatly facilitate its solution. When taken in large doses, it produces vomiting, which relieves the stomach of a portion of the poison. An instance of this kind occurred in Glasgow some years ago, when not less than a quarter of an ounce of the poison was discovered in the stomach of the deceased person, who had been violently sick for some time before death. The symptoms of arsenical poisoning are, violent retching, heat in the throat and palate, a metallic taste in the mouth, and great irritability of the whole system. The face wears an anxious appearance; and, indeed, most of the symptoms produced by irritant poisons are manifested. It is of the utmost importance that medical aid should at once be secured; but in the absence of this, the only antidote which can be readily obtained, is that of the peroxide of iron. To obtain it, add carbonate of ammonia to the ordinary tincture of steel, as long as a powder is thrown down; and to save time, pour off the clear liquid, adding water to the powder; again pour off the liquid, and add sufficient water to allow of the powder being readily suspended in it. Stir it up, and administer a wine-glass full continually, taking care that as much as possible of the oxide be swallowed at each dose. Meanwhile medical aid may have been obtained, and the patient so left in experienced hands. When the remedy cannot be arrived at, every attempt should be made to make the patient vomit, so as to clear the stomach as much as possible of the poison. If such precautions be taken before inflammation commences, considerable chance exists of preventing a fatal termination, because, as we before remarked, the comparative insolubility of arsenic favours the chance of recovery.

When any suspicion of foul play exists, every drop thrown up from the stomach should be carefully preserved, and be left untouched until placed in competent hands for analysis. Many a life has been preserved through the over-cunning of criminals. A small dose of arsenic is far more likely to prove fatal than a large one, for reasons we have already assigned; but the non-success of one attempt by no means leads to the supposition that it will not be repeated. Therefore, if symptoms such as we have described have been noticed, and any suspicion exist, then the analysis of the ejected matter may, if it do not lead to detection, terrify by the discovery it affords.

In post-mortem examinations, much chemical skill is required; and we cannot but remark on the careless and loose manner with which such delicate operations are entrusted to what we may safely call unpractised and ignorant persons. The ordinary medical practitioner is often one whose education has been generally on each branch of the knowledge of his profession; and those of us who are acquainted with the course of chemistry through which most students pass in our hospitals and colleges, previously to passing their examination, would not trust to such the analysis of a piece of chalk. Chemical analysis requires, for its successful pursuit, a most extensive knowledge, a careful manipulation, and a delicately-balanced judgment—which nothing but years of practice can afford—when detection, in cases of poisoning, is required. Other qualifications are also requisite; for if a chemist be merely informed that death has been caused by *an* irritant poison—unless he have sufficient medical knowledge to enable him to anticipate his progress by an acquaintance with the symptoms, &c.,

he may grope long enough, and not only not succeed, but waste the preserved matter, and so prevent discovery or accurate analysis impossible. Two instances of this nature came under our notice some few years ago. In one case, it was suspected that wine, which had been partaken of by several persons, had accidentally been kept in a bottle which had contained poison. The analyst was a clever chemist, but no physiologist; he never asked respecting the symptoms which had exhibited themselves. The quantity of poison, whatever it was, was exceedingly minute; and, for want of a proper clue, he examined for antimony, corrosive sublimate, &c. We happened to suggest, that as it was wine, it was highly possible arsenic might have been communicated to the bottle by its having been cleaned with shot. We also learned that the usual symptoms of arsenical poisoning had been noticed, but in a mild form. On using Marsh's test, a minute quantity of arsenic was actually discovered. In this case, had the chemist possessed medical knowledge, he might have gone straight to his work.

The second instance to which we shall refer, was that of suspected poisoning by arsenic; in which the medical man was utterly deficient of all the capabilities of a chemical analyst. In attempting the analysis, the entire contents of the stomach, with itself, were put into an evaporating dish; heat was applied; and, for want of proper care and experience, the dish was cracked, and the whole of its contents lost. The fragments, however, were collected; and, in more experienced hands, afforded the evidence sought for.

We may, therefore, be permitted to urge on coroners and juries the necessity, in every case in which suspicion lurks, that all available material should be placed in competent hands only, lest that which is of value may be lost, or crude and indigested opinions be expressed, to the damage of the suspected one, or the defeat of the ends of justice.

The directions we are about to give, are simply intended to enable the tyro in chemical science to apply his knowledge in gaining an insight into the *modus operandi*. If he be desirous of repeating the experiments on animals, he will do best to choose rabbits for his purpose, because he will not have to experience that disgust which the analysis of the stomach of cats, dogs, &c., is apt to excite. An anatomist soon gets over all squeamishness in the matter, whilst a tyro has to overcome many offensive details.

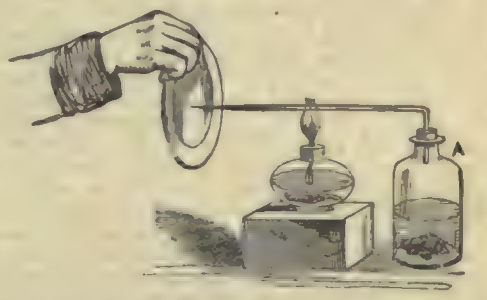
The belly of the poisoned animal is to be carefully opened by means of a sharp knife, or lancet; and the whole of the stomach, from the throat to the gut, removed, *unopened*—just as is done in trussing fowls. We shall be excused by our professional friends if we use unprofessional and plain language. The stomach, &c., is then to be placed in a clean dish, and divided lengthwise by means of the lancet, so as to expose the whole interior. This may be then carefully examined by means of a Stanhope lens, to detect the presence of any white powder. If such be present, remove all of it carefully with a *bone* spoon, or spatula, and wash it off carefully into a test-tube; put this aside for a time.

Supposing no powder to be seen—which will depend on the quantity of arsenic given, and the length of time which has elapsed from its administration—put the whole of the contents of the dish into an evaporating dish containing a little distilled water; and turning the stomach and gut inside out, wash them carefully for some time. This will wash or dissolve out all the unobserved powder, and that which has been dissolved or suspended in the food. Add to the mixture some strong acetic acid; and then cautiously evaporate the whole to dryness, taking care not to do so beyond what is absolutely necessary to ensure that all vapour is driven off. Allow the contents of the dish to cool, and then add some perfectly pure hydrochloric acid: great care must be taken in this respect; because all commercial acid contains arsenic, which would vitiate the result. Heat the acid with the contents of the dish for some time, adding more as evaporation proceeds; and after the lapse of half-an-hour, pour the liquid into a clean glass. By these means all the arsenious acid will have been converted into the chloride, and the solution will be free from organic matter. The rest of the process is very simple. Part of the solution may be boiled with some pure copper, according to Reinsch's plan, and the rest introduced into the hydrogen bottle, according to the method of Marsh. By means of either process, both of which we have already described, any arsenic present will be at once detected.

The powder previously removed into the test-tube may be heated with hydrochloric acid, and the same tests applied as above, when the results afforded will, of course, be the same, although more distinct in their indications.

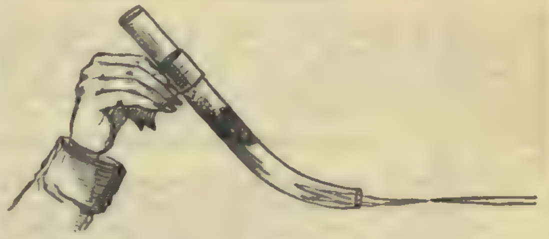
We have thus endeavoured to put the student into possession of what we consider to be the best mode of conducting an elementary analysis for the detection of arsenic. We need only add, that in this, as in all other chemical investigations, care and keen observation are eminently required. In analysing vomited matter, the practitioner must follow the same course; if, however, Marsh's test be adopted, care is required that the animal matter do not cause so much frothing up as to cast the contents out of the hydrogen bottle. This may partly be prevented by pouring a few drops of almond oil on the surface of the liquid in the bottle. It is an excellent plan to heat the tube through which the gas issues before reaching the jet. This is easily done by bending the tube in the manner shown in the following engraving

Fig. 68.



The flame may be received in a bent tube, as represented below, when the double layer of metallic arsenic, and the white arsenic, will be readily noticed.

Fig. 69.



We have already frequently noticed the combination of arsenic with copper, forming the pigment termed Scheele's green. The chloride has also been often mentioned in our previous remarks. The chief other compounds of the metal are those with sulphur; one of which, realgar, is an ore of the metal, of a red colour, containing one equivalent of arsenic to two of sulphur. The other is known by the name of orpiment; and it has a yellow colour.

Arsenic, like copper and iron, produces an acid bearing its name; its symbol is $As\,O_5$. It forms salts with bases; is a white substance; and yields a red precipitate with nitrate of silver alone; whilst arsenious acid requires the addition of ammonia. By this difference, with the colour of the precipitate, the two may be distinguished. Before concluding these remarks, we refer our readers to what we have stated in reference to the combination of antimony with hydrogen, as distinguishing it from that of arsenic with the same gas.*

MANGANESE.

This metal is never found in a native state; and its attraction for oxygen is so great, that it almost immediately passes into a state of oxide after its preparation. It may be obtained from its protoxide by fusing, on exposing the latter, with charcoal and borax, to an intense white heat. Metallic manganese, so produced, presents a similar appearance to cast-iron, which it resembles in many other respects. Its symbol is Mn; the equivalent, 27·5; and its specific gravity about 8.

As we have already stated, manganese readily unites with oxygen. The protoxide is to be obtained by passing hydrogen gas over the binoxide; and it forms salts with acids, of which the sulphate is best known. The most important oxide is that represented by the symbol MnO_2, which is largely employed in various ways. In the laboratory it is used as a source of oxygen gas; and chlorine is produced, by its aid, from common salt. In Glasgow, Manchester, and Newcastle, immense quantities of the peroxide are employed in the manufacture of chloride of lime; and it is also used in calico-printing, for the purpose of producing brown and black colours. Some of the salts of manganese have had similar applications to useful purposes; and common writing-inks have been made from them—the advantage in their use consisting in the fact, that the marks produced cannot be altered, but are rather deepened by age. Some proto-salts of manganese have been used as a test for the presence of ozone. For this purpose, manganic acid, MnO_3, in combination with potash, as the manganate of potash, has been proposed, which darkens to a purple tint as the permanganate, on exposure to air containing free ozone. The chief uses of the oxide of the metal, beyond those already indicated, are in connection with the manufacture of glass. If heated with oxide of iron during the melting of glass, it deoxidises that metal, and so diminishes the tint which oxide of iron affords. If heated in quantities, it affords a blue or amethyst tint; and for a similar object it has been employed in the production of artificial gems. The chief source of proto-salts is the carbonate, and in the manufacture of chloride of lime: this is produced by converting the sulphate into that salt, and thence obtaining the metal again in a state of peroxide. We have observed this process adopted only at the works of Messrs. Tennant, of Glasgow.

COBALT.

This metal is, except in its state of combination, little more than a chemical curiosity. It may be obtained by heating the oxalate with charcoal: when fused, it resembles a mass of cast-iron in many respects; and, amongst others, in that of being magnetic. Its equivalent is 29·5. Specific gravity a little over 8; and its symbol, Co.

In union with one equivalent of oxygen, it affords a protoxide, which may be obtained by adding a solution of potash to the sulphate, by which a hydrate is afforded of a fine blue colour. If chlorine be transmitted through water holding the protoxide in suspension, the sesqui-oxide (Co_2, O_3) is afforded.

The proto-chloride of cobalt has been employed as a sympathetic ink. Words written by means of a quill pen with this ink are almost invisible, or of a very slight pink colour, if the solution be dilute. If, however, the paper on which they are written be held near the fire, the writing will appear of a fine blue colour, which will vanish on the paper becoming cool. Landscapes painted with this and the chloride of copper, have a very pretty and interesting effect.

Nitrate of cobalt is chiefly used as a blow-pipe test, in which respect we shall have to speak hereafter of it.

The most important combination of cobalt, in a commercial point of view, is that with siliceous matter, which produces the substance called "smalts." This is obtained by roasting the ore, and subsequent fusion with sand and potash, by means of which a kind of glass is formed. This, in the state of fine powder, is employed by paper manufacturers, bleachers, and others, for the purpose of giving a blue tint to their goods. Oxide of cobalt is also employed in the manufacture of artificial gems, to which it imparts a blue colour.

CHROMIUM.

In its metallic state chromium is of no importance; but in combination with potash as a chromate, it is largely used for various purposes. The metal is obtained from its oxide by heating it with charcoal powder and oil, with which it is made into a paste. An intense heat reduces the metal, which then presents several of the characters of cast-iron. Its ore is a chromate of iron, found in many parts of Europe. Chromium has an equivalent of 26·7. Its specific gravity is nearly 6; and its symbol, Cr.

Chromium readily unites with oxygen, producing oxide and an acid. The protoxide is an unstable compound, passing rapidly to a greater state of oxidation. The sesqui-oxide has a green colour, and may be produced by heating chromate of potash, and passing over it a stream of chlorine gas, by which chloride of potassium and the sesqui-oxide are afforded. This substance, in union with iron, forms the chromate of that metal, and consequently the ore called chrome iron.

Chromic acid is the most important of the oxygen combinations. It results from a union of one equivalent of the metal with three of oxygen, CrO_3; and may be obtained from the bichromate of potash by means of sulphuric acid. The latter unites with the potash, setting the acid free, which has, like some of its salts, a rich ruby-red colour. Combined with potash it forms both the chromate and bichromate—the former affording lemon-coloured crystals, and the latter having a rich orange or red colour. The bichromate of potass is used by calico-printers and dyers; and chromate of lead affords the well-known pigment—chrome yellow. A higher state of oxidation affords perchromic acid, which, however, has not been completely investigated.

Chromium combines with chlorine, forming two chlorides. With oxygen and chlorine, chloro-chromic acid is produced. This may be obtained by fusing together common salt and bichromate of potash; and, by subsequently adding sulphuric acid, and distilling the mixture in a retort, the chloro-chromic acid passes over as a deep red-coloured liquid. The other compounds of chromium are of no special importance. The oxides are used to produce coloured glass; and by the union with potash and other alkalies, a kind of alum is produced, analogous to those afforded by alumina and the alkalies.

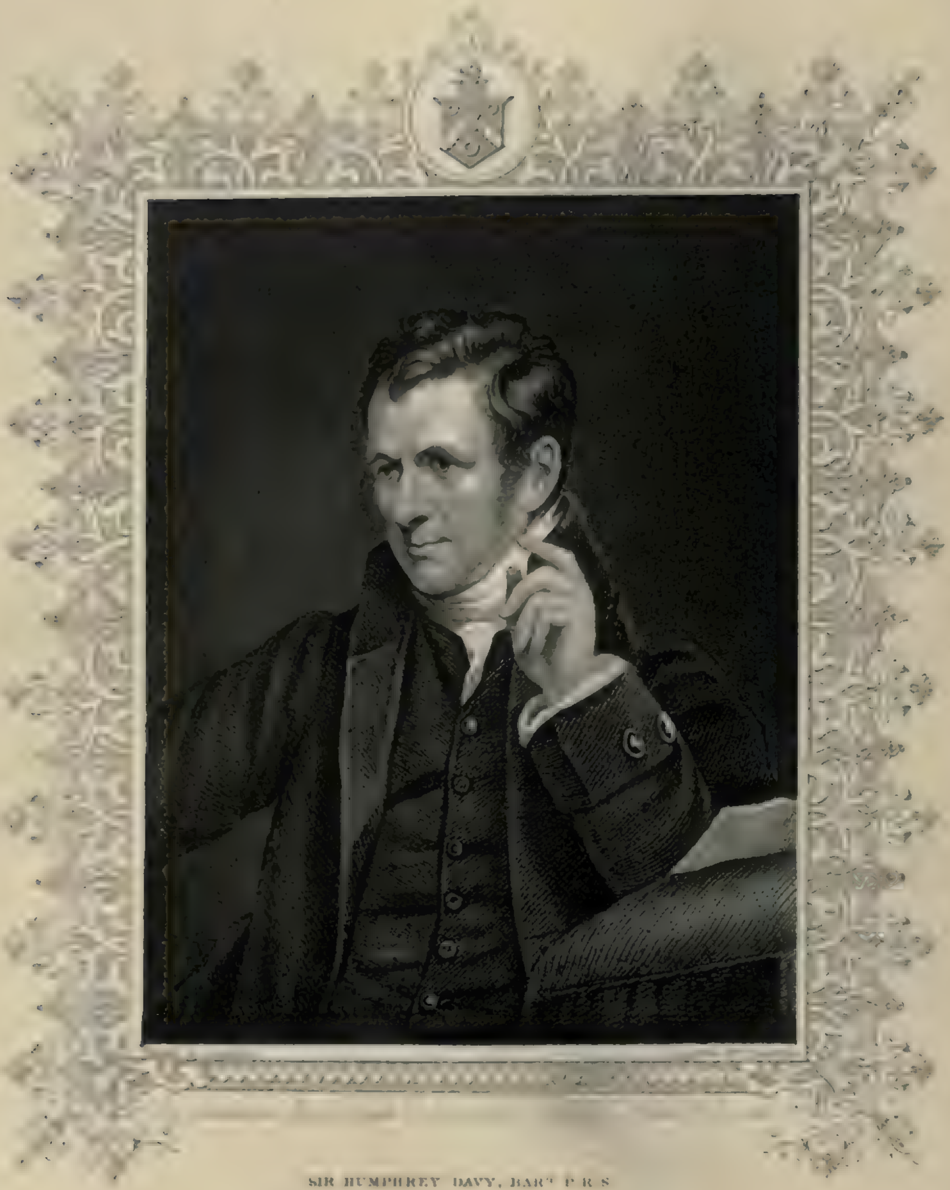
CADMIUM.

Our readers will have noticed that we have described each metal in the order of its comparative value and general importance; and this course has been chosen in the belief, that the general reader and the student would have their interest in our subject best maintained. We are now approaching that limit beyond which the natural history of the elements becomes a matter of importance to the experienced chemist only.

Cadmium generally occurs in combination with zinc, and, like that metal, is volatile. It is dissociated from zinc through its greater volatility; and its presence during the distillation of that metal, is evidenced by the production of a brown-coloured flame; that of zinc having a blue tint. Cadmium is somewhat like silver in appearance, but much softer, and is readily fusible. Its equivalent is 56: specific gravity, 8·6; and its symbol is Cd. Its combinations with oxygen and the salts produced from its protoxide, have no special application in the arts, &c., and are only of interest as the productions of an individual element.

---

* See *ante*, p. 381.



SIR HUMPHREY DAVY, BART. P.R.S.

Humphry Davy

[illegible]

OSMIUM, PALLADIUM, IRIDIUM, RHODIUM, AND RUTHENIUM.

THESE metals are found associated with platina. Osmium has a specific gravity of about 10: its equivalent is 99·6; and the symbol, Os. It somewhat resembles platina in appearance; with oxygen, it forms several compounds, amongst which is the osmic acid. This forms salts with bases, termed osmiates.

Palladium—symbol, Pd; equivalent, 53·3; specific gravity, 11·8—also resembles platina, but is soluble in nitric acid. Its other combinations are extremely analogous to those of platina. Its chief uses have been for purposes in which a freedom from ready oxidation is required; and it has lately been largely employed as a substitute for gold in fixing teeth, and in making artificial palates.

Iridium much resembles, in every respect, the metal platina. It combines with oxygen, chlorine, &c. Its chief use has been to form the points of steel pens, &c., for which purpose its extreme hardness renders it valuable. Rhodium and ruthenium much resemble platina in their properties. Rhodium has had a similar application to that we have named in respect to iridium.

VANADIUM, TUNGSTEN, MOLYBDENUM, URANIUM, ETC.

THESE metals are all so rare as to scarcely ever come under the observation of the chemist. Vanadium is found in combination with iron and lead, from which it is separated as vanadic acid. It combines, in various proportions, with oxygen, forming oxides; and with chlorine, two chlorides are producible.

Tungsten is obtained from a mineral called wolfram, and with oxygen produces a binoxide, and an acid called tungstic acid. A combination of this with soda, the tungstate of soda, has lately been highly recommended as a material by means of which ladies' cotton and other dresses may be rendered non-inflammable. We fear that its use in this respect is extremely limited, however valuable its properties may be.

Molybdenum is a white metal, forming oxides and the molybdic acid. This produces salts with bases. The metal is obtained from the native sulphide—a somewhat rare mineral.

Uranium is obtained from a mineral called pitchblende. It forms oxides, the chief use of which is that of colouring glass. The substance so formed has peculiar optical properties in reference to epipolic dispersion of light.

Titanium is obtained from a mineral called rutile. It combines with oxygen, producing oxides and the titanic acid. In some of its combinations it resembles the earth silica.

Tellurium may be termed a quasi metal. It resembles silver in colour, and with oxygen forms the telluric acid. Some analogy exists betwixt this element and selenium.

Our readers will find, in our list of the elements, many other substances belonging to the family of metals proper. Their properties are, however, so uncertain, and their interest so slight, as not to require any detailed notice. The two most interesting metallic elements lately discovered by means of the spectrum analysis of Messrs. Bunsen and Kirchoff, have been named cæsium and rubidium; but the quantities of these yet produced are so small as not to warrant any dependence on the characteristics they present.

KALIGENEOUS METALS, OR THOSE PRODUCING ALKALIES.—POTASSIUM.

FROM the barren waste of information presented by our limited knowledge of many of the elements we have just referred to, we turn with pleasure to the description of the alkaline metals, in which every interest of a scientific and social nature is involved. There are few substances more completely identified with our daily life, manufactures, domestic matters, &c., than the alkalies, potass and soda. All our cleansing, bleaching, and numerous other processes depend on their use. The production of soaps, candles, the purification of oils, the constitution of common salt, and many other products, are identified with them. And we therefore feel it necessary to give an extended notice both of their elements and their numerous combinations.

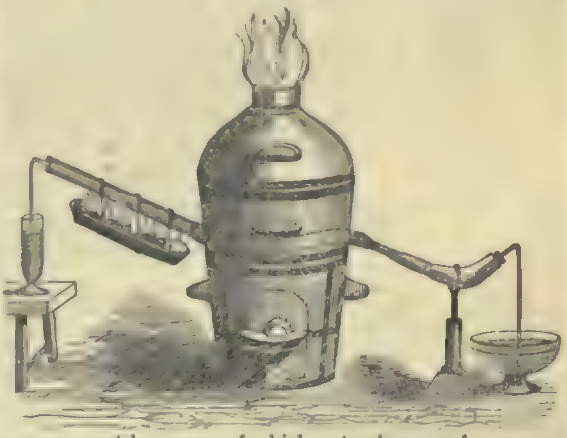
Perhaps no discovery ever made in chemical science, gave rise to such general excitement as that by which Sir Humphry Davy demonstrated that potash and soda contained metals as a constituent. We learn that all ranks crowded daily in the laboratory of the Royal Institution, to witness the new productions. Indeed, by means of these metals, our knowledge of the constitution of numerous other bodies has been largely extended. Each earth was successively examined; and as potassium and sodium have so great an affinity for oxygen, it is a matter of no surprise that this affinity was employed as a means of analysis, and that, too, with successful results. Perhaps the most surprising practical application of the discovery, has been that of an abundant production of a valuable and useful metal, in large quantities, from common clay, or other compounds of alumina. Chemistry is ever affording us surprising and unlooked-for results; and chemists, whilst constantly hoping for new discoveries, do not forget their duty to mankind at large, in applying for the benefit of mankind, in a useful form, that which, seen by the light of scientific research, is regarded by them with philosophical interest only. With these prefatory remarks, we shall now proceed to describe the character of the alkaline metals, commencing with potassium and its compounds.

POTASSIUM, as its name would imply, is obtained from potass. If a piece of fused potass be placed on some platina foil connected with a powerful voltaic battery, whilst a platina wire is brought into contact with the alkali, considerable effervescence will take place. Bright sparks will fly off; and if a little mercury be placed also in contact with the potass, it will form an amalgam with the potassium thus produced. The amalgam, if dropped into water, will decompose the liquid, owing to the associated potassium combining with the oxygen, and setting the hydrogen free.

By this mode of producing potassium, the voltaic current is employed to separate the oxygen from the metal; the oxide of potassium is thus decomposed, and the metal obtained in minute quantities.

Potassium, however, is readily procured in any quantity by means of the following process. The oxide of potassium, or potass, is first fused, and then allowed to run over iron-turnings heated to whiteness. These seize the oxygen of the potass, and the metal potassium is thus set free. The following engraving illustrates an arrangement by means of which potassium can be manufactured on the small scale. In the centre is a furnace,

Fig. 70.



containing an iron tube, filled with iron-turnings. On the left is another tube, holding the potass, which is fused by a small furnace hung beneath it. From this the fused potass runs on to the iron-turnings, when, being decomposed, the potassium is produced. This distils over, and falls into a basin holding naphtha free from oxygen. The tube, on the left-hand side, acts as a kind of safety-valve for the escape of vapour, and prevents any risk of accident in case the iron tube should become filled up.

There are other modes of making potassium on the large scale; but that we have described will acquaint our readers with the general principles of its manufacture.

Potassium has a specific gravity of ·86; its symbol is K (kalium); and its equivalent, 39·2. In its ordinary form, as sold at the shops, it is in the shape of peas, having, externally, a black appearance, owing to the decomposition of the naphtha in which it is preserved for the purpose of preventing its oxidation. If one of these globules be cut open, a shining metallic appearance is presented, which, however, is soon lost, owing to the action of the oxygen in the atmosphere. If a piece of potassium be cast on to water, that liquid is at once decomposed, and the liberated hydrogen combining with a portion of potassium in the form of potassiuretted hydrogen, catches fire. This fact was applied by Mr. Macintosh to the construction of a new kind of shell for warlike purposes. An ordinary bomb-shell was to be filled with any inflammable liquid, and at the opening a few small pieces of potassium were fixed. This shell, on being fired from a mortar and striking an object, would break, and its contents falling out, the potassium would inflame the liquid. A simple experiment, illustrating the principle, may be easily tried by filling a thin glass globe with ether, and dropping into it a pea of potassium. If the glass be then thrown into a vessel of water, so that it may be broken at its sides, the shell will break, and the potassium, coming in contact with the water, will at once inflame the ether. However ingenious this plan may be, the practical difficulties existing in its application have prevented its adoption. We need scarcely add that ether and potassium are articles scarcely fit to be entrusted in the hands of our sailors. Potassium fuses at a temperature of 150°, and may be distilled over like water, if out of contact with the atmosphere. It may also be, in one sense, welded together at common temperatures, as it has a kind of paste-like consistency.

Potass, potash, or pearlash, is an oxide of potassium (KO): the two latter names being applied to the article as found in commerce. It is produced as a hydrate when potassium is exposed to the action of the atmosphere. Commercially, it is obtained by burning various plants; hence its name of potash. The salts set free are then dissolved out by water, when the carbonate of potash, one of the products, is decomposed by boiling with lime. The latter seizes the carbonic acid, forming chalk, and the liquor is then concentrated in iron vessels, until a nearly solid substance is produced. The temperature being raised, the potass becomes fused, and is poured into moulds. In the ordinary state it is a rough mass; but as sold by the chemists, it is generally in the shape of small sticks, which, from their action on animals, are used as a caustic. Potash readily absorbs, in this state, both moisture and carbonic acid. As a liquid, it forms what is termed "oil of tartar."

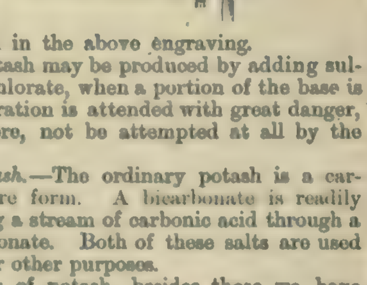
Potash is largely employed for various purposes. With oils it forms soft soaps. Its detergent properties make it of great value to the bleacher, the laundress, and others. A peroxide of potassium is produced when the metal is burned in oxygen gas.

Sulphur and potassium unite to form a sulphide, on potass being fused, together with sulphur. The various salts produced by the union of potass with acids require an individual notice, from their general importance.

There are two sulphates of potass. The sulphate is produced when sulphuric acid and potass, or almost any of its salts, are added together. It is a crystalline substance, and affords no acid reaction. The bisulphate is produced by heating the sulphate with sulphuric acid; by means of which an extra equivalent of acid is added to it. The nitrate of potash—common nitre, or saltpetre—is of great value; forming the chief ingredient of gunpowder. It is imported in large quantities from India; which, in fact, is the chief source of its supply. It is found on the surface of the earth; and results from the decomposition of animal matter. For the same reason it is always present in wells situated near a churchyard; and is the cause of the peculiar cooling taste water presents when obtained from such offensive and dangerous sources. Saltpetre requires refining before being employed in the gunpowder manufacture; and this is effected by means of repeated solution and crystallisation. In its purest form, nitre is found in beautiful six-sided crystals. When fused into balls, it affords the sal-prunella of the shops. Heated alone, it gives off oxygen and nitrogen; but in contact with carbonaceous matter, it affords its oxygen; and carbonic acid, and carbonate of potash, are the results of the combustion. Nitre is extensively used by firework-makers; it is an anti-septic, and may be used in curing meat; and for similar reasons it was employed by the Egyptians in the process of embalming.

Chlorate of Potash.—We shall describe this salt next to nitre, because in almost every respect it resembles that substance. It is produced by passing chlorine through a solution of potass, by which the chloric acid resulting unites with the base. The liquid is then crystallised, and the chlorate is afforded in small flat crystals. This salt has become of great importance in connection with the manufacture of lucifer-matches; and from being only a chemical curiosity, it is now an article of extensive manufacture. On being heated it affords pure oxygen gas. Carbonaceous matter mixed with it deflagrates with great violence. It was proposed to use it in place of nitre; but it so readily parts with its oxygen, and forms with sulphur so explosive a compound, as to present the greatest danger in such an attempt. A few grains of chlorate of potash in powder, mixed with sulphur, and rubbed in a mortar, or struck with a hammer, explode with great violence. If a little sugar and chlorate of potass be mixed together, they may be inflamed by means of a drop of sulphuric acid. And so readily does this salt promote combustion, that pieces of phosphorus in a glass of water, with a few of its crystals, may be inflamed under water. This experiment is best accomplished by pouring on to the crystals and phosphorus some strong sulphuric acid through a funnel, in the manner represented in the above engraving.

Fig. 71.



Perchlorate of potash may be produced by adding sulphuric acid to the chlorate, when a portion of the base is removed. The operation is attended with great danger, and should, therefore, not be attempted at all by the student.

Carbonate of Potash.—The ordinary potash is a carbonate in an impure form. A bicarbonate is readily produced by passing a stream of carbonic acid through a solution of the carbonate. Both of these salts are used in medicine, and for other purposes.

The combinations of potash, besides those we have named, are very numerous. The chloride of potassium is afforded when the chlorate of potass is heated until all its oxygen is driven off, when a white crystalline mass is left, which is very soluble in water—produces great cold during its solution, and is analogous to common salt. The iodide of potassium has been frequently named in our previous pages, especially in connection with photography; in which, also, the bromide is largely used. With tartaric acid, potash produces the ordinary bitartrate, or cream of tartar. With chromic acid, the chromate and bichromate are formed, of which we fully spoke under the head of Chromium. The acetate, oxalate, citrate, malate, prussiate, and numerous other salts, are produced by the union of potash with the respective acids. Were we to attempt to give a list of all the salts producible by the union of potass with acids, we should have to include the whole of the latter. All the combinations of potash are soluble in water; and hence they become of great value as tests in the laboratory. The carbonate is often employed as a flux, both for blow-pipe investigations, and for the analysis of siliceous matters. Potassium itself is largely employed as a deoxidising agent, owing to its powerful attraction for oxygen.

SODIUM.

In many respects sodium resembles the metal potassium. It is prepared in an exactly similar manner; the carbonate of soda, however, being used. Its specific gravity nearly equals that of water; its symbol is Na, and the equivalent 23. Sodium will not inflame if cast in cold water. If, however, hot water be used, or the metal be placed on a piece of wetted blotting or filtering-paper, it will decompose water, and afford a yellow flame. The production of this colour by salts of soda in flame, is a general characteristic of their presence.

Soda is the protoxide of sodium; and, as an article of manufacture, it is of great importance. The ordinary soda of commerce is a sub-carbonate, from which the hydrate may be obtained by boiling a solution of the salt with lime. The earth combines with the carbonic acid, and so leaves the soda itself in its caustic state.

Common salt is the source whence soda is manufactured. The salt is mixed with dilute sulphuric acid, which so forms the sulphate; the hydrochloric acid passing off in a gaseous state. The sulphate is then mixed with sawdust or small coal, and roasted for some time. By this the sulphur is deoxidised, and the sulphuric acid decomposed. An impure carbonate of soda is produced, which is purified by solution and crystallisation. Soda ash, as it is termed, is the same substance in the form of a powder. It, however, generally contains a less proportion of carbonic acid; approaching more nearly to a pure fused hydrate.

Soda is largely employed for numerous purposes. With oils, it forms ordinary hard soap—uniting with the stearine of the fat, and so producing a stearate of soda. The common yellow soap of commerce often contains resinous matter, which is used for the sake of cheapness. Mottled soap is produced by adding a small portion of copperas (sulphate of iron), by which the veins, noticed in that article, are obtained. The better kind of soaps, such as curd, &c., are made from mutton fat; and brown Windsor, and other scented preparations, are manufactured therefrom. In bleaching, soda is used to remove grease and resinous matters from the yarn and cloth; but of late years, lime has been substituted for it, as being a cheaper material. The domestic uses of soda we need not refer to.

Soda unites to form soluble salts with most of the acids; and the following are amongst the chief of its salts:—Sulphate of soda, formerly known as Glauber's salts, is easily prepared by adding sulphuric acid to any salt of soda. It is extremely soluble in water; and may be employed by the student in initiatory experiments on crystallisation. If this salt be dissolved in boiling-water to saturation, and the solution be put away to cool in a glass flask carefully corked up, it will not crystallise if kept quite still. The instant the cork is removed or a small piece of sand be dropped in, the whole liquid will shoot out into beautiful crystals, and be converted into a solid mass. If the external part of the vessel be held in the palm of the hand, a considerable evolution of heat will be also noticed.

Soda and sulphur unite to form sulphites and the hyposulphite. The latter salt has been extensively employed as a "fixing" agent by photographers; and is produced by heating the sulphate with sulphur. It is a crystalline body; and in a solution with water, readily dissolves oxide of silver—hence its employment in the way we have named. Nitrate of soda is prepared by adding nitric acid to any of the soda salts, with the exception of the sulphate. In its properties it greatly resembles nitre;* and, in fact, is sometimes employed as a substitute for that material, in the manufacture of gunpowder and fireworks, for which purpose it is largely imported into this country from India. Its natural production is due to the presence of decomposing animal matter, which affords the nitric acid of the salt.

Chloride of sodium is the well-known common salt. This substance abounds in nature; and is a constituent of sea and river water, in variable proportions. It is obtained from various sources—as the evaporation of sea-water. Our supplies for domestic use are drawn from the salt mines, of which the most notable are those of Cheshire, in England, and Cracow, on the continent. The rock-salt has a yellow or brownish colour, owing to the presence of oxide of iron. On being dissolved, however, this oxide falls down in an insoluble form. The liquor is then evaporated, and left to crystallise, when white salt, such as is used at our tables, is afforded. Pure chloride of sodium is obtained by adding hydrochloric acid to a solution of carbonate of soda.

Common salt seems to be essential to animal existence; for not only is it used as a condiment by man, but it is a great favourite with almost all animals, forming a constituent of their bodies. We may refer our readers for further information on this subject, to the remarks of Dr. Moleschott, at a previous page.†

We have already described the carbonate of soda, as obtained from common salt. In an impure form it is produced from the ashes of sea-plants; and, as such, is known as barilla in commerce. At one time, the only source of soda was that of burning sea-weed; and in many parts of the English and Scottish coasts, the names of small villages are derived from the "pans" in which the barilla, or kelp, was produced. If a stream of carbonic acid be passed through a solution of the carbonate, a bicarbonate is afforded, which is largely used as an antacid in medicine. A natural carbonate, containing two equivalents of soda to three of carbonic acid, is found in some places; but not in quantities to make it of much value as an article of commerce.

Borax, which is a biborate of soda, is largely imported from Tuscany, which affords a natural supply of boracic acid. This salt is much used by metallurgists and others, as a flux; and with many oxides it affords a glass. It is much used in the production of artificial gems.

With acetic, oxalic, and other vegetable acids, soda unites to form salts; but as these are of no special importance, we shall not further allude to them.

LITHIUM.

This metal, like potassium and sodium, may be obtained from its oxide by means of a powerful voltaic battery; and in its general characteristics it is much like them. Its equivalent is 6·5; the symbol, L; and its specific gravity much less than either of the alkaline metals. Its oxide, lithia, is analogous to soda and potass; and, like them, possesses alkaline properties. It is a constituent of the tourmaline and other minerals; and forms a link between the alkalies and earths. As, however, it is of great rarity, we shall not occupy any space in its consideration. We may observe, that Messrs. Bunsen and Kirchoff have discovered, by means of their spectrum analysis, a new element, which has been termed cæsium, in some of the compounds of lithia.

TERRIGENEOUS METALS, OR THOSE PRODUCING EARTHS.

Having described the properties of the metals proper, and of those producing alkalies, we shall now turn to a very interesting branch of chemical science, and proceed to describe those metals which, by oxidation, produce earths. Although the face of nature presents a most diversified appearance, from the barren rocks to the cultivated soil, still the number of earths is very limited; and taking the average of the soil, &c., of this kingdom, we do not find its essential ingredients to exceed three or four in number, of which silex, lime, and alumina are the chief. Of course, in minute quantities, many other substances are present, which are essential to the growth and existence of plants. Common clay is a mixture of alumina and oxide of iron. The sand of our hills and the sea-shore is composed of silicious matter, or pounded flint. Gravel is mostly composed of silex and oxide of iron, which gives it its colour. The chalk rocks, which abound in Kent and other places, are nearly pure carbonate of lime. Granite, felspar, quartz, &c., which form the primitive rocks, are chiefly composed of silex; whilst those of the secondary and other formations have alumina, silex, magnesia, and lime, in constantly varying proportions. The earths have been divided into classes; namely, earths proper, and alkaline earths; of the latter, are lime, magnesia, baryta, and strontia. To the general observer of nature, as well as to the geologist and chemist, the disintegration of the rocks, and the productions of soil, are matters of deep interest. The action of air and water gradually crumbling down the most solid mass; the first evidence of vegetable existence, as seen in the humble moss, which, whilst robbing the rock to supply itself with food, converts that rock from a barren waste to a fruitful soil; the liberation of the constituents of the rock, which afterwards afford nourishment to the grass and tree;—these and numerous other changes, gradually but constantly taking place, invest the study of the earths with the deepest interest. But we must reserve our remarks on this subject for that of Agricultural Chemistry, in which we may more properly dilate on the variety of changes which occur in the production of soil, plants, &c.; and we shall at once proceed to describe the earths, the metals, and compounds, together with their varied uses in commerce, medicine, and manufactures.

---

* See *ante*, p. 386.

† *Ante*, p. 354.

ALUMINIUM.

ONE of the greatest curiosities of modern times, is the production of a valuable metal from common clay, which, in its pure form, is simply an oxide of the metal aluminium, or, as it is also called, aluminum. Its discovery has resulted from those of Sir Humphry Davy, who, as we have already remarked, was the first to prove that the alkalies, potass, and soda are the oxides of metals. Aluminium has a specific gravity of 2·5; and is therefore of about the same as that of glass; its symbol is Al; and the equivalent = 13·7.

It is best produced by the process of M. St. Claire Deville, of Paris, to whom we are indebted for the commercial importance of the metal. A mineral called "cryolite" is its most convenient source; but the following plan may be adopted to procure it from clay:—This material, with sugar and charcoal, is to be made into a paste, which is then to be placed in a platina tube. The tube is to be heated in a convenient furnace to a red heat; and chlorine gas is passed over the paste. By these means the chloride of aluminium is produced through the following chemical change which takes place. The oxygen leaves the aluminium of the clay, and the chlorine takes its place; so that we find the chloride formed in place of the oxide. Now, as the chloride of the metal is very easily sublimated or removed by heat, it speedily passes away from the platina tube, and collects in a receiver placed at the other end of the tube, in the form of a primrose-coloured powder. Great care must be taken that the atmosphere has no access to the receiver, because the moisture it naturally contains would be absorbed by the salt-like substance, and such would be thereby rendered unfit for the purpose of obtaining the metal. The chloride thus produced is then heated with the metal sodium, by means of which the chlorine is taken from the aluminium, and combines with the sodium, forming common salt. The metal aluminium is then found at the bottom of the crucible, of a white colour, and having the appearance of silver: and in many of its qualities it is similar to that metal.

The first bar of aluminium which was exhibited in this country, was sent by the present Emperor of the French to the Polytechnic Institution, Regent-street, London; and it excited, at the time, the deepest interest in scientific circles. On the occasion of its first exhibition, many of the leading scientific celebrities of the kingdom were present; and Messrs. Hunt and Roskell, of Bond-street (her majesty's jewellers), kindly lent numerous specimens of emeralds, and other precious stones, for the purpose of elucidating the *rationale* of the process. We may here remark, that emeralds, rubies, garnets, and the corundum, with other gems, are largely composed of aluminium in the state of oxide—such as the pure alumina, of which we have been speaking.

Aluminium is susceptible of a high polish. It has naturally a whiter colour than pure silver; and whilst that metal soon tarnishes, or loses its polish when exposed to air containing sulphur, which invariably occurs in places wherein coal-gas is burned, aluminium retains its polish, because its affinity for sulphur is very slight. It is very ductile, and may therefore be drawn into a wire. It may also be easily beaten out into sheets or plates, and in that form may be employed for a vast variety of purposes. It has been made into brooches, spectacle-frames, helmets, spoons, chemical apparatus, and various other utensils; and, so far as we can judge, it promises to be of extreme value, generally speaking, in its employment for all purposes where freedom from action by chemical agents is required.

The sulphuric, nitric, and hydrochloric acids have but a slight, if any action on it. Indeed, in our own experiments we have found that its chief enemy (if we may so call it) is any kind of alkali, such as potass and soda.

If a bar of the metal be immersed in either of these alkalies, the water in which they are dissolved is at once decomposed, and hydrogen gas is given off. A jelly-like substance forms on the surface of the metal; and on chemical examination, such is found to be the hydrate of alumina. This, however, only occurs when the alkaline solution is very strong—a circumstance rarely, if ever, occurring in daily life.

It will thus be observed, that modern chemistry, although it does not turn whatever it touches literally into gold, yet it has the power of producing from the very dust which we shake off our feet, a metal valuable to us in the highest degree. It may be safely said of experimental science—

"Whatever it touches it adorns."

Give the chemist the refuse of our manufactures, and he will, by the potent aid of his art, almost create that which is truly valuable from that which appeared next akin to nothing. He calls out of the chaos of nature its most valued elements; and by the intelligence which he exercises, he invests with interest that which had been a matter of offence and repugnance.

Alumina is the only oxide of the metal; and it may be produced by adding a solution of carbonate of ammonia to one of common alum. The precipitate, when dried, affords a white powder, which is the earth alumina.

This substance, as found in the form of clay, is of great importance; and as such, is the material from which China, pottery, bricks, &c., are produced. The colour of clay varies considerably; the purest, or "kaolin," being nearly white. London clay has a slate or blue colour; whilst that from which the lower kinds of pots, pans, bricks, and tiles are produced, is of a brown tint before being heated, and attains a red colour after undergoing the process of baking.

The quality of whiteness, comparative transparency, &c., found in the highest kinds of porcelain, are due to the nature of the clay employed in the manufacture. With the kaolin, a quantity of flint, reduced to an impalpable powder, is mixed, so that an homogeneous paste is produced. This then undergoes the process of fashioning into the shape of the articles required; but as, in the process of baking, the material contracts nearly one-third in bulk, allowance is made in the size of the article as it leaves the hands of the potter. Of all implements of manufacture, the potter's wheel seems to have undergone the least alteration by the lapse of time; for, on comparing the instrument in use at the present day with those employed three thousand years ago, as illustrated in ancient drawings and sculpture, their identity is almost complete.

The process of firing or baking is one requiring the greatest care, because, if the material have been improperly mixed, the different parts will contract unequally, and the vessel will be destroyed. Each article, as it is produced by the potter, is removed to a kiln fitted with shelves, on which the vessels to be baked are arranged. A fire is then kindled in the centre of the kiln, and by it the mass of the articles is aggregated and made into a compact body. The vessels so baked are allowed to cool gradually, and so to assume their proper shape and consistency. In this state, however, they are porous, and unfit for domestic use. The next process, therefore, is that of glazing, by means of which the external surface is converted into a kind of glass. This is effected by washing the surfaces of the vessels by means of a mixture of powdered felspar, borax, &c., for the better class of goods, and of common salt for common goods. The articles are again removed to a kiln, and by means of an intense heat the surface is fused, and a glaze formed thereon. On cooling, the pottery is then ready for sale. If patterns such as we observe in china and plates, &c., be required, such are painted on before glazing; and in that process they are "burnt in" on the surface of the ware.

The preceding remarks afford a general insight into the manufacture of all kinds of ceramic ware. Our limits proscribe us from entering into minute details. Those of our readers who may be desirous of full information on the subject, and yet have not the opportunity of visiting a pottery, may trace every part of the process in the brick-field, which is a rough but accurate type of every class of the manufacture.

Alum.—Alumina, in combination with an alkali and sulphuric acid, gives rise to a series of compounds known in commerce as alums. The manufacture of alum is always carried on in close proximity to the place where the slate or suitable clay is found; and at Campsie and Hurlet, near Glasgow, immense quantities of the article are produced. The slate is first roasted, by which it is reduced into powder. Exposed to the atmosphere, a chemical decomposition ensues. Sulphuric acid is produced by the oxidation of the sulphide of iron, and so a sulphate of alumina is formed. Potash being added thereto, a double salt results, forming a sulphate of potash and alumina, which is the ordinary alum of commerce. Instead of potash, soda or ammonia may be substituted with a similar result.

The chief uses of alum are those in dyeing; for the alumina which it contains has the power of attracting the colouring matter of vegetable bodies. For this reason it has been termed a mordaunt. The principle of its employment for this purpose may be readily understood by adding an infusion of many vegetable colouring substances to one of alum, and on precipitating the alumina by means of an alkaline carbonate, a coloured precipitate will be produced. In the process of dyeing, the yarn or cloth is first steeped in a solution of alum, and subsequently boiled in one of the colouring matter, by means of which the colour is precipitated in a solid form, and fills up the minute tubes of which the fibres of cotton and wool are composed. Alum is also employed in medicine as an astringent. The other combinations of alumina do not require special notice.

SILICON.

We have placed this substance amongst those producing earths, rather as a matter of convenience—silica, its oxide, being one of the most common constituents of rocks and soils. It may be obtained from pure silex, which is a combination of silicon with oxygen, by heating the silex with the potassium. It is a powder of a dark-brown colour, and, in some respects, is more analogous to carbon than to the metals. Its symbol is Si, and its equivalent 21·3.

Silica, silex, or silicic acid, is found in its purest state as rock-crystal; it is also the chief constituent of common flints, and of the sand of the sea-shore, &c. It is composed of one equivalent of silicon with three of oxygen, $Si\,O_3$. It may be prepared artificially by fusing sand with four times its weight of carbonate of soda: the product is afterwards to be dissolved in water and hydrochloric acid, and the solution is evaporated to dryness, when a white insoluble powder is afforded, which is the silica. It has a gritty feeling in the mouth, and is hard to the touch. Silica, in a crystallised state, is often to be noticed on the outside of some kinds of grasses. A chloride of silicon may be produced by similar means mentioned for obtaining chloride of aluminium, silicon being substituted for silica in the process. Silicic acid unites with soda, &c., to form silicates; and, by such means, a soluble glass is formed, which has been much used as a preparation for coating stone liable to decay by atmospheric influences. The application of silica promises to be of great importance; and it has been proposed to arrest the progress of decomposition now going on in the stone used in building the Houses of Parliament, which is rapidly being disintegrated by a variety of causes.

The most important use of silica, in a commercial point of view, is that of the manufacture of glass of all kinds, of which it is an essential ingredient. For this purpose, sand is fused with soda, together with a little oxide of lead, to give it fusibility. The "metal," as it is called, is kept in a state of fusion for some hours, until all the ingredients are completely mixed. The colour of glass varies, and has a greenish tint if oxide of iron be present. Coloured glass is produced by burning various metallic oxides into ordinary glass at a high temperature. The oxides used for this purpose have already been named in our previous pages, under the heads of their individual metals. (See Iron, Copper, Cobalt, Chromium, Manganese, &c.) If a proper proportion of alkali be employed, ordinary glass is unacted on by air and moisture. The lapse of time, however, indicates that a very slight action takes place on most kinds of glass, although the progress is very slow. Artificial gems are produced by melting together metallic oxides, silica, and alkalies; and to so great a perfection has this art arrived, that some productions of this kind almost equal the true stone in their beauty of colour and other qualities. Hydro-fluoric acid is the only one in which silica is soluble, and it is accordingly employed in etching on glass surfaces.

CALCIUM.

This metal, which is at present very rarely obtained, may be produced by heating lime with potassium or sodium. Its equivalent is 20, and the symbol Ca. It is highly possible that if the attention of chemists were turned to its production in quantities, another valuable addition would be made to our stock of useful metals. The general properties of calcium are but little known.

The well-known earth, lime, is an oxide of the metal, $Ca\,O$; and it may be obtained by heating chalk (its carbonate) to redness in an open vessel. By this, the carbonic acid is driven off: access of air is required, because the gas is liable to form a heavy superstratum if the operation be carried on in a closed vessel. On the large scale, lime is produced by burning chalk or limestone in a kiln. Soft and hard lime are respectively produced by the use of these two materials.

Lime is used for a great variety of purposes. With sand, it forms mortar, after being slaked; during which process, a great amount of heat is set free; sufficient, indeed, to set fire to wood. It frequently happens that wooden stores, sheds, carts, &c., are set fire to when a shower of rain falls on lime stored in them. The value of lime in mortar, consists in the fact that it gradually becomes a compact solid, by the absorption of carbonic acid from the air, for which it has a great attraction. It is used by bleachers as a cheap detergent; and candle-makers employ it to saponify tallow in the process of the stearine manufacture. It is an essential constituent of all soils; and is found in almost every vegetable and animal, in the form of either sulphate, carbonate, or phosphate. In the process of tanning, it is used to remove hair from the skins; and in solution as lime-water, is a useful depiliatory for removing superfluous hairs from the head and face.

Chloride of lime, so called, is produced by passing chlorine gas over slaked lime, by means of which the gas unites with the earth, to form what is termed a hypochlorite. The manufacture of this substance is carried on to a large extent for the use of bleachers; and perhaps no chemical product is of more value to us, in a social point of view, than this substance. By means of its solution in water, as much cotton yarn or cloth can be bleached in a few hours, as would have required weeks under the old system of bleaching in the air. The process is conducted as follows:—The yarn is first boiled in lime and water, to remove grease, resin, &c., and then immersed in dilute sulphuric acid, to dissolve out the oxide of iron usually present. It is then immersed in a tepid solution of chloride of lime; and having been taken out and drained, it is dipped into a trough containing acid and water, which sets free the chlorine. After being washed in abundance of water, the yarn is then dried; and will have acquired a perfectly white colour during the process. Chloride of lime is much used also as a disinfectant, for which it is extremely valuable.

Lime unites with chlorine, forming the chloride of calcium. This substance is much used in chemical laboratories to absorb moisture. It is prepared by saturating hydrochloric acid with lime; and after evaporating the water as far as possible, the crystals are fused in a crucible. The chloride must be preserved from contact with the atmosphere, or it will speedily become liquid from the absorption of water.

Fluorine and lime unite to form a fluoride, of which a well-known mineral, fluor spar, is composed. This is the chief source of fluorine and hydro-fluoric acid. The phosphide of lime has been already described, under the head of Phosphorus.*

Sulphate of lime forms the well-known plaster of Paris. It may be prepared by adding sulphuric acid to the carbonate; but, on the large scale, it is produced by burning the crystallised form of the salt, called gypsum. Its uses are numerous; amongst which, the most important are that of producing a cement, and for making casts, statues, &c. It has a great attraction for water, and so becomes solid on being mixed with that liquid; hence its employment for the purposes we have referred to. Crystals of the sulphate abound in London clay, wherein they may be readily distinguished by their glistening appearance.

Carbonic acid and lime unite to form the carbonate, which abounds in some parts of the world as chalk and limestone. Chalk is the source whence lime is obtained; and both are much used as a dressing for land. Carbonate of lime is found in both the vegetable and animal kingdoms in abundance. Although insoluble in pure water, it is readily dissolved by water holding carbonic acid in solution. It is the chief cause of the hardness of water; but it may be removed by adding lime-water, which precipitates the lime in solution as bicarbonate, by seizing its carbonic acid. Dr. Clarke, of Aberdeen, very ingeniously proposed to apply this process for rendering hard water soft; and it has been long in use at Charlton, near Woolwich, where, owing to the water being obtained from the chalk hills, the water is very hard. On boiling water containing chalk in solution, the latter is deposited; hence the cause of the fur in tea-kettles and steam-boilers. Stalactites are formed by the dripping of water charged with the bicarbonate of lime, through crevices in caves, &c., of which there are numerous instances in Derbyshire. The doubly refracting Iceland spar, and the beautiful mineral Arragonite, are both carbonates of lime. These may be generally found in the crevices of limestone rocks; and are produced by crystallisation of the soluble carbonate, as it trickles down their surface. Marble is a carbonate of lime which has undergone fusion. If chalk be rammed into a gun-barrel, and then exposed to an intense heat in a smith's forge, it will present, on cooling, the appearance of marble. When pure, that substance is of a white crystalline texture; and the black or coloured veins in it are produced by the presence of metallic oxides, especially that of iron.

Some of the most important salts of lime are the phosphates. They form, as we have frequently remarked, an essential constituent of bone. The super-phosphate, so called in commerce, is produced by adding sulphuric acid to calcined bones, when sulphate of lime is also afforded. This is a valuable manure, and as such, is highly prized by farmers. Guano, and all animal excrementitious substances contain it in considerable quantities. A phosphate may be readily produced by adding phosphate of soda to the chloride of calcium in solution.

In medicine, lime, as a carbonate, the creta preparata of the shops, is used as an antacid, which is also an excellent dentifrice. It is an essential ingredient in sea-water; hence the large quantities of chalk contained in sea-shells. The eggs of all birds are chiefly composed of it and albumen; and it is a singular fact, that pod-bearing vegetables bear no fruit in its absence; whilst in the animal kingdom, birds will lay eggs without shells if deprived of its use.

MAGNESIUM.

THIS metal forms the basis of the well-known earth magnesia. It is obtained by heating potassium and the chloride of magnesium together, in a test-tube or crucible. At the moment that decomposition takes place, both light and heat are evolved, and the metal magnesium is set free. It has an appearance similar to silver; its symbol is Mg, and its equivalent 12·2. Magnesia is an oxide of the metal; and is a somewhat abundant earth. It is a constituent of many rocks, especially of the magnesian limestone. Sea-shells also contain it; and as a chloride it is found in the water of the ocean. In its pure state it is a white powder, scarcely soluble in water, and belongs to the alkaline earths. Its chief salts are the sulphate and carbonate.

The sulphate is the well-known Epsom salts, so largely employed in medicine. It is a constituent of many mineral waters, and derives its name from the town of Epsom, in the wells near which it is found. It is obtained by digesting sulphuric acid with magnesian limestone; the solution being afterwards crystallised.

The carbonate of magnesia, also used in medicine as an antacid, is found abundantly in a native state, combined with lime. The rocks formed of these materials are termed dolomite; and they are extensively used for building purposes; the new Houses of Parliament, and many other public buildings in London, &c., being constructed of it. When first precipitated, the carbonate is a bulky white powder, which, on being heated, contracts considerably. The two kinds are sold in the shops as light and heavy magnesia. It is soluble in excess of carbonic acid; and in that way can be obtained in crystals. Murray's fluid magnesia is prepared by dissolving the carbonate in water containing carbonic acid in solution.

The chloride is produced by adding hydrochloric acid to the carbonate; or, still better, by the addition of sal-ammoniac to this solution; when, after evaporation, it is to be fused. It must be preserved from access to air, as it is highly deliquescent. As we before mentioned, the metal is obtained from this substance.

Magnesia combines with nitric acid, forming a nitrate; and with ammonia and phosphoric acid, it produces a double salt, scarcely soluble in water.

---

* *See ante*, p. 371.

Neither magnesia nor its salts have any application to the arts or manufactures; and their uses are almost entirely confined to medicinal purposes.

BARIUM.

THIS metal is obtained by the action of potassium on baryta, its oxide, and presents a similar appearance to those obtained from other earths. Its symbol is Ba, and the equivalent equals 68·5.

Baryta derives its name from its great specific gravity, being the heaviest of the earths. It is the protoxide of the metal, and may be obtained by heating the carbonate to redness, when a grayish-white powder is produced, much resembling lime in its leading properties. In the state of a hydrate, baryta may be crystallised; it has an alkaline reaction on test-papers, and is highly poisonous.

The sulphate of baryta, or heavy spar, is found in many places. It may be prepared artificially, by adding sulphuric acid or a sulphate to any soluble salt of baryta; and the affinity between the base and acid is such, that baryta can separate sulphuric acid from any of its salts in solution. Baryta salts are, in fact, the usual tests employed in the laboratory for the presence of that acid. The nitrate is easily obtained by dissolving the native carbonate in nitric acid; and it is used as a reagent. If dissolved in alcohol, it gives a rich green flame on ignition of the spirit. It is largely employed by firework-makers as an ingredient in green fire. The chloride, which is also a useful test, is readily produced by the solution of the carbonate in hydrochloric acid, from which the salt, in a crystallised state, is readily obtained.

A peroxide of baryta is an interesting compound, from the fact that it enables us to procure a peroxide of hydrogen. It is produced by heating caustic baryta in oxygen gas, at a temperature a little short of a red heat.

STRONTIUM.

THIS metal, like barium, is, at present, only obtainable in minute quantities, either by voltaic action as an amalgam, or by the action of heat and potassium on strontia. It has similar properties to barium; its equivalent is 43·8, and the symbol, Sr.

Strontia is obtained by heating the carbonate, which is a somewhat abundant mineral, found at Strontian, in Scotland. It has an alkaline action on test-papers, and is soluble in water, from which it may be obtained as a crystalline hydrate. Native sulphate of strontia is termed celestine, and is found in some of the northern counties of England and Scotland in a crystalline state, some of the specimens presenting a beautiful appearance. The nitrate is produced by dissolving the carbonate in nitric acid. This salt affords a fine deep-red flame when burned with spirits of wine, and is used in the manufacture of fireworks to produce coloured fire, &c., which affords a splendid deep-red colour. The carbonate, as we have remarked, is found in a natural state. It may be produced artificially, for laboratory uses, by exposing the hydrate to the action of carbonic acid. The chloride and other salts are producible by means similar to those for making barytic salts.

It only remains for us to mention, that there are four earths very rarely met with, which complete the list of that class of bodies. They are Thorina, Yttria, Glucina, and Zirconia. Thorina is obtained from the mineral called Thorite. Yttria from Gadolonite, &c. Zirconia from Zircons; and Glûcina from a few minerals, amongst which the emerald is the chief. The properties of these earths generally agree with those of alumina or other earths already described; but as they have been scarcely investigated, any description of their individual properties is almost impossible. They respectively afford metallic bases analogous to those of earths generally.

TESTS FOR METALS, ETC.

IN our previous pages we have described the leading properties of metals proper, alkaline, and earth-producing metals; and we shall presume that our readers have become well acquainted with their individual characteristics. We shall now proceed to mention the usual mode of detecting the presence of the leading metals and their compounds. This will serve the double purpose of teaching the art of testing and of giving exercises, by means of which the student may become practically acquainted with the various states and conditions in which metals and their oxides are met with in nature, or in the course of laboratory practice. We shall resume the plan of experiments, and point out the various tests, and the mode of using them in the manner adopted by analytical chemists. Our readers, by trying the following experiments, will thus obtain an insight into the methods of inorganic and organic analysis, on which we shall have to dilate hereafter.

The object of a test is to discover, by the addition of one body to another, the presence of that which is being sought for; and our article on Arsenic illustrates one application of this fact. To apply the proper test in any case requires that we should be fully acquainted with the properties of the test, and also of the substance tested; and nearly every substance so employed has already been fully described. If our readers, therefore, have any difficulty in this respect, they need only refer to the substances named under the heads of the respective metals, when they will at once obtain the required information.

The state of solution, if not always necessary, is, at all events, the most convenient for the purposes of testing. The particles of a body are then in the most favourable condition to obey the laws of chemical affinity. Being suspended in a fluid, they are easily moved; and so, whether remaining in solution or precipitated as a powder, they are at once under our command. For the following experiments a number of test-tubes, Florence flasks, some filtering paper, a funnel, stirrers, &c., are required. We may also notice, that in many cases slips of window-glass, or white plates, will answer every purpose; for on either of these the peculiar and distinctive colour, &c., produced by a test, are readily observed.

To assist our readers, we shall give a list of a few tests which will be needed; and shall also refer to the page in which they have already been mentioned. With the exception of the acids, all the tests should be dissolved in *distilled* water, and kept in glass-stoppered bottles. Besides the sulphuric, nitric, and hydrochloric acids, the following are the chief tests:—

Hydro-sulphuric acid	See p.	370.
Hydro-sulphate of ammonia	,,	370.
Caustic potass	,,	386.
Carbonate of potass	,,	386.
Prussiate ,, ,,	,,	378.
Caustic soda	,,	387.
Carbonate of soda	,,	387.
Chloride of sodium	,,	387.
Sulphate of iron	,,	377.
Liquid ammonia	,,	324.
Carbonate of ammonia	,,	324.
Chloride of barium	,,	391.
Nitrate of baryta	,,	391.
,, ,, silver	,,	374.
Sulphate of soda	,,	387.
Chloride of platina	,,	372.
Chromate of potass	,,	384.
Nitrate of cobalt	,,	384.
Iodide of potassium	,,	386.

Besides the above, a few slips of copper, zinc, and iron, and some litmus and turmeric paper should be provided.

We shall now show how these tests are employed; first giving some introductory experiments to initiate our readers, before we proceed to give separate tests for each metal.

Experiment 68.—Dissolve a crystal of the proto-sulphate of iron in distilled water; and divide the solution into three test-tubes. Into one pour a few drops of a solution of the prussiate of potass; a blue precipitate will be produced.

Experiment 69.—Into another of the test-tubes pour a few drops of tincture of galls, which is sold by all chemists and druggists; a black colour will be afforded.

Experiment 70.—Into another test-tube drop some solution of carbonate of soda; a dark-green precipitate will fall down, which, on being exposed to the air, will turn to a red colour.

It follows, from the above experiments, that the presence of iron may be detected by three methods; each test employed affording a different result. We have chosen iron as the subject of our illustration, because the characteristics of its presence are so easily noticed.

But such is not the case with many other substances. For instance, white powders or precipitates are thrown down from many solutions; and to distinguish between them is by no means easy. Each precipitate, however, has a distinctive character, as the following experiments will prove.

Experiment 71.—Add together, in a test-tube, solutions of common salt and nitrate of silver. It will be noticed that the white precipitate has a peculiar appearance, like curdled milk.

Experiment 72.—Add a little solution of chloride of barium to one of sulphate of soda. A white precipitate will be produced in a pulverulent form.

Now these two precipitates, although both white, are readily distinguished by their physical appearance; and may be still more so by the action of light; for if that of the silver be exposed to the rays of the sun, it will turn black, whilst the precipitate of sulphate of baryta, in the last experiment, will maintain its white appearance.

In precipitates which are coloured, very little difficulty exists, as the colours vary so considerably. But in some cases great caution is required in the amount of test which is used; because an excess will not only re-dissolve a precipitate, but will even prevent its production. Of this the following are two instances:—

Experiment 73.—Add a *little* soda-water to some lime-water. Carbonate of lime will be thrown down. Afterwards add soda-water in abundance, when the *excess* of carbonic acid will at once re-dissolve the precipitate.*

Experiment 74.—To a solution of corrosive sublimate, add a few drops of one of iodide of potassium. A yellow precipitate will be afforded. Add still more of the iodide, when the biniodide of mercury, which has a red colour, will be produced. Afterwards add the iodide of potassium in excess, and the precipitate will be entirely dissolved. A few drops of the corrosive sublimate being added to the liquid, will first produce a red, and then a yellow iodide, which would be again dissolved by an excess of the iodide of potassium.

These experiments will impress on the mind of the student the necessity of caution and care in testing; and will, we trust, correct the almost invariable practice of the tyro in using *large* quantities of any test.

We may now show how accidental circumstances will often cause considerable difficulty to the careless or ignorant person; and even experienced chemists may, through the neglect of proper precautions, be led into error. Not only is it required that proper tests be employed, but that they should also be perfectly pure, and free from all foreign matter.

Experiment 75.—Dissolve a little nitrate of silver in distilled water, so as to obtain a perfectly transparent solution. Fill a test-tube with distilled, and another with river-water; and to each add a few drops of the solution of the silver salt. The distilled water will afford no change, but the river-water will give an opal-coloured precipitate, owing to the presence of common salt and other chlorides.

We may here remark on the necessity of great cleanliness in all vessels used for testing purposes. In long laboratory experience, we have noticed numerous failures occurring to young analysts through neglect in this respect. In very accurate experiments, test-glasses, &c., should invariably be washed by distilled water, lest some of the salts contained in common water should remain on the surface after washing.

Occasionally precipitates do not readily exhibit themselves, as may be seen in the following experiment:—

Experiment 76.—Add a little tartaric acid to a solution of carbonate of potass, in a test-tube perfectly free from scratches, &c., on the glass surface. No precipitate will be noticed. Now rub the surface of the glass by means of a stirrer, or rough substance of any kind. A precipitate, composed of minute crystals, will soon be produced, owing to an angular surface, which is favourable to crystallisation being carried on.

Occasionally chemical changes soon take place in substances kept as tests. An instance of this may be found in the solution of iron; for if the proto-sulphate, in a pure state, be tested by means of prussiate of potass, a light greyish-blue precipitate will be produced. If, however, the solution of the iron-salt has been kept for any length of time in a bottle *half filled* with it, the oxygen of the air in the bottle will have converted the protoxide into the peroxide; and the precipitate, by means of the prussiate of potash, will have a dark-blue colour.

Many metallic oxides, &c., may be readily distinguished by the colour which they afford to flame; of which the following are instances:—

Experiment 77.—Dissolve common salt in spirits of wine, and ignite the solution; a yellow flame will be afforded.

Experiment 78.—Dissolve in the same way, separately, the nitrates of baryta and strontia. These will afford, respectively, a green and red flame.

In using the blow-pipe, these indications are of extreme importance, and are relied on by the chemist when minute quantities of bodies alone can be obtained.

Hydro-sulphuric acid, and hydro-sulphate of ammonia, are much employed as tests for metals. Either may be produced by the methods described at a previous page;† and the study of their indications will be of the utmost importance to the student, and absolutely necessary before he commences a course of analytical chemistry.

The solution of many metals may be decomposed, and the metal set free by immersing slips of other metals; of which the following afford instances:—

Experiment 79.—Immerse a piece of silver foil in a solution of chloride of platina. The latter metal will be deposited on the silver as a black powder.

Experiment 80.—Into a solution of nitrate of silver, introduce a piece of polished copper, when the silver will be at once reduced to a metallic state.

Experiment 81.—Dip a piece of clean iron into a solution of sulphate of copper. The latter metal will be at once precipitated on the iron as a brown powder, which consists of pure copper.

The foregoing experiments will familiarise the minds of our readers with the general principles which must be followed in examining the characteristics of metals, &c., by testing. For the methods of bringing them into solution, our previous observations and instructions, under their separate heads, must be followed; and we strongly advise all who are desirous of acquiring and maintaining the knowledge of the properties of metals, to keep the precipitates produced in the experiments by them in a dry state. Such should be put into corked test-tubes, and properly labelled, with the name in full, together with the symbol showing their constitution. By such an arrangement, the results of previous investigations are kept ready for reference; and in the course of further investigations, many difficulties may thereby be avoided. In our earlier days, in chemical study, we adopted this plan; and in subsequent investigations of a more scientific nature, have often arrived at speedy conclusions; whilst our companions had to refer to half-a-dozen books for descriptions, in print, of what they ought to have had visibly before them. Of course, when a person becomes experienced, such aids are unnecessary, but never useless. Our remarks have still more force when applied to crystalline substances, in which the external form varies so greatly.

We shall now proceed to point out the various tests which may be applied for each metal; and which our readers should employ, if they would obtain an extended and practical knowledge of chemical science. Of all branches of science, that of chemistry is essentially experimental.

---

* See *ante*, p. 390.

† See *ante*, p. 370.

Platina.—A full description of the leading properties of this metal has been given at page 372. The following are tests for its presence in solution:—

Solution Tested.	Test.	Results.
Bichloride	Silver plate	Black powder.
—	Sal-ammoniac..........	Yellow crystalline precipitate.
—	Hydro-sulphuric acid	Black sulphide.
—	Hydro-sulphate of ammonia	Do.

Gold.—See p. 372.

Chloride	Proto-sulphate of iron	Metallic gold.
—	Proto-chloride of tin..	Purple powder.
—	Hydro-sulphuric acid	Black sulphide.
—	Hydro-sulphate of ammonia	Do.

Silver.—See p. 373.

Nitrate............	Copper plate..........	Metallic silver.
—	Common salt.........	A white curdy precipitate, which turns black on exposure to light.
—	Iodide of potassium..	Yellow powder.
—	Hydro-sulphuric acid	Black sulphide.
—	Hydro-sulphate of ammonia	Do.
—	Potass, ammonia, soda, lime, &c. ...	Brown oxide.
—	Cyanide of potassium	White powder.

Mercury.—See p. 374.

Chloride, Corrosive sublimate, or other soluble salt.........	Iodide of potassium..	Yellow powder.
—	Do. in excess......	Red do., eventually re-dissolved.
—	Alkalies................	Black oxide.
—	Hydro-sulphuric acid, hydro-sulphate of ammonia	Black sulphide.
—	Plate of copper or zinc	Metallic mercury.

Copper.—See p. 376.

Sulphate, &c. ...	Potass	Blue powder.
—	Ammonia............	Do., which re-dissolves in excess of the test, affording a deep-blue colour.
—	Hydro-sulphuric acid and hydro-sulphate of ammonia	Brown-black sulphide.
—	Iron or zinc plate.....	Metallic copper.
—	Prussiate of potass....	Red-brown powder.

Iron.—See p. 376.

Proto-sulphate, &c.	Ferro-cyanide of potassium	Light-blue precipitate, which speedily darkens.
Per-salts	Do.	Dark-blue precipitate.
Proto-salts	Ferri-cyanide of potassium	Deep-blue precipitate.
Per-salts	Do.	No precipitate, but a red-coloured liquid.
Proto-salts	Alkalies................	Green powder, turning to red.
Per-salts	Do.	Red oxide.
—	Sulpho-cyanide of potassium...........	Blood-red liquid.

Lead.—See p. 378.

Solution Tested.	Test.	Results.
Soluble salts.....	Hydro-sulphuric acid, hydro-sulphate of ammonia	Blackish-brown sulphide.
—	Chromate of potass...	Yellow chromate.
—	Alkalies................	White precipitate.
—	Hydrochloric acid and chlorides	White chloride.
Soluble salts.....	Sulphuric acid and sulphates	White sulphate.
—	Iodide of potassium..	Yellow iodide.
Acetate...........	Metallic zinc..........	Metallic lead.

Zinc.—See p. 379.

Soluble salts	Hydro-sulphuric acid, and hydro-sulphate of ammonia	White sulphide.
—	Alkalies.................	White oxide.
—	Carbonates of alkalies	Do.—That in excess of ammonia is redissolved.

Tin.—See p. 380.

Soluble salts.....	Hydro-sulphuric acid, and hydro-sulphate of ammonia.........	Yellow or brown sulphide.
—	Alkalies.................	White oxide.
—	Chloride of gold......	Purple powder (See *Gold.*)
Per-salts	Metallic zinc..........	Metallic tin.

Nickel.—See p. 380.

Soluble salts ...	Hydro-sulphate of ammonia	Black sulphide.
—	Hydro-sulphuric acid	No precipitate.
—	Potass, &c............	Green oxide.
—	Cyanide of potassium	Do. cyanide.

Bismuth.—See p. 380.

Soluble salts ...	Hydro-sulphuric acid, and hydro-sulphate of ammonia	Black sulphide.
—	Alkalies	White oxide.
—	Chromate of potass...	Yellow chromate, soluble in nitric acid, by which it differs from chromate of lead.

Antimony.—See p. 380.

Soluble salts ...	Hydro-sulphuric acid	Red sulphide.
—	Hydro-sulphate of ammonia	Red sulphide soluble in excess.
—	Alkalies	White oxide.
—	Metallic zinc	Metallic antimony as a black powder.

(See remarks as to antimoniuretted hydrogen, at p. 381.)

Arsenic—Arsenious Acid.—The student is referred to our extended remarks on the detection of arsenic, at p. 381, *et seq.*; in which full information on the various tests usually employed is given.

Manganese.—See p. 384.

Solution Tested.	Test.	Results.
Soluble salts ...	Hydro-sulphate of ammonia	Flesh-coloured precipitate of the sulphide.
—	Alkalies	White oxide, turning to nearly black by exposure to the atmosphere.

Cobalt —See p. 384.

Soluble salts ...	Hydro-sulphate of ammonia	Black sulphide.
—	Hydro-sulphuric acid, with neutral solutions..................	Do.
—	Potass..................	Blue precipitate, turning green in the air.
	Ammonia..............	Blue precipitate, resoluble in excess, producing a red liquid.
—	Carbonates of alkalies	The pink carbonate of the metal.

With borax a blue glass is produced by the heat of the blow-pipe, which is highly characteristic of cobalt.

Chromium.—See p. 384.

Solution Tested.	Test.	Results.
Soluble salts ...	Potass	Green oxide, soluble in excess.
—	Acetate of lead	Chromate of lead.
Chromic acid and salts	Nitrate of silver	Purple chromate of silver.

Cadmium.—See p. 384.

Solution Tested.	Test.	Results.
Soluble salts	Hydro-sulphuric acid and hydro-sulphate of ammonia	Yellow sulphide.
—	Potass, &c.	White oxide.
—	Carbonates of alkalies	White carbonate.

Omitting potassium and sodium, and their compounds, which do not afford insoluble precipitates or other effects similar to those we have described in connection with the metals in the previous list, we pass on to consider the tests for the terrigeneous earths and their oxides.

Aluminum.—See p. 388

Solution Tested.	Test.	Results.
Alumina in solution, as alum, &c.	Potass	White hydrate.
—	Ammonia	Do.

With proto-nitrate of cobalt it produces a sky-blue mass under the blow-pipe, if heated to redness on charcoal.

Silicon.—See p. 389.

Silica.—Its insolubility and general characteristics distinguish silica from every other substance.

Calcium.—See p. 389.

Solution Tested.	Test.	Results.
Lime, solution of, in water	Carbonic acid	The carbonate, or chalk. This precipitate is soluble in excess of the acid.
Lime salts	Sulphuric acid and sulphates	The sulphate as a white powder.
—	Oxalic acid	White oxalate.
—	Oxalate of ammonia	Do.
—	Alkalies and their carbonates	White precipitate.
—	Phosphoric acid	Do.

Magnesium.—See p. 390.

Solution Tested.	Test.	Results.
Magnesia	Ammonia	White hydrate.
—	Potass	Do. do.
—	Phosphate of soda	Do. phosphate.
—	Oxalate of ammonia	Do. oxalate.

Barium.—See p. 391.

Baryta, salts of	Alkaline carbonate	The white carbonate.
—	Sulphuric acid and sulphates	The white sulphate.
—	Phosphate of soda	White phosphate.

Salts of Baryta.—Tinged flame of a rich green colour.

Strontium.—See p. 391.

Strontia.—The tests for baryta exhibit a similar reaction with salts of strontia. The sulphate, however, is partially soluble in water. The chloride and nitrate give a rich red colour to flame, which is highly characteristic of their presence.

The foregoing tables of tests for metals and their compounds, will afford the student an opportunity of making himself acquainted with their leading properties and characteristics; and will also be a valuable introduction to the principles on which chemical analysis of inorganic bodies is carried on. We should advise that he first prepare the salts of the chief metals, and retain the products in both a crystalline and dissolved state. He may afterwards apply the tests we have named to the solutions, and note the resulting products. The more extended the course of experiments which he may institute of this kind, the more perfect will be his acquaintance with the nature of substances he may afterwards meet with, or which are produced in analytical investigations. In fact, without such a preliminary study, his attempts at analysis will prove but guess-work, resulting in disappointment and loss of time.

CHAPTER V.

INORGANIC ANALYSIS.

HAVING described the chief properties of all the elementary bodies which the student is likely to meet with; and having also mentioned the different tests which may be employed to detect their presence, and that of their compounds, we shall proceed to describe the methods adopted by chemists in discovering the composition of bodies which may be casually presented for examination.

We need scarcely say that the object of an analysis is to find out either the proximate or ultimate elements of which a substance is compounded. In most cases we are content to find the proximate substance, rather than to separate the elementary bodies entirely from each other. Thus, for instance, in analysing a piece of limestone, we are content to find how much lime, magnesia, &c., it may contain; and do not trouble ourselves about the metals of which those earths are the oxides. In some cases, however, we must ascertain the quantity of the elementary body present. Thus, in examining the ores of gold and silver, we always desire to ascertain how much of the pure metal is present. But chemical analysis may be divided into two parts; that is, qualitative and quantitative analysis. By the former, we merely ascertain the fact that a body is present; but by the latter, we arrive at a knowledge of its quantity in any substance which may be analysed.

Qualitative analysis always precedes that of quantitative; because, of course, we must first detect the presence of a body before we can ascertain in what proportion it exists. We shall, therefore, first draw the attention of our readers to that branch of the science, and point out the various methods which may be adopted.

Generally speaking, substances presented for analysis contain several compounds; and it requires considerable skill to apply the proper test, so that only one compound at a time shall be removed or detected. For instance, supposing a solution contained both sulphuric and hydrochloric acids. If one of nitrate of silver were added to it, then both acids would be precipitated together as the sulphate and chloride of silver; and they would either have to be separated by troublesome processes, or be left as an unresolvable mass. But if we first precipitate the sulphuric acid, by means of nitrate of baryta, in the form of the sulphate of that earth, we shall only leave nitric and hydrochloric acid and their compounds in solution. We filter off the insoluble sulphate of baryta; and pouring the clear liquid into another vessel, we may then add nitrate of silver, when all the chlorine will combine with the metal as the chloride, which will then be precipitated.

But even in this simple process another precaution must be attended to; for if, in the last case, we added *chloride* of barium to the solution, for the purpose of precipitating the sulphuric acid, then we should introduce more chlorine into the liquid, which would be thrown down on the addition of the nitrate of silver: hence, such a careless analysis would afford far more chlorine than should really have been present. This instance will suffice to show that we must not try tests at random, but in an orderly and consecutive manner; which is a point of great importance to the young student; for many attempt tests at a venture, and so only succeed in confusing themselves—becoming frequently disgusted at their want of success. We have seen such take the first out of a row of test-bottles, and trying one thing after another, in the vain hope of discovering the substances contained in a solution; and after expending considerable time in a chemical steeple-chase, they have ended with the conviction that they could not undertake analysis; in which opinion their tutors have often most rationally acquiesced.

We shall first give some preliminary and practical directions, and then proceed to point out a systematic course of qualitative chemical analysis.

Before commencing, it is well to provide a sufficiency of glass vessels of various sorts, for the operations which have to be pursued. And, to the young beginner, test-tubes are of great value. He can, by means of them, boil solutions, test them, and perform many operations on the small scale. To commence with—a few test-tubes, Florence flasks, two or three evaporating dishes, a spirit-lamp, pestle and mortar, some glass tubing, a funnel, and some filtering-paper, are the chief requisites. A book should be kept, in which *every* experiment should be registered; and small pieces of paper, marked with the letters of the alphabet, and others with the numerals, must also be at hand. Such are employed to distinguish the results of the different tests. Thus, one *series* of experiments may be called A; whilst each separate addition of a test in the series may be marked 1, 2, &c., on the test-glasses. By such means the experiments are classified; and they should be registered after the same order in the note-book. To illustrate this, we may refer to our directions for arsenical analysis;[*] in which we supposed, that after the arsenious acid had been brought into solution, three different methods, viz., Marsh's, Reinsch's, and the liquid tests, had been employed. The original liquid and the results might have been marked as follows:—

A.—Solution of Arsenious Acid.	Results.
1. Marsh's test	Arsenic deposited.
2. Reinsch's do.	Metallic arsenic reduced.
3. Liquid	Precipitates afforded.

By such a plan the progress of the analyst is materially assisted, errors are prevented, and the results kept for reference. It is also of great importance that the notes of experiments should be made at the moment the results are obtained. Young chemists, and even old beginners, are so eager to arrive at the end of their examinations, that they neglect these intermediate precautions. After they have thus proceeded for some time, they become perfectly bewildered, and are quite at a loss to distinguish one result from another, simply because they will not take the trouble to note each step as they proceed. In most laboratories for young pupils, it would be an advantage if the old fable of the tortoise and the hare were printed in capitals around the room. We proceed to practical details.

SOLUTION.—The first step in an analysis is to bring the body into solution, if it be not already in that state; and this may be effected in various ways. Some bodies are readily soluble in water; and the substance, in that case, may be dissolved by that fluid alone. It must be remembered, that most substances are more soluble in hot liquids than at ordinary temperatures; and hence the application of heat is required. Sometimes long boiling is requisite; and for such purposes Florence flasks and test-tubes may be employed. No more liquid should be used than is absolutely necessary, because this increases the bulk of the solution, and also diminishes its strength. As the water evaporates, more should be added, or otherwise a portion of the solid will be deposited on cooling, and crystallisation may also take place. All bodies more soluble in hot than in cold water will deposit some portion on cooling, if a hot saturated solution be made—that is, when the *hot* liquid has dissolved as much as it can.

It is always best to reduce a solid substance into powder, because, by that means, more particles are brought into contact with the fluid in the same time. The operation is thus facilitated. For this purpose, the pestle and mortar are to be used; the mass being first broken up into fragments, a *little* of which at a time is to be reduced to powder in the mortar. If too much be employed at once, the pulverisation will be incomplete. In pulverising some substances great difficulty is experienced; but this can be overcome by various expedients. Thus it is impossible to reduce camphor to a powder by itself; but the addition of a few drops of spirits of wine renders the operation quite easy. Flints, again, are difficult to pound; but if they are heated red-hot, and then quenched suddenly in cold water, their pulverisation may be readily performed.

Some substances are quite insoluble in water; and we may here state that we are confining our remarks, for the present, entirely to inorganic or mineral bodies. With such, a different course of treatment must be adopted. Take, for instance, a piece of chalk, which is entirely insoluble in distilled water. If it be placed in dilute sulphuric acid, no solution would be effected for the purpose of analysis, because the insoluble sulphate would be afforded. If, however, nitric or hydrochloric acid were employed, a solution would be at once produced. But such a solution would differ considerably from an aqueous one; for, in the latter, the substance is merely suspended—as sugar dissolved in water; which may be restored, without chemical change, to its previous solid state; whilst a solution of chalk in nitric acid is attended with decomposition, the nitrate of lime being produced in place of the carbonate. Still, for all analytical purposes, the result is the same, so that the body be in a state of solution at last. Clay may be taken as another example; for all except its silicious portion may be dissolved by acids, with the aid of heat, and thus a solution is afforded which can afterwards be conveniently tested.

The mention of silicious matter—such as sand, flint, quartz, &c.—brings us to remark on a class of bodies which are insoluble in all menstrua, with the exception of hydro-fluoric acid; and which, from its nature, forbids its employment, except in very peculiar cases. Supposing it were required to analyse a piece of flint, it would be necessary to fuse it with a flux, by means of a red heat at least. The plan to be adopted in such cases is as follows:—The body having been reduced to a fine powder, is to be mixed in a mortar with three or four times its weight of carbonate of potass, or soda. The mixture is to be put into a Berlin porcelain, or, in rough experiments, a Hessian or English crucible. It is then to be exposed to a red heat for two or three hours. By this process the silicious matter will form a soluble glass, and so a solution will be afforded, which may be dealt with in a manner we shall presently describe.

The metals and their alloys are all more or less soluble in some acid, but their ores have sometimes to be disposed of differently. At times they must be roasted, to drive off the combined sulphur, &c. This is effected by placing the substance in a common crucible, and exposing the contents to a red heat for some time. The residual mass may then be generally dissolved in an acid or other solvent. Some means may be occasionally tried, which produce secondary but required results: thus, the lead ore called galena is decomposed into sulphate of lead by long boiling with nitric acid.

Supposing solution to have been effected by any of the foregoing means, or others, the next step is that of examining or testing the solution, which affords either a precipitate or a change of colour. In some cases, neither of these results may follow. In this case, our next resource is crystallisation. Each of these cases we shall proceed to examine.

PRECIPITATION.—When a solid body is removed by means of a test from a solution, the substance so separated, whether it fall down or not, is called a precipitate, of which so many examples have already been noticed. We shall not repeat here the numerous instructions already given on this point, but rather mention minutiæ of practice to which we have not yet alluded. Some precipitates will not fall down or separate, owing to the extreme fineness of their particles; in such cases, heat is to be applied to the vessel containing them, which will generally cause the particles to coalesce. During precipitation, the liquid ought to be constantly stirred to assist the process; and an abundance of fluid, if not otherwise objectionable, is, generally speaking, an advantage. If it be desired to preserve the precipitate, the contents of the vessel, after being well stirred, are to be poured into a funnel holding filtering-paper. The paper should be first moistened, so as to facilitate the process; and the precipitate will thus be separated from the liquid, which will pass through, and may be received in another vessel. The precipitate, whilst on the filter, should be carefully washed with the solvent, so that any soluble portion may be removed; and the washings, as they are termed, are to be added to the liquid already passed through.

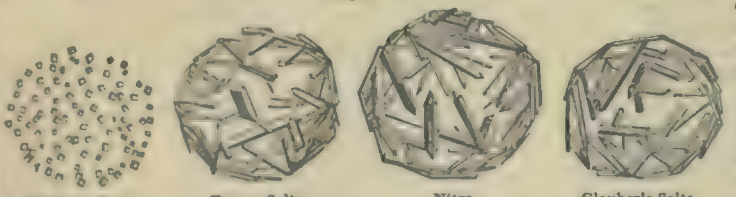
---

[*] See *ante*, p. 382, *et seq.*

If a precipitate be not formed, but a coloured liquid produced, great care should be taken as to the way in which the colour is examined. Some liquids afford a different colour when viewed by transmitted in place of reflected light. In such cases, the best plan is to pour a small portion of the liquid on to a clean white plate or dish, when the colour may then readily be noticed. Occasionally precipitates will change colour by exposure to the air; as, for instance, the cyanide of iron, the oxide of manganese, &c. Others will change colour by the application of heat—*e.g.*, the oxide of zinc—all of which, and many other circumstances, must be keenly and carefully noticed.

Crystallisation.—In many cases in which no precipitate is afforded, the process of crystallisation may be employed. By this we are enabled to give the solid body a definite form; for almost every salt crystallises in some peculiar shape so as to make it recognisable. The following engraving affords an illustration of the fact.

Fig. 72.



Common Salt. Epsom Salts. Nitre. Glauber's Salts.

Now here we observe four different forms of crystals, each of which is readily distinguished from the other. The student may readily produce these crystals by dissolving each of the salts separately in hot water to saturation, and then placing a drop of each on a piece of window-glass. As the liquid evaporates, the salt will reassume the solid form, and present its characteristic development.

The process of evaporation is generally carried on in evaporating dishes, heat being applied until a pellicle forms on the surface of the liquid. The vessel is then to be removed to a place where it will not be disturbed, when crystals will gradually be formed. The slower the evaporation is conducted, the more regular will the crystals produced be. By such means, highly soluble and less soluble salts may be separated. Thus chlorate of potass and chloride of potassium are simultaneously afforded in the production of the chlorate; but the latter is easily *crystallised away* from the former by its greater insolubility. In a similar manner, alum is purified from iron and other substances. The best vessels for crystallisation only, are rough glazed earthenware dishes, which, by their uneven surface, assist crystallisation; whilst for refined experiments, vessels of Berlin porcelain, silver, or platina, are usually employed. The two last, however, are only needed for special purposes. After a liquid has yielded as many crystals as it can, on fresh evaporation more will be afforded. Occasionally, however, a liquid will actually redissolve crystals which have been formed in it. This arises either from an increase of temperature, or from a difference of specific gravity in the upper and lower portions of the fluid.

Some crystals, when exposed to the air, *deliquesce*; that is, they absorb moisture from the atmosphere. This occurs with chloride of calcium, chloride of aluminum, and many other substances. Others lose water, or *effloresce*, as in the case of sub-carbonate of soda in crystals (the ordinary "soda" of commerce), which is thereby converted into a powder-like substance.

Large and perfect crystals may be obtained from a solution by immersing in it a crystal of the crystallising body. A perfect one should be chosen for this purpose; and, by such means, enormous crystals of the prussiate and bichromate of potass may be produced.

Distillation and Sublimation.—These operations differ more in name than in principle, their object being to separate volatile from solid substances. By distillation, water, alcohol, &c., may be separated from bodies which may have been dissolved in them. Mercury, in a similar manner, is distilled from its amalgams and ores, and obtained in a pure state. For such purposes, glass retorts are employed when a temperature less than a red heat is required; whilst, for other operations, vessels of porcelain, iron, or platina must be used, as in the preparation of potassium, sodium, the chloride of aluminium, &c.

Sublimation can generally be effected by means of flasks or test-tubes. Thus sulphur, arsenic, iodine, &c., may be volatilised in a manner already mentioned under their separate heads in our previous pages. This operation, however, is by no means common in the course of analysis.

The Blow-Pipe.—We have thus given an outline of the leading operations in analysis, and shall now make a few remarks on the blow-pipe, an instrument of great use in experimental chemistry, and by means of which we can get, on the small scale, all the results of the most powerful furnace. We can hardly recommend, as the *best*, any form of the instrument; but, for our own part, always employ either the common tinman's blow-pipe, or that invented by Dr. Black, which can be obtained at any instrument-maker's.

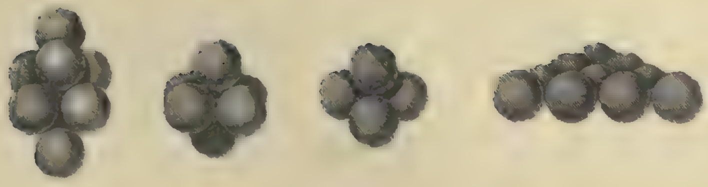
Much art is required in using the blow-pipe. The air should be blown from the cheeks only, and not from the chest. By that plan, a person may keep up a continuous stream of air for a long time without fatigue, and the mouth may be replenished with air from the lungs by an operation something like the reverse of swallowing. It is impossible further to describe the method, as practice alone is of use. The object the student should have in view, is that of keeping up the stream of air, free from puffing, and to thereby maintain a steady flame.

The flame consists of two parts. The inner one ends with a blue colour, at the point of which the most intense heat is produced. The outer flame—that is, that farthest removed from the jet—affords much less heat, being in direct contact with the external air. The uses of these two flames are accordingly different; the inner one is employed for reduction, and the outer one for oxidation. A wax or composite candle affords a suitable flame for the blow-pipe. Small rings of platina wire, some platina foil, and pieces of charcoal, are needed as supports for the substances to be examined. It must be borne in mind, that the charcoal is employed as a deoxidator—that is, for the purposes of reducing oxides to their metallic state; whilst the ring, or foil of platina, is used to produce beads, &c. If the latter were employed in reduction, the metals would form an alloy in many cases, which would destroy the platina support. The use of the charcoal may easily be seen by placing a little red oxide of lead in a small hole made in the charcoal support by means of a penknife. If the blue flame be then directed on it, metallic lead will be at once reduced.

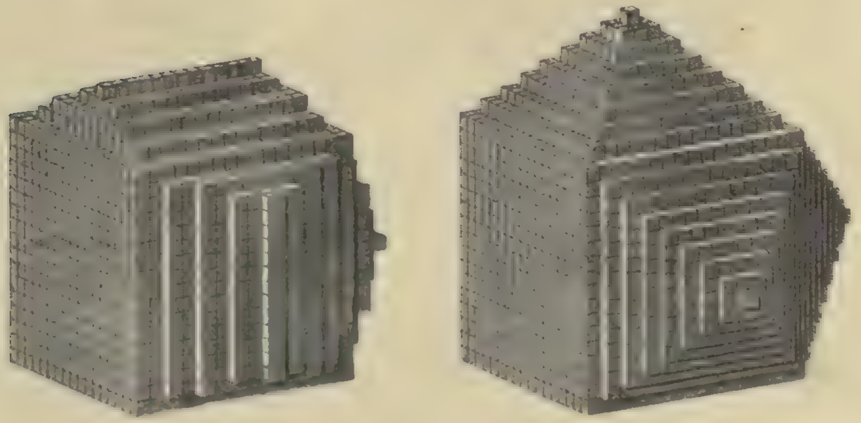
By means of the blow-pipe, a preliminary examination of many substances may be made, which will save a vast deal of time in subsequent processes. This remark especially applies to metallurgical chemistry, and to the examination of minerals generally. It should be the object of the young chemist, therefore, to familiarise himself, by constant practice, with the use of the blow-pipe. He may commence by reducing metals on charcoal supports, using only a minute portion of the oxides, &c., for the purpose. The use of the oxidating flame may similarly be tried on metals. Employing a little borax, carbonate of soda, &c., he may proceed to produce coloured buttons, by the fusion, at the reducing flame, of those substances, for

Crystallization.

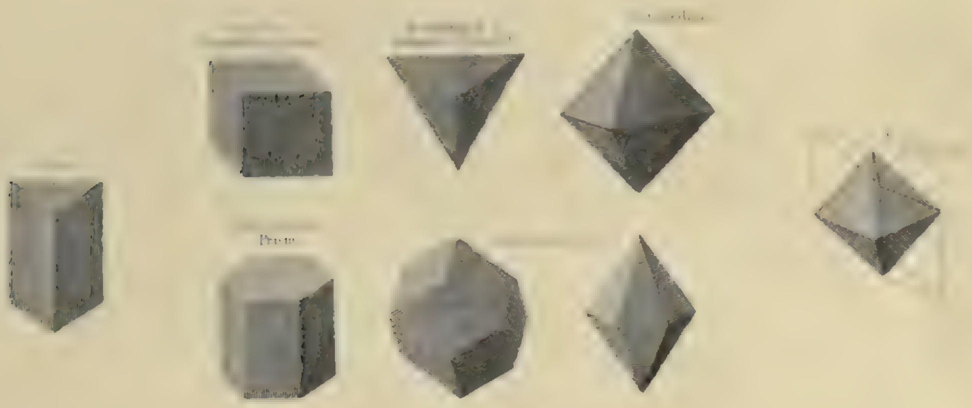
See Page 396



Arrangement of the Molecules of A Body having A Crystalline Form



Molecular Constitution of A Crystalline Body



Various Forms of Crystals, in Relation to their Geometric Elements.

Crystals Revealing their Elementary Forms during Solution

which rings of platina wire are to be employed. The flux is first melted so as to form a little bead, which will fill up the ring. On this the oxide is placed, and fused with the flux. The oxides of cobalt, manganese, and chromium are useful for initiatory experiments. In all cases the heat should be employed gently at first, until the required temperature be obtained. In the absence of this precaution, charcoal supports and refractory minerals will fly into pieces; and it is by no means unlikely that the first intimation of this result will be feelingly conveyed to the operator by the lodgment of a red-hot fragment in the eye, by which he will be forcibly impressed with the necessity of care for the future.

Presuming that the reader will have become acquainted with the various processes involved in general analysis, we shall proceed to give details of the methods adopted in laboratory practice.

QUALITATIVE ANALYSIS.

In the following pages we shall not follow the usual plan of giving directions for a systematic course, by means of which every body which can possibly be met with may be detected, but confine ourselves to instances which will afford types of the methods to be employed. To those of our readers who may be desirous of entering extensively into the subject, we recommend the works of Fresenius, Parnell, and Rose; in which may be found directions for almost every analysis which can be undertaken. We shall adapt our directions chiefly for such who have never attempted to analyse, and so fit them for a perusal of the works we have named, and for the subsequent prosecution of more elaborate researches.

The external qualities of a body will often give a general insight into the nature of its composition. The value of this, however, will depend on the extent of general information which the operator may possess. An experienced chemist can often give an approximate idea of the composition of bodies by a few preliminary experiments, or even by simple inspection. The physical characters of specific gravity, colour, form, whether crystalline or amorphous, suggest the connection of any substance with others of a similar class. Thus, no one having any acquaintance with mineralogy would mistake quartz for Iceland spar; for one is hard, crystallises in prisms having six sides, will scratch glass, &c.; whilst the latter is soft, splits into rhomboids, and may therefore be readily scratched by glass, iron, or almost any other body. Metallic alloys, oxides, &c., are generally to be distinguished by their specific gravity, lustre, and colour; and hence, for them, the usual tests for metals may be employed.

Almost every inorganic substance is composed of oxides of metals proper, or those of the alkaline and terrigeneous metals; and maintaining the distinction incident to the individual character of each class, the student may often make a rough and tolerably accurate guess of the substance under examination.

In illustrating the different methods of qualitative examination, we shall take instances of well-known substances, progressing from such as afford comparatively little difficulty, to others of a more complex character.

Our first attempt shall be a qualitative analysis of a piece of marble, by which we shall show that it mainly consists of carbonic acid and lime. The student will thus learn to detect the presence of a gas and an earth, and so take a first step in his analytical progress.

Experiment 82.—Take a small piece of marble, of the size of a pea; and having reduced it into powder, boil it for some time in distilled water. Pour some of the liquid on to a piece of clean window-glass, and hold it over the spirit-lamp flame until the glass be dry. No deposit will take place, because the marble is insoluble in water.

(*a.*) The next step is to find some acid which will dissolve the marble; and for this purpose dilute hydrochloric acid may be poured on the powder, which should be placed in a test-tube of considerable size. The acid should be added little by little, waiting till all effervescence has ceased before more is poured into the tube. It will be evident that a gas, which formed part of the marble, is escaping; but this we will consider hereafter.

(*b.*) Having effected the solution, we must next test it, and discover, if possible, what the solid substance which has dissolved consists of. It is evident that that has united with the hydrochloric acid, and the substance with which it was previously in combination has been removed. The very appearance and source of the marble indicate that it belongs to the earths, and it must therefore consist of one of these. But as all the earths are soluble in hydrochloric acid, we must add some test which shall detect that really present; and herein lies the art of the analyst. If we add alkalies or their carbonates, in solution, we may have *any* of the earths precipitated as a white powder; hence, for the present, they will not assist us. But we find that sulphuric acid will not precipitate *all* the earths, for the sulphate of magnesia and alumina are soluble in water. We accordingly add a little dilute sulphuric acid to the solution made in *a*, and find a copious white precipitate thrown down.

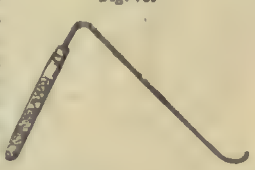
(*c.*) The precipitate obtained in *b* may either be the sulphate of baryta, strontia, or lime; and for all practical purposes we may consider one of these to be present. A portion of the precipitate may accordingly be taken, and having been washed in a test-tube with distilled water, the washings being thrown away, the powder is first to be agitated in abundance of distilled water, and a little of the liquid is then to be poured on a piece of clean window-glass, or platina foil. This is to be held over the spirit-lamp until quite dry. If any deposit be effected, it must either be sulphate of strontia or sulphate of lime, because the sulphate of baryta is insoluble in water. We therefore conclude that the solid substance dissolved in *b* must be one of the two former earths.

(*d.*) As we may infer that either the sulphates of strontia or lime alone are present, we add to the solution obtained in *c* one of sulphate of lime, which may be made by agitating that substance with plenty of cold water, and filtering off the clear solution. A portion of this being added to solution *c*, if a precipitate fall, we know that it cannot be sulphate of lime, for that would not be thrown down by a solution of itself. We therefore at once infer that strontia is present. For an equally good reason, we are assured that strontia is *not* present if *no* precipitate take place. In such a case we conclude that lime alone could be present, and therefore that earth must have been the solid matter dissolved in *a*, by the hydrochloric acid.

Having so far gained a knowledge of one of the constituents of the marble, we proceed to examine the nature of the gas given off whilst the solution was being effected; and this may easily be done as follows:—

(*e.*) Take a small piece of the marble, and put it into a test-tube fitted with a cork and bent tube, as represented in the margin. Add a little dilute hydrochloric acid; and having fitted in the tube, allow the gas which is given off to bubble through some lime-water. If no precipitate be produced, then the gas is not carbonic acid. If, however, a precipitate be thrown down, then carbonic acid is certainly present, which will be at once evident by the formation of chalk or carbonate of lime.

Fig. 73.



It will thus be shown that the marble is chiefly composed of two substances—lime and carbonic acid: and another step may be taken to verify the investigation.

(*f.*) Heat a small piece of the marble in an *open* crucible, or in an iron ladle, at a red heat for some time. It will be found that the colour and appearance of the remainder will have entirely changed—a yellowish-coloured substance will remain. If this be placed in a few drops of water it will heat and fall to powder; and, in fact, will present every characteristic of the earth, lime.

The marble having thus afforded carbonic acid and lime, will also, most likely, contain a small portion of iron ; hence another step is necessary to detect the oxide of that metal.

(*g.*) To a small quantity of the solution *a*, add a few drops of nitric acid, and heat it. Then pour in a few drops of a solution of prussiate of potass, when, if iron be present, a blue precipitate will at once be produced.

We may now consider the qualitative analysis of the marble to have been completed and verified ; and to make our progress more easy, we shall recapitulate each step we have taken.

1. We tried the solubility of the marble in water.
2. In *a* we effected a solution in hydrochloric acid.
3. In *b* we obtained a precipitate by means of sulphuric acid.
4. In *c* we showed that only the sulphates of strontia or lime could have been produced.
5. In *d* we found that the precipitate could be sulphate of lime only.
6. By the process named in *e* we proved the presence of carbonic acid.
7. We verified our previous discoveries by heating the substance as in *f*.
8. And, lastly, anticipating the presence of iron, we tested for its oxide, and obtained a precipitate of Prussian blue in *g*.

We have thus succeeded in obtaining, separately, each of the constituents of the marble by way of analysis. Each step, it will be observed, depends on that taken previously ; and from this easy example, the student may learn the general method of conducting the qualitative analysis of many substances.

In carrying out this initiatory experiment, we have chosen a substance which is so simple in its constitution as to leave no doubt of accurate results, because every specimen of marble and chalk has, as near as possible, an identical constitution. We must, however, inform the student, that baryta, strontia, lime, and magnesia, present, as near as can be, the same appearance when tested in solution by some reagents. For instance, the carbonate of the alkalies would precipitate the carbonate of each of these earths as a white powder. The same may be said of oxalic acid and oxalate of ammonia. Hence, had such tests only been employed, the student would scarcely have advanced a step, because the indications produced would have been undistinguishable. By the plan, however, which we have described, each source of error was successively eliminated, and so the true composition of the marble was at last arrived at. The progress in chemical analysis, when properly conducted, is just as logical as a problem in geometry or an equation in algebra. The value of lines or quantities is gradually estimated in those sciences from data ; and similarly in chemistry, we obtain, in a physical form, analogous results.

We must next examine more difficult instances ; and by suggesting mixtures of various substances, shall indicate the means to be employed in detecting their constituents.

Experiment 83.—We shall now proceed to analyse a piece of clay, which, generally speaking, contains four or more substances. Our attention, however, will be confined to the detection of the silica, alumina, lime, and iron ; and the following plan may be adopted.

(*a.*) Take a small piece of the brown-coloured clay, such as is used in brickmaking, and heat it for some time in a ladle, but not red-hot, for the purpose of driving off water in a free state, and to break up the crystals of sulphate of lime which may be present. Transfer the mass so obtained to a glass flask ; add abundance of distilled water, and agitate the contents of the vessel for some time. This will dissolve out a portion of sulphate of lime, which is more soluble in cold than in hot water. Let the whole stand for some time, and then pour off the clear liquid into another vessel. Evaporate a portion of the liquid to dryness in an evaporating dish ; if a powder be obtained which is barely soluble in much water, it may be assumed as sulphate of lime, but may also be tested as in Experiment 82.

(*b.*) A brown-coloured mass will be left in the flask, which is insoluble in water. To this add dilute hydrochloric acid, and boil for some time to dissolve all soluble matter out. By this the carbonate of lime, alumina, and iron, will be removed. The clear liquid is accordingly to be poured off into another vessel, and more hydrochloric acid added to the powder in the flask. The contents are to be boiled, and when cool, are to be added to the previous solution. The remaining mass is to be washed with distilled water, and the washings are also to be added to the solution already effected. By these means, all matter soluble in dilute hydrochloric acid will have been removed, and little else but silica, which is insoluble, will remain. Of this we shall speak hereafter.

(*c.*) The solution from *b* will contain lime, alumina, and iron ; and each of these is to be tested for separately. Were we to add alkalies, or an alkaline carbonate, we should obtain an abundant precipitate of *all* the bodies in solution ; and this would only perplex us, and compel a re-solution of some of them. Our object, however, may be readily attained by first removing the lime as sulphate ; secondly, the alumina ; and, lastly, the iron may be discovered by a separate process. Now, as alumina and iron are both soluble in sulphuric acid, and lime produces an almost insoluble precipitate with it, we add dilute sulphuric acid to the solution, and so obtain the sulphate of lime. By this we get rid of one of the three constituents of the clay—namely, the carbonate of lime ; the existing sulphate having already been disposed of.

(*d.*) The solution freed from the salts of lime most likely to be present, now contains alumina and oxide of iron ; and after adding a little nitric acid, boil for a short time in a flask ; then divide the liquid into two portions. To one add prussiate of potass, when the iron will fall down as a blue precipitate. The presence of iron is thus evidenced.

(*e.*) To the remaining portion of the solution in *d*, add a *dilute* solution of potass. A precipitate will at once be afforded of alumina : allow it to settle, and then add an *excess* of a solution of potass, and heat it. The alumina will be completely dissolved. To this add a solution of sal-ammoniac, when the alumina will be again thrown down. The alumina present in the clay is thus detected.

We have thus discovered that clay consists of alumina, lime, and oxide of iron ; but have yet to examine the insoluble matter left in process *b*, after digesting with hydrochloric acid. This leads us to another branch of analysis—namely, that in which matter containing silica is to be examined. The following course must be adopted.

(*f.*) As silicious matter is insoluble in all liquids except hydrofluoric acid,* we must bring it into a soluble state by means of a flux. The mass left in *b* is therefore to be removed, washed, and dried, and then to be mixed in the mortar with three or four times its weight of carbonate of soda, or potass. It is then to be transferred to a Berlin porcelain or English crucible ; and heat for two hours at a full red heat. A gas-furnace may be employed if a Berlin crucible be used ; or a common coke fire will answer equally as well, if common crucibles are adopted. The sand and alkali will unite, and form a silicate, which is easily soluble in water. As soon as the entire mass is completely fused, the crucible is to be removed from the fire, and allowed to cool. The whole may then be placed in a large evaporating dish, and dilute hydrochloric acid is to be poured into the crucible ; or its contents may be broken out, and put into the evaporating dish alone, as a little loss is no object in a qualitative analysis of this kind.

(*g.*) The resulting mixture from the last process is to be cautiously evaporated to dryness ; and when the dish is quite cool, dilute hydrochloric acid is to be poured in. This will dissolve out all but the silica, which will be left as a gritty white powder. It is thus also removed from the clay.

* See *ante*, p. 339.

(*h.*) But the solution effected in the last process by hydrochloric acid, after the silica is removed, may contain both alumina and oxide of iron. It may be tested in exactly the same manner as indicated under *d* and *e*, when these substances, which had been held in chemical union with the silica, will also be discovered.

By such means the presence of silica, alumina, lime, and iron may be detected in clay; and also the combination of the three last-named bodies in union with the silica as sand. In this analysis, we still further discover the necessity of a successive process in analytical investigations, if we would command reliable results. We may recapitulate our analysis as follows :—

1. We removed matter soluble in water.
2. We effected the solution of a portion of the clay in hydrochloric acid, leaving the insoluble part for further experiments (*b.*)
3. We next got rid of the carbonate of lime in the form of a sulphate (*c.*)
4. The iron was removed by the next process (*d.*)
5. The alumina was precipitated as a hydrate in *e.*
6. We afterwards effected the decomposition of the sand, and obtained its silica as a white powder (*f* and *g.*)
7. And lastly, the other constituents of the sand, in chemical union with the silica, were also discovered (*h.*)

The foregoing examples of qualitative analysis may serve the student as types of the methods generally to be pursued in inorganic qualitative analysis, when earths alone are sought for; and to the agriculturist such may prove a kind of general guide to a rough analysis of an average soil. We shall next give some instances, in which the detection of metals proper are more especially involved, and which may prove useful to those desirous of investigating the nature of veins of metallic ores, which may occur in their neighbourhood. Before proceeding to the following experiments, the reader is advised to peruse the tables of tests for the metals, given at a previous page;* by which he will be the better prepared to understand the operation of each reagent in any special case.

Experiment 84.—Dissolve together, in a test-tube, a few crystals of sulphate of copper, and proto-sulphate of iron. You will thus obtain a mixed solution of the two metals; the object being to detect the presence of each separately. Now, if the ordinary method of precipitating the oxide, carbonate or prussiate, were adopted, by means of those salts of the alkalies, the salts of the metals would be thrown down together. Other means must therefore be tried: and either of the two following methods may be adopted :—

1. Divide the solution into two parts, in separate test-tubes. Into one immerse a piece of clean iron plate, having first added a few drops of sulphuric acid. Chemical action will at once ensue, and the copper will be reduced to a metallic state, completely from the liquid.

2. Immerse two pieces of platina foil, attached to each wire proceeding from a single cell of a voltaic battery, in the other solution, and allow the current to pass for some time. Eventually the copper will be reduced at the negative pole in the metallic state.

3. The copper may be removed from an *acid* solution of the two metals, by means of sulphuretted hydrogen. For this purpose, some sulphuric acid is first to be added to the solution of the salts of the two metals, and then a current of sulphuretted hydrogen is to be passed through. The black sulphide of copper will be at once produced; whilst the iron still remains in solution. It can afterwards be precipitated by means of any of the alkalies; but the solution must first be boiled, to remove any hydro-sulphuric acid left after the precipitation of the copper. This experiment illustrates methods by which voltaic action may often be employed for the removal of platina, silver, mercury, and copper, from mixed metallic solutions.

Experiment 85.—We shall now offer a more complex experiment, in which two metals and an earth are found in solution; the object being to detect and remove each separately. Dissolve a few grains each of the nitrates of silver, lead, and baryta together in a test-tube; and from this solution precipitate each substance as follows :

(*a.*) Add common salt in solution to the above solution. The chlorides of silver and lead will be precipitated together. Filter these off by means of the funnel, &c., preserving the clear liquid, and washing the precipitate with distilled water, which must then be added to the original solution left after filtration. Put the precipitates into a test-tube, and add liquid ammonia. This will dissolve the chloride of silver, and leave the lead untouched, by which that metal will be removed entirely.

(*b.*) To the solution of silver by ammonia, produced in *a*, add an excess of dilute hydrochloric acid, when the chloride will be precipitated, and may be known by changing to a dark colour by the action of light.

(*c.*) The original solution will now only contain the salt of baryta, which is readily precipitated by adding a sulphate, or dilute sulphuric acid; and thus the baryta will also be removed.

Now, had we used sulphuric acid in the first instance in *a*, we should have precipitated together the sulphates of each of the bases, and would have lost almost all chance of dividing them. This, again, is another illustration of the necessity of rule in using chemical reagents. It is of the utmost importance, in adding a test, that we take care not to introduce any substance which may in any way invalidate or modify the different steps of an analysis. Thus the chloride of barium, or nitrate of baryta, may sometimes be used to precipitate sulphuric acid from solutions. At others, the introduction of chlorine would cause insoluble precipitates, and so render the result fallacious in that or other ways, as the following experiment will show :—

Experiment 86.—Add a few drops each of sulphuric and hydrochloric acid together. To the solution add some of *nitrate* of baryta, when an insoluble sulphate of baryta will be precipitated. Then add, after the removal of the sulphuric acid, a little nitrate of silver to the original solution: a precipitate of chloride of silver will be produced; and the hydrochloric acid will then be also removed. Now, had the chloride of barium been used instead of the nitrate, then it would of itself have produced a precipitate of the chloride of silver, independently of the hydrochloric acid already present; and hence if a quantitative analysis had been desired, the amount of chlorine would have been indicated far in excess of the truth. We may here mention another source of error, which occasionally arises in testing with either of the salts we have named. Both the chloride of barium and the nitrate of baryta are apt to be precipitated as very minute crystals, when used as tests in concentrated solutions. They, however, immediately disappear when water is added, being readily soluble in that fluid. They are, of course, thus at once removed from the insoluble sulphate.

We may make a practical application of some of these facts in undertaking a quantitative analysis of mineral waters. But as some of our readers may not have access to any, we shall suggest a way of imitating the composition of one. For this purpose dissolve a few grains of each of the following salts in a pint of distilled water; viz.—Sulphate of magnesia (Epsom salts); chloride of sodium (common salt); sulphate of lime (plaster of Paris); sulphate of iron (copperas).

Now, these substances are generally found in most mineral waters; and very often in common river-water. The salts are all to be well shaken up; and will dissolve, with the exception of the sulphate of lime, of which only a small portion will enter into solution. It is required that we should detect the bases, *i.e.*, the magnesia, lime, and iron, and the common salt. The solution must be filtered so as to be perfectly clear; and the following steps are to be taken :—

(*a.*) Pour a portion of the solution into an evaporating dish, capable of holding about two fluid ounces; and evaporate by the heat of a spirit-lamp; adding more of the fluid as it is lost in vapour. By this means the solution is to be concentrated, and at last evaporated to dryness. This should be effected at the conclusion of the process, by means of a water-bath, lest the basin exposed to the heat of the flame should crack. Such an arrangement is easily made, by placing the evaporating dish in another of larger size, filled with boiling-water, and kept at that heat; or the small dish may be placed on the top of a tin saucepan, the water in which is to be kept boiling. All the solid substances will thus be removed from solution; and if only a very small quantity of boiling-water be then poured on to the mass, all the substances will be again dissolved, with the exception of the sulphate of lime, which is thus removed from the mixture. The fluid is then to be poured into a clean test-tube; more water added to it; and the remaining sulphate of lime may be tested as directed in Experiment 82.

---

* See *ante*, p. 393.

(*b*.) We shall now have left in the solution a very minute portion of sulphate of lime (which we may neglect), and the sulphates of magnesia and iron with the common salt.

The common salt, or rather its chlorine, is first to be removed by means of nitrate of silver, as in Experiment 85. The solution must then be cleared of the precipitate by means of filtration.

(*c*.) The clear solution now only contains sulphate of magnesia and iron; and we have to obtain these two separately. A little hydro-sulphate of ammonia is to be added, when the iron is precipitated as the black sulphide.

(*d*.) We have now nothing remaining but the salt of magnesia. The solution having been filtered from the sulphide of iron, is to have added to it some solution of potass, and to be boiled, when the magnesia will be precipitated as a white hydrate.

Thus the lime, common salt, iron, and sulphate of magnesia, may successively be detected in the manner we have pointed out.

We have thus given some experiments illustrating the methods by means of which inorganic substances containing earths and metallic oxides may be analysed. We shall now proceed to what will be more difficult to the tyro—namely, the means we have of detecting the presence of alkalies. These substances and their compounds are, with few exceptions, soluble in water; and they therefore cannot be generally detected in the manner, or with the ease, that the metals are susceptible of. Some of the salts are more easily detected than others. Thus the nitrates and chlorates of each of the alkalies, deflagrate with burning charcoal, producing carbonates, which may be distinguished from those of the earths by their great solubility in water. The salts of potass give a violet tint in the blow-pipe flame; whilst those of soda afford a yellow colour. Potass and soda may, however, be distinguished by means of the chloride of platina and tartaric acid. With the chloride of platina, potass combines and affords a yellow crystalline substance. With tartaric acid, it produces the comparatively insoluble bitartrate of potass, or cream of tartar. Now soda produces no precipitate with the platina salt, and none with tartaric acid, unless a very concentrated solution be employed. The chloride of platina also affords a yellow crystalline product with ammonia and its salts. But the latter alkali may always be distinguished by the smell, which may be produced by heating its salts with lime or potass. The ammonia is set free; and if a piece of moist turmeric paper be held over the fumes, it will turn red—a colour which is lost as the alkali evaporates. A glass rod moistened with hydrochloric acid, affords white fumes of sal-ammoniac. If a piece of horn or flesh be heated, and burnt in a test-tube, and either of these tests be applied, the presence of ammonia will at once be made evident. All the alkalies change the yellow colour of turmeric to red, and restore the colour to blue, of previously reddened litmus-paper. We advise the student to make repeated experiments with potass and soda in the blow-pipe flame, so that he may acquire the knack of distinguishing them. He may also watch the effect of their giving colour to the flame of burning spirits of wine. We may suggest the following experiments, as calculated to familiarise the mind with some of the appearances of the alkalies, as met with in analysis.

Experiment 87.—Fuse some sand in a crucible, with four times its weight of carbonate of potass. Separate the silica as directed in Experiment 83, (*f*); but add nitric instead of hydrochloric acid, to dissolve out the glassy matter. Having filtered the solution from the silica, evaporate to dryness, and take the residue away, throwing it on a piece of red-hot charcoal. By this means a deflagration will take place, and the charcoal and oxygen of the nitric acid forming carbonic acid, carbonate of potass will be produced. Put the piece of charcoal into distilled water, to dissolve away the alkaline carbonate; and having filtered the solution, add some chloride of platina.* The yellow crystalline double salts of chloride of platina and potassium will be produced. In this experiment, three points may be noticed—the production of the carbonate of potass; its easy solubility; and the production of a double salt of platina and potassium.

Experiment 88.—Ammonia is never met with in what we may term a mineral state, and is always the product of organic decomposition. Its reaction, however, may be noticed by adding the platina salt to a solution of sal-ammoniac, when a double salt, analogous to that of potass, will be formed. It has, however, a lighter colour than the potass precipitate. We shall have to give full details as to the detection of ammonia when we treat on organic analysis.

There is a class of substances often met with in inorganic analysis, which may, generally speaking, be obtained from their combinations by means of sublimation. Of these, arsenic and sulphur are the most likely to claim the attention of the student. Any ore containing, or suspected to contain, either of these substances, may be placed, being first reduced to powder, in a test-tube or Florence flask. Heat is then to be applied, when the arsenic present will sublime as the white arsenious acid, and the sulphur settle as a yellow crystalline substance; but, if ignited, producing sulphurous acid gas. The sulphides of some of the metals may be readily analysed by the following method.

Experiment 89.—Take a small piece of galena, the native sulphide of lead; and having reduced it to powder, digest it in a flask with nitric acid, until the whole is converted into a white powder. This is the sulphate of lead, produced by the oxidation of the sulphide at the expense of the nitric acid. Occasionally sulphur will be set free in the solid form, but this is easily recognised by its general properties.

Mercury is also a volatilisable body, but will only be met with in those conditions in which its presence will be easily recognised. The same may be remarked in reference to iodine and bromine.

Our previous remarks and experiments, with the tables of tests given at page 393, will thus enable the student to undertake a general qualitative analysis of most of the substances which he may ordinarily meet with in inorganic analysis; and we shall give a systematic arrangement which is generally applicable in all cases. In this we have interwoven the plan recommended by Fresenius with that which we have generally adopted ourselves. We shall suppose that a great variety of all sorts of compounds may be present, and that each is to be separately eliminated in the course of analysis. Such a state of combination cannot occur in nature; but the plan has the advantages of pointing out the various appearances and indications of most of the compounds which can possibly be met with in an extended and long practice in analytical investigation.

GENERAL PLAN FOR INORGANIC QUALITATIVE ANALYSIS.

1. Ascertain, as far as possible, the specific gravity and other physical characters of the body; and refer to the general properties of metals, alkalies, earths, and salts, for general ideas of its constitution.

2. Reduce, if requisite, to powder. Heat this, and

---

* See *ante*, p. 372.

observe whether partial fusion, sublimation, or other notable change takes place. If, on heating, the mass turn black, organic matter must be present. If any smell be produced, test for ammonia, sulphur, &c.

3. If any particular change do not take place, proceed to dissolve in water, first employing the fluid in a cold state, then heating to ebullition.

4. Use any indication which the blow-pipe may afford. By this, oxides may be reduced by charcoal supports. Earths may produce glasses; and some oxides may afford coloured glasses with borax, carbonate of potash, &c., on platina foil or wire.

5. If insoluble in water, use dilute hydrochloric or nitric acid. In most cases these acids act as solvents; and, with the exception of silica, few substances withstand their separate or joint action. If solution be effected, proceed to test for earths, oxides of metals proper, and alkalies, as already pointed out.

6. Consulting the tables and experiments already given, employ such tests as shall not interfere with the general result. Do not introduce any substance which might vitiate the ultimate requirements of the analysis.

7. Leave all substances insoluble in the acids, &c., already named, for fusion with fluxes, as most likely such would consist chiefly of silica and silicates.

8. As a general rule, leave the detection of any alkalies supposed to be present to the end of the process. The possible presence of ammonia alone is to be excepted, as it is desirable that this alkali should be disposed of as soon as possible.

9. A careful use of hydro-sulphuric acid and hydrosulphate of ammonia, is one of the most valuable guides the chemist possesses, as by them the peculiar character of metals may be readily classified. The following table will be found useful in directing to a general knowledge of the sulphides formed by their use. We have also included the results afforded on adding the alkalies to the various solutions of the oxides, salts, &c.

TABLE *of Precipitates afforded by Hydro-sulphuric Acid (sulphuretted hydrogen) and the Hydro-sulphate of Ammonia, in Solutions of most of the Elementary Bodies and their Compounds, and those obtained by testing with Potass, Ammonia, &c.*

Elements, Oxides, &c.	Test. Hydro-sulphuric Acid.	Test. Hydro-sulphate of Ammonia.	Potass.	Ammonia.	Carbonate of
Alkalies. Potass Soda Ammonia	No precipitate	No precipitate	No precipitate	No precipitate	No precipitate.
Alkaline Earths. Baryta	Do.	Do.	Hydrate in concentrated solution	Do.	All alkalies. Carbonate.
Strontia	Do.	Do.	Do.	Do.	Do.
Lime	Do.	Do.	Do.	Do.	Do.
Magnesia	Do.	Do.	Hydrate	Partial precipitate of hydrate	Potass—The carbonate and hydrate precipitated. Ammonia—scarcely.
Alumina.	Do.	White precipitate of the hydrate	Hydrate, soluble in excess	Hydrate, soluble in excess in the absence of potass and soda	
Chromium, Oxide of	Do.	The black hydrate	Hydrate, green, soluble in excess	Hydrate, scarcely soluble in excess	
Zinc. Oxide	White sulphide in neutral solutions. In acid solutions—none	White sulphide from neutral solutions: precipitate not redissolved by excess	White hydrate, soluble in excess	Hydrate, soluble in excess	Potass — Carbonate insoluble in excess. Ammonia — Carbonate soluble in excess.
Manganese. Protoxide	No precipitate in acid or neutral solutions. A flesh-coloured precipitate from alkaline solutions	Flesh-coloured sulphide from neutral solutions, changing to dark-brown when exposed to the air. Insoluble in excess of the test	White hydrate, which changes to brown, and at last to black, on exposure to the air by both alkalies		
Nickel, Oxide of	No precipitate in acid or neutral; a black in alkaline solutions	Black sulphide in neutral solutions; partly soluble in excess	Green hydrate, insoluble in excess	Hydrate, soluble in excess, turning to blue	
Cobalt. Protoxide	Scarce precipitate in neutral solutions; none in acid; black in alkaline solutions	Black sulphide in neutral solutions	Blue, turning to green on exposure to air	Same as potass, but soluble, producing a brown-coloured fluid	

Elements, Oxides, &c.	Test Hydro-sulphuric acid	Test, Hydrosulphate of Ammonia.	Potass.	Ammonia.	Carbonate of
Iron.					
Protoxide	None in acid solutions; black in alkaline	Black sulphide	Green hydrate, turning to red on exposure to the air	Same as potass	
Peroxide	In neutral and acid solutions a precipitate of sulphur	Black sulphide	Red hydrate	Do.	
Silver.					
Oxide	Black sulphide	Do.	Brown oxide, insoluble in excess	Brown oxide, readily soluble in excess	
Mercury.					
Protoxide	Black sulphide	Do.	Black oxide, insoluble	Same as potass	
Peroxide	White, orange, or black, according to quantity of test	White, orange, or black, according to quantity of test	Red-brown oxide, turning to yellow by excess	White precipitate	
Lead.					
Oxide	Black sulphide	Black sulphide	White precipitate, slightly soluble in excess	White precipitate, insoluble in excess	
Copper.					
Oxide	Brown-black sulphide	Brown-black sulphide, slightly soluble in excess of the test.	Blue hydrate, becoming black on being boiled	Blue, soluble in excess, affording a deep-blue liquid	All alkalies—Carbonate.
Bismuth.					
Oxide	Black sulphide	Black sulphide	White hydrate, insoluble	Same as potass	
Cadmium.	Yellow sulphide	Yellow sulphide	White hydrate, insoluble	White hydrate, readily soluble	Alkalies—White carbonate insoluble in excess.
Gold.					
Peroxide	Black sulphide	Black sulphide, soluble in excess of the test	None.—In very concentrated solutions a yellow peroxide	Yellow fulminating compound	
Platina.					
Peroxide	From acid and neutral solutions, black-brown sulphide	Black-brown sulphide, soluble in excess of the test	Yellow crystalline double salt Both these precipitates may be redissolved in excess of precipitants, on being boiled therein	Same as potass	
Antimony.					
Oxide	Scarce from neutral; orange-red sulphide from acid solutions	Orange-red sulphide, soluble in excess	White hydrate, soluble in excess	White hydrate, insoluble in excess	Alkalies — Same as ammonia.
Tin.					
Protoxide	From neutral and acid solution, a brown sulphide	Brown sulphide, scarcely soluble in excess—Yellow bisulphide if the test contain free sulphur	White hydrate, soluble in excess	White hydrate, insoluble in excess	Do.
Peroxide	Yellow bisulphide, from acid and neutral solutions	Yellow bisulphide, soluble in excess of the test	Do.	Do.	Do.
Arsenic.					
White oxide, or arsenious acid	Yellow sulphide in acid, and none in alkaline solutions	None till the addition of an acid	Form with alkalies, &c., arsenites and arseniates. See article "Arsenic" for full tests (p. 381, *et seq.*)		
Arsenic acid	None in alkaline and neutral; yellow sulphide in acid solutions	Do.			
Uranium.					
Oxide	None	Brown sulphide	Yellow hydrate	Soda—Same as potass	

By means of the indications thus afforded by hydrosulphuric acid and hydro-sulphate of ammonia, the characteristics of the metals, in respect to their sulphides, are readily grouped; and hence a great assistance is afforded in analytical investigations. The results obtained by the addition of the alkalies and their carbonates are equally valuable; and the previous tables will thus be found of essential service to the student. As they are the result of direct experiment, he may place every reliance on them, although a repetition of the experiments will prove of great use, as tending to impress the facts on the mind.

We have thus afforded the student ample means for commencing a course of qualitative analysis. Commencing with bodies of which he knows the constitution, or can find it by referring to our previous pages, he may gradually pass on to examine others of a more complex character. From such he may proceed to analyse minerals of various kinds; and having acquired tact, skill, extended information, keenness of observation, and last, but by no means least, *patience*, he will be qualified to detect the presence of poisons, under circumstances in which, from the minuteness of their presence, all his chemical knowledge and qualifications will be called into exercise. We shall now give general directions for the prosecution of *quantitative* analysis, presuming that our readers have already acquired sufficient information in the previous department of analytical research to enable them to make further progress.

INORGANIC QUANTITATIVE ANALYSIS.

Whilst in the qualitative analysis of any substance we are content to simply ascertain the *presence* of the various constituents, the object of quantitative analysis is that of finding the *quantity* of each substance composing the body under examination. We need hardly state that great skill and care in manipulating is required. In former days 100 grains were generally taken for an analysis; a course which, whilst in appearance would afford a chance of obtaining reliable results, actually defeated that object, by the diffusion, of both the substance tested and the reagent, in large quantities of liquids. The operations, of course, were on the large scale. Furnaces, vessels, and every apparatus were of the largest size; and a laboratory for such purposes could only be commanded by persons possessed of great pecuniary resources. At the present time, a table, a gas-furnace, test-tubes, and other small apparatus, are considered quite sufficient for all purposes. Only a few grains of any substance are needed; and in some cases less than a grain satisfies the requirements of an experienced chemist. Former sources of error are entirely avoided; and an accuracy, which in the earlier days of chemical science was not dreamt of, is expected from even the pupil; much more so from the professor. It will be impossible for us to give detailed instructions for the quantitative analysis of every class of bodies which come under examination in the laboratory. For such information we must refer our readers to works exclusively devoted to the subject. We shall be content to give general outlines for the direction of the student, and must leave to his industry and skill the chance of his becoming proficient in this interesting branch of experimental science.

Of course, before attempting to ascertain the relative quantities of the constituents in any substance, their existence must be ascertained by means of a qualitative analysis. And this must not be cursorily performed; for if any one, however minute, of the bodies constituting the whole quantity be neglected in a preliminary examination, then an accurate quantitative analysis cannot be effected. Hence, as we have already remarked, considerable chemical experience is necessary to qualify any one for an analyst. A vast variety of minor circumstances must also be kept in mind. Thus, some substances almost entirely insoluble in distilled water, are readily dissolved if others are present; and this often occurs through the introduction of salts, &c., in the course of analysis. For instance, many oxides, &c., precipitated by an exact equivalent of potass and ammonia, are insoluble in water. If, however, an excess of the test be present, a portion of the precipitate will be redissolved, and a source of serious error introduced. Many cases of this kind may be noticed in the tables of tests, &c., in our previous pages. Occasionally, the presence of certain salts, or their absence, will interfere with precipitation completely. Thus, the sulphate of lead is readily precipitated from the acetate by means of sulphuric acid, or a sulphate; but if the sulphate of ammonia, or other salts of that alkali be present, precipitation may be entirely prevented.

In quantitative analysis, it is of the utmost importance that the whole of the precipitate be thrown down. This will not occur where a sufficiency of liquid is not used; but caution in this respect is requisite, for an excess may interfere injuriously—*e. g.*, the sulphate of lime, which is barely soluble in water, and may be almost entirely precipitated in strong solutions; whilst a portion will remain in solution in those which are soluble. Temperature, also, materially influences precipitation; for occasionally a precipitate will remain suspended in the fluid at ordinary temperatures; whilst, on boiling, it will be speedily thrown down. Such is the case with the ferro-cyanide of iron, and many other salts. At times the physical condition of the precipitating vessel will influence the result—*e. g.*, the bitartrate of potass will only be thrown down on a roughened surface.

Great care is required in collecting precipitates during filtration. In transferring them from the precipitating jar to the filter, a lipped vessel should always be used, which should be repeatedly washed out, and the washing added to the filtrate. The choice of filtering-paper is also of great importance. Two sorts are sold for chemical purposes; one being of a porous, open nature, suitable for common operations; and the other of a fine texture, which alone should be employed for analytical purposes. All paper contains a portion of earthy matter, the quantity of which varies according to the material employed, and the water used at the mill. In some parts of England we have detected both lead and iron in paper manufactured with water derived from proximity to mines of those metals. It is therefore a good plan to purchase a quantity of filtering-paper of one manufacture; and having ascertained the amount of ash it affords per 100 grains, by burning it—the next step is to make a qualitative analysis of the ash, so as to learn the possible nature of the impurity it may communicate. Some recommend to soak the paper in dilute nitric or hydrochloric acids; but this, whilst not affording any great advantage, is a troublesome process; and even, if not carefully employed, may introduce fresh sources of error. Thus, if the paper were soaked in hydrochloric acid, and every trace of the latter had not been removed, an analysis of any substance containing salts of silver or lead, would afford a deficiency of the base, by the conversion of a portion into a chloride of the metal, which would most likely remain in the pores of the paper itself.

In very delicate investigations account must be taken of the moisture which the paper contains. Persons unaccustomed to the delicate nature of some analyses, would scarcely credit how necessary it is to ensure accuracy in all respects. It is best to use the filtering-paper after completely drying it. Pieces are then to be cut off, as near as possible the same size, one of which is employed to weigh the substance before analysis, and the others in its course; for nothing should be weighed in the scale-pan itself. The exact weight of the dried filter must, of course, be ascertained, and carefully noted down. It is by no means a useless plan to make a nick on all the papers likely to be used for one analysis, as by that means a chance of error may be avoided; and no inconvenience can arise, because they can thereby be all identified as belonging to the same kind of paper, and to be used for the same purpose.

For quantitative analysis a most delicate balance is required. In the previous experiments, any pair of scales capable of weighing as low as grains, may be employed; but in estimating the quantities of constituents, a balance which will weigh accurately to the $\frac{1}{1000}$th part of a grain, is absolutely needed. Of course, we cannot recommend the instrument made by any particular manufacturer; but we may point out various particulars, to which the attention of our readers must be directed, if they would obtain reliable results in their investigations.

In the balance, we observe a lever whose fulcrum is midway between its two extremities, and which, when perfect, should lie in an exact horizontal line, or parallel to one drawn through the fulcrum. The operation of weighing consists in the addition of two weights, one at either extremity of the lever; which, if in excess of each other, shall cause the lever to be depressed beneath the horizontal, on the side on which the excess rests; but which, if equal to each other, shall allow the whole lever to be parallel to the horizontal line of rest. Now, at first sight it would seem to be an easy matter, according to the skill of the workman, to construct an accurate balance; but one or two points have to be attended to. That of the centre of gravity is an essential one; for if that be in the centre of the lever, then the scales will have a tendency to "set" when over-loaded—that is, the horizontal line will not be regained when even exactly the same weights are on each part of the scale. This difficulty is overcome by so arranging the centre of oscillation, or that on which the beam turns, with the centre of gravity, so that the latter may be above the former. In proportion as this point is attended to, then, within certain limits, does the value of the balance depend. The homogeneous character of the metal of which the balance is composed, is another matter of some importance; for although, theoretically, we *presume* the lever to be inflexible, it is really not so; and an excess of weight, or carelessness of weighing, may seriously damage the balance-beam—in many cases partly through a want of homogeneity in its parts.

In the operation of weighing, many precautions have to be attended to. As we have already said, no substance should be weighed except on paper or in a glass tube; for if the operator be neglectful of this, the scale-pan may become oxidated, and so prove heavier than its fellow. Besides, portions of the substance are sure to adhere; and the rough usage required to remove them is totally opposed to the delicate treatment a good balance should receive at the hands of its owner. Heated substances should not be weighed, because, as they would tend to expand the arm of the beam under which they are placed, they would seem to weigh heavier than they really did; and hence a serious source of error would be introduced.

The pans should never be loaded whilst suspended from the arms of the beam. This never need be done; for in all chemical balances, arrangements are made by which the pans, arms, &c., can all be suspended simultaneously for the operation of weighing, and be brought to rest again when it is concluded. By such means all undue or unnecessary strain on the arms of the balance is avoided, and a highly possible source of injury removed. The balance should always be kept away from the fumes of acids, &c. They are generally enclosed in glass cases, which, except when in use, prevent any great risk of injury.

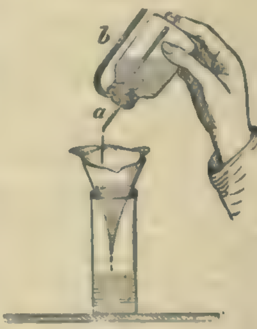
The analyst will require a considerable variety of weights, from the fraction of a grain upward; the smaller being made of platina. Small weights are readily made from fine platina wire by weighing a portion, and then dividing it for halves, quarters, &c., of the normal weights. The weights should not be touched by the finger, but put into, and removed from, the scale-pan by means of a pair of tongs. Small pieces of tin or lead-foil, or small shot, are useful in counterpoising crucibles, &c. They must be kept scrupulously clean. Glass beads are preferable, because they do not acquire an increase of weight by oxidation.

It must be kept in mind, that many substances, whilst being weighed, acquire a certain amount of moisture from the air, and so increase in weight; as, for instance, caustic potass, soda, barytes, lime, &c. These are termed hygrometric substances; and such should always be weighed in very thin test-tubes. This is a point of considerable importance in organic analysis, in which the substances operated on are generally minute in quantity, and the black oxide with which they are burned being hygrometric.

In very delicate balances, which will turn with at least the $\frac{1}{1000}$th part of the weight in the scale—say with a load of 500 to 800 grains—the indications of an index will assist in a further attainment of accurate weighing, and thereby another decimal figure may be added to the result. This, however, can only be done by an experienced person. Meanwhile, we direct the attention of the tyro to the fact, so that he may gradually acquire a knowledge of the peculiarities of the chemical balance.

Before proceeding to make remarks specially applicable to certain precipitates, we may give a few more general directions. The precipitate having been collected on the filter, must be carefully washed by means of a gentle stream of water, if insoluble in that liquid; and this is best done by means of a washing-bottle. This may be of any form or shape: a convenient one is represented in the margin. It consists of an ordinary glass bottle, fitted wth two glass tubes, having a bore equal to about the tenth of an inch. That marked *a*, is one from which the water flows; whilst the air passes through *b*, to take the place of the escaping fluid. It is easily filled by drawing air out by the mouth through the tube *b*, whilst *a* is immersed in a vessel of distilled water. When thus filled, the bottle is used for washing, as shown in the cut. The tube *a* should be drawn to a jet-like point, so that the stream of water may flow gently on to the precipitate, and not drive holes in the filter.

Fig. 74.



The removal of the filter from the funnel requires care, because the filtering-paper has little tenacity, and hence may readily break in pieces. The best plan is to tilt the funnel on one side, and blow between the paper and the glass surface. This will separate them, and a good hold may then be taken of the filter for its removal. The next step is that of drying the precipitate; and this requires care. In most cases a water-bath is all that is requisite; and one of these is readily constructed by means of two evaporating dishes. The filter being placed in one, it is floated in another containing water kept at a boiling state. This or any other similar plan may be adopted. Water-baths, however, made in Berlin porcelain, may be procured of the instrument-makers. If a higher temperature be required, as for the evaporation of acids, &c., then a sand-bath must be used; for which purpose an iron or copper bowl, filled with sand, and placed over the spirit-lamp or furnace, will answer. The evaporating dish containing the filter, &c., to be dried, is placed in the sand. In some cases it is desirable to burn the filter, and to weigh the residual precipitate. This is best done in a Berlin or platina crucible. We must here warn our readers never to burn precipitates containing oxides of metals proper, either with paper or in a platina crucible. The charcoal of the paper would most likely reduce the metal. And metals such as lead, &c., if coming in contact with a red-hot platina crucible, would render it useless by forming an alloy. The alkalies, earths, and their compounds alone, should find a place in a platina vessel at a high temperature. Some substances, during drying, decrepitate; that is, they cast off small portions, owing to the formation of steam, which, expanding between their particles, affords small explosions. Such occasion loss; and a cover of any kind, such as another evaporating dish, should be inverted over that containing the drying precipitate. In employing the sand-bath, care should be taken, if a filter is being dried, that it do not attain a temperature sufficient to char it, as that would occasion a loss of weight, owing to the decomposition of the paper.

When a filter is very dry it also becomes rigid; and the least touch may break it, or cause the dry powder it contains to jerk out. This is a point requiring attention and care. We have seen young students destroy all the hoped-for reward of their previous attempts, for want of delicacy of touch and manipulation in this respect.

In some instances, the only result obtained—which is, generally speaking, far from being satisfactory—is that of crystalline product. Under this head the alkalies must be placed; as, with little exception, no solid precipitate can be obtained from which they can be estimated. Potass, for instance, may be weighed as a sulphate, nitrate, &c. Soda may be similarly estimated. In such, and many other similar instances, when crystallisation is had recourse to, it must carefully be noticed whether the crystals are likely to possess water as a constituent. We do not here refer to water in a liquid state, but in chemical combination. In some cases crystals lose their water of crystallisation, and from this cause serious loss may occur in the estimation of the base. The water may not be driven off at the boiling temperature; hence a water-bath may be used. Generally speaking, all such salts, however, suffer loss when the temperature is raised beyond that point; and the sand-bath must therefore be employed with great caution.

Presuming that the student has mastered the details through which we have been proceeding, his last step will be that of finding the relative value in respect to the chemical equivalents of bases, &c., of the products which he has obtained. This, however, is not a question of very great difficulty; because the simplest rules of arithmetic alone are involved. In fact, the Rule of Three or Proportion is that which is to be employed, and of which we shall give some examples.

Suppose, for example, that in Experiment 82, p. 397, in our remarks on qualitative analysis, 100 grains of marble had been employed, and that after dissolving the solid in hydrochloric acid, of which a known weight had been added, it was found that 44 grains had been lost. Now, as by the subsequent part of the process it was discovered that the gas which had escaped was carbonic acid, and that the solid with which the acid was in combination was lime, we wish to know how much lime was actually present in 100 grains of marble. As that substance lost 44 grains of carbonic acid, and as 28 grains of lime unite with 22 grains of carbonic acid to form 50 grains of marble, we should have the following proportions :—

	One equivalent of CO_2.		The amount of CO_2 in 100 grains of marble.		One equivalent of lime, Ca O
As	22	:	44	: :	28

Now multiplying 44 by 28, and dividing by the first term as in ordinary Proportion, we obtain—

44
28

352
88

22) 1232

56

Hence there will be 56 grains of lime in 100 grains of marble. Of course this long sum was not required to prove the fact; as it is evident that there will be twice as much lime in 100 as in 50 grains of marble; but we give this easy illustration that our readers may understand the process.

We will give another illustration, which, although on the same principle, yet involves a little more apparent difficulty. We will suppose that an alloy has been dissolved in nitric acid, and that the silver has been precipitated as chloride of silver, of which there are 48 grains obtained; how much chlorine and silver are individually in that quantity?

Now the equivalent of chloride of silver is—

Chlorine	36
Silver	108
	Or 144

And we must accordingly make two proportions to ascertain the amount of each element present.

Commencing with the silver, we say—

	Ar Cl	Ar Cl		Ar		Ar
As	144	: 48	: :	108	:	36 as below.

108
48

864
432

144) 5184 (36 grains of silver.
432

864
864

In this the 48 is placed in the second term of the proportion, because the answer must necessarily be smaller than the third term.

With the chlorine we say—

	Ar Cl	Ar Cl		Cl		Cl
As	144	: 48	: :	36	:	12 grains as below.

36
48

288
144

144) 1728 (12 grains of chlorine.
144

288
288

Now, by the first proportion, we find of silver	36 grs.
,, by the second proportion, of chlorine	12 ,,
	48

Hence we find the total equal to that of the number of grains found in the precipitate.

We shall now take another case; in which, having ascertained, as above, the exact amount of each substance in a precipitate, the per-centage of each, or its proportion in one hundred grains, is desired. This is a very common question, especially in assaying and metallurgical processes generally.

The method to be adopted is precisely similar to that illustrated above; and we will take our last example to show the *modus operandi.*

Supposing that the 48 grains of chloride of silver were precipitated from 600 grains of a lead ore containing silver: how much *per cent.* of silver does the ore contain? We state it as—

600 : 36 : : 100 : 6 per cent. as below.
36

600) 3600 (6
3600

Hence such an ore would contain 6 per cent. of metallic silver; or, in other words, every 100 grains of the ore will afford six grains of pure silver.

Occasionally, the proposition is in the reverse form; that is, the per-centage being given—required the amount in any number of grains; say, for instance, in 600. Then we state it—

: 100 : 6 : 600
6

100 3600

36, or 36 grains in 600 of the ore.

Our readers not well conversant with arithmetic, must be cautious how they draw out their proportions. Some years ago, we entrusted to a pupil the analysis of some copper ore, by way of trying his abilities. We gave him fifty grains on which to try his skill. In the course of a day or so, he stated that he had obtained 200 grains of pure copper from it. The result was certainly astonishing, but its wonder immediately lessened on the arithmetical process being examined. The analysis was near enough; but in casting the proportion, he had misstated it, and brought out 200 grains instead of two per cent., by some mysterious process of calculation.

It will be seen, from the preceding remarks, that an extended knowledge of the equivalents and constitution of chemical compounds is essential to progress in quantitative analysis, and a free use of the symbols is equally requisite, as much time is saved thereby. It is an excellent plan for the student to copy out the equivalents of all the simple and compound bodies he can gain information of, and writing them, in a tabular form, on a piece of cardboard, he should hang it up in some conspicuous place in his laboratory. By this much time is saved, and reference to books is rendered unnecessary. The latter soon get spoilt in a laboratory. It is also advisable to have extended tables of specific gravities, and other particulars, for the purpose of constant reference, which should always be ready to hand.

The foregoing general hints will be sufficient to remind the student of many important matters requiring his attention whilst pursuing quantitative analysis. We shall now pass on to give an instance or two of the practical method, and to mention various particulars which have to be attended to in special cases. We must mention, however, the following rules as never in any case to be neglected.

1. A qualitative analysis should always first be made.
2. Care must be taken in quantitative analysis never to lose a drop of solution or a particle of a precipitate.
3. All washings must be added to the original solution from which the precipitate has been thrown down, and the precipitate itself must be washed (if insoluble in water) until every trace of soluble matter has been removed.
4. The precipitate must be thoroughly and carefully dried. It is not to be weighed till cool; and if hygrometric, must, for that purpose, be placed in a thin glass tube, or between two watch-glasses.
5. And, lastly, every step of the analysis must be carefully noted down as it occurs, and each vessel should be labelled with letters, &c., corresponding to those attached to entries in the note-book.

PRACTICAL ILLUSTRATIONS.—For the sake of more fully explaining the methods adopted in quantitative analysis, we shall select the following examples, which may be taken as types of the general plans to be followed in most cases. There will be sufficient variety to enable the student to comprehend numerous other instances with which he may meet.

Experiment 90.—Dissolve a three-penny piece in nitric acid. Now, as silver is always alloyed with copper to form the material from which our coin is manufactured, nitrates of silver and copper will be left in solution. It is required to make an analysis affording the actual weight of each metal composing the coin. The solution is to be diluted with distilled water, and to this a solution of common salt is to be added so long as a white precipitate is formed. The silver is thus removed as the chloride, whilst the copper remains in solution.

(*a.*) Pour solution and precipitate cautiously and gently on to a weighed filter,* supported in a funnel, and receive the liquid, which will run through, in another vessel. Wet the filter with distilled water before pouring in the solution, &c.† When all the liquid has passed through, wash the precipitate by means of the washing-bottle,‡ so as to remove every trace of the copper solution, &c. As the latter will spread by capillary attraction through every part of the paper, wash the filter as carefully as the precipitate itself. The washings, of course, must run through to the solution in the lower vessel, as they will contain a minute portion of copper. When the washing is completed, remove the filter carefully from the funnel,§ and place it on the water-bath, leaving it there till completely dry. Whilst the chloride of silver is being dried, the copper left in solution may be obtained.

(*b.*) If the solution left after removing the chloride have been largely increased in bulk by using too much water for washing, evaporate until not more than an ounce in measure is left. To this add a little hydrochloric acid, and then a few zinc shavings or some clean iron scraps. Heat the solution gently for some time, and then evaporate nearly to dryness. Add a little dilute sulphuric acid, to remove all excess of iron or zinc. The precipitate produced will be metallic copper, which is to be collected on a weighed filter, and well washed. It is then to be quickly dried by means of the water-bath.

The next step is to weigh each product of the analysis. We will take the chloride of silver first. If the operation have been properly conducted, and supposing the filter to weigh 20 grains, it and the precipitate together should weigh $46\frac{3}{4}$ grains nearly. Hence the precipitate will afford $26\frac{3}{4}$ grains of chloride of silver. The amount of silver is easily found from this;‖ for the proportion will be—

As an equivalent of chloride of silver is to that of the product of the analysis, so is the amount of silver contained in an equivalent to that contained in the precipitate; or, expressed in figures—

$$\text{As } 144 \;:\; 26\tfrac{3}{4} \;::\; 108 \;:\; 20\tfrac{1}{16} \text{ grains.}$$

$$\begin{array}{r@{\,}l}
 & 108 \\
 & 26\frac{3}{4} \\
\hline
 & 648 \\
 & 216 \\
 & 54 \\
 & 27 \\
\hline
144) & 2889\ (20\tfrac{9}{144} = 20\tfrac{1}{16} \text{ grains.} \\
 & 288 \\
\hline
 & 9
\end{array}$$

We thus find that the coin contained $20\frac{1}{16}$ grains of pure silver.

If the copper be then weighed after drying, it will afford about $1\frac{3}{4}$ grains. Thus the composition of the three-penny piece will be—

Of silver	$20\frac{1}{16}$ grains
Copper...........................	$1\frac{3}{4}$
Total	$21\frac{13}{16}$ grains.

Which is a little less than that of the new coin, as issued from the mint.

It is usual to express all figures in an analysis in whole numbers and decimals; the latter being used in place of fractions: the results of the analysis will then stand as under:—

Silver	20·0625
Copper...........................	1·7500
Total	21·8125 grains.

The above examples may be easily repeated with successful results, because both the products of the operations are insoluble in water; and therefore no error can arise except that proceeding from carelessness. In many instances, the slight solubility of a precipitate interferes with the accuracy of the result, and in such cases the total of the original weight is made up after analysis, by adding in to the amounts of the found bodies, figures representing the actual loss, and marking them as such.

In the next example we shall confine our attention to weighing only one of the substances present in the body analysed—namely, the sulphuric acid.

Experiment 91.—Dissolve twenty grains of the sulphate of potash in an ounce of distilled water, and add thereto so much solution of the chloride of barium as is required to precipitate the whole of the acid as sulphate of baryta. When the precipitate is complete, filter, wash, and dry as before; and after drying, weigh with the filter. With such a quantity of the sulphate of potash, a precipitate of twenty-nine grains of sulphate of baryta will be produced. Now the equivalent of sulphate of baryta = 116; and that of sulphuric acid in the anhydrous state = 40. And hence we have,

---

* See *ante*, p. 403.

† *Ante*, p. 396.

‡ *Ante*, p. 404.

§ See *ante*, p. 404.

‖ *Ante*, p. 405.

$$\begin{array}{lllllll} \text{As } 116 & : & 29 & :: & 40 & : & 10 \\ & & & & 29 & & \\ \hline & & & & 360 & & \\ & & & & 80 & & \\ \hline & & & 116\,) & 1160 & (\,10 \text{ grains.} & \\ & & & & 1160 & & \end{array}$$

Hence we find that twenty grains of sulphate of potass contain, according to the analysis, ten grains of sulphuric acid. The actual composition of the salt is

$$\text{Equivalent of} \left\{ \begin{array}{l} \text{Sulphate of} \\ \quad \text{potass} \ldots \end{array} \right\} = \begin{array}{ll} \text{Sulphuric acid} & 40 \\ \text{Potass} \;.\;.\;.\;. & 47{\cdot}2 \\ \hline & 87{\cdot}2 \end{array}$$

So that a little error has been made in such an analysis.

The preceding will afford initiative experiments for the beginner; and by practising simple examples, he will gradually acquire the dexterity and accuracy only obtained by constant practice and experience.

In quantitative analysis, there are some processes which are specially applicable for certain purposes. One of these, cupellation, we shall now describe, because it is extensively used both by analytical chemists and by metallurgists in refining and assaying. A peculiar form of furnace is requisite for this operation, and an instrument called a muffle. In the preceding engraving, a view of a furnace externally, and as arranged for the reception of a muffle, is shown. On the left hand view, an opening is seen in the body of the furnace, into which the muffle is introduced.

Fig. 75.

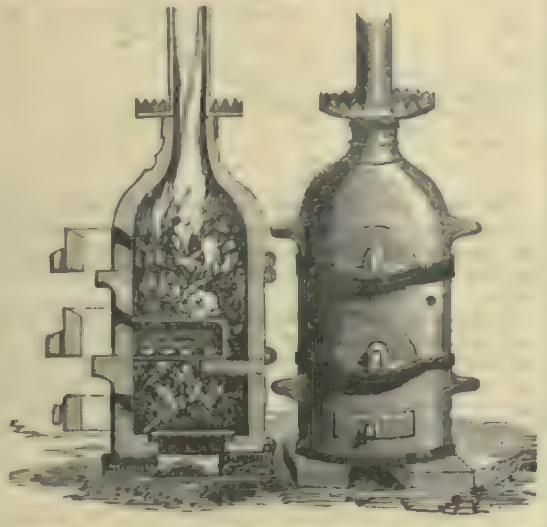


Fig. 76.

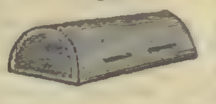


The muffle is made of earthenware, and in this the cupel is placed. A view of an ordinary form of the muffle is represented in the margin. The cupel itself is a small vessel, made of bone ashes, which are employed on account of their porosity.

The operation of cupellation depends on the fact, that, when gold and silver, which do not become oxidised at a red heat, are alloyed with metals that do, the latter separate from the noble metals, leaving them in an almost pure state. Supposing silver is to be assayed, a few grains are put into some pure lead foil. The two are then placed in the muffle, already red-hot in the furnace. By the peculiar arrangement of the whole apparatus, a current of air passes over the silver and lead; and so long as lead or any other readily oxidisable metal remains, the two present a dull appearance. The operator must carefully watch; and quite suddenly he will perceive the silver to present a most brilliant appearance, owing at that moment to the almost entire removal of all the baser metals. The process is then concluded; and the cupel having been allowed to cool, the button of pure metal may be removed and weighed. The cupellation of gold is conducted in a similar manner, with the exception that silver and lead are both employed, instead of lead by itself. By this an alloy of silver and gold is produced at the conclusion of the cupellation. The silver is afterwards removed by means of nitric acid; the gold being thus left in a pure state.

This process is one requiring considerable care; for at times the metals, at the instant of their becoming pure, swell up. This is especially the case with silver; for its bead occasionally bursts, by which a loss of metal is sustained.

With this we shall conclude our remarks on quantitative analysis, so far as inorganic bodies are concerned. The subject is of so extensive a character, that were we to attempt to give full details, we should have to far exceed the limits which our plan imposes on us. We have already named the best works which the student can consult.* In them almost every substance which can be met with, is treated on in full particulars. Analysis, from its numerous uses, has become a distinct branch of chemical science; and one in which, to be proficient, requires an undivided attention. Our object has been to give a general idea of the subject, so that the beginner may have an opportunity of learning leading principles and methods only.

CHAPTER VI.

THE CHEMISTRY OF VEGETABLE SUBSTANCES, AND THEIR PRODUCTS.

It has long been customary to arrange the description of the chemical properties of organic bodies under the head of Organic Chemistry; but owing to the extension of our knowledge during the last few years, the distinction which had existed between the animate and inanimate creation, in a chemical point of view, has been removed, or so greatly modified as to scarcely exist. We propose, therefore, to devote the following chapters to a description of such bodies as exist in, or are, the products of vegetable substances only. With respect to the chemistry of animal life, that has been so fully dilated on in the chapter on Food, &c., as to leave nothing to add to it.

During the last twenty years, the study of the chemistry of vegetable substances, &c., has made astonishing progress. To Dr. Liebig, of Giessen, we are preeminently indebted for masterly and accurate researches in this branch of experimental science. It has been chiefly owing to his discoveries that so deep an interest has been generally taken in the subject, and that agriculture has advanced to the rank of a science, in place of being a pursuit of chance and speculation, as it had formerly existed.

In other branches of industry, similar results have accrued, owing to the rapid applications which have been made of newly-developed principles. These have been so numerous as to defy enumeration. In the art of dyeing, for instance, the discovery and use of aniline has completed an entire revolution in the processes employed; and gas-tar, which previously was employed almost solely for the preservation of timber, is now the source of those beautiful colours, mauve, Magenta, &c., which afford such rich tints to cotton and silken fabrics.

---

* See *ante*, p. 397.

We shall first give a general account of such substances, &c., which being directly or mediately produced from plants, have for their chief component parts, the elements of hydrogen, oxygen, and carbon, or any two of these. Having thus, as it were, given the elementary principles of this department of chemical science, we shall proceed to examine other and more complex bodies.

With scarcely an exception, vegetable bodies consist entirely of carbon and water, or the elements of water united with carbon in various proportions. To familiarise the mind of the student with the products of vegetable substances resulting from chemical action, we shall here give the formulæ of water, carbonic acid, and other compounds, in which these or their elements are involved. We shall use their symbols, to save space in indicating their composition.

Water . . .	HO
Carbonic acid . .	CO_2
Alcohol . . .	$C_4 H_6 O_2$
Ether . . .	$C_4 H_5 O$
Acetic acid . .	$C_4 H_3 O_3$
Oxalic acid . .	$2CO + O = C_2 O_3$
Tartaric acid . .	$C_8 H_4 O_{10}$
Sugar . . .	$C_{12} H_{11} O_{11}$
Starch . . .	$C_{12} H_{10} O_{10}$

Now, on inspecting the above list, we find that a union of the same elements, in various proportions, is capable of producing substances having entirely different properties. Thus, alcohol, ether, acetic acid, tartaric acid, and sugar, each contain precisely the same elements, but in different proportions; and yet there is not the least apparent similarity in their specific properties. These facts just point out the extensive variety of forms and substances which carbon, oxygen, and hydrogen can produce by their union, and the learner may thus have some idea of the wide range of that interesting field of investigation into which we are now entering.

We shall here point out two singular and instructive facts connected with the composition of four of the substances to which we have called attention—namely, sugar, alcohol, ether, and acetic acid. In producing alcohol from sugar, as in the ordinary process of fermentation, we find that carbonic acid is largely produced, which passes off in a gaseous form. This accounts for the difference of composition between the sugar and alcohol. In producing ether from alcohol, we lose no carbonic acid, but only an equivalent of water; so that alcohol may be regarded as composed of ether + water. Acetic acid (which is the cause of the acid flavour of ordinary vinegar) is readily produced from alcohol, and in that process we lose three equivalents of hydrogen and gain one of oxygen, by the oxidising effect of the atmospheric air employed; so that acetic acid may be regarded as a compound of four equivalents of carbon united with three of water. We can thus produce from sugar, so far as we have gone, three different bodies having exactly the same elements in various proportions, each different, and yet chemically analogous.

Referring now for a moment to oxalic acid, we find that really consists of a union of carbonic oxide (CO) with carbonic acid (CO_2), for the two would afford two equivalents of carbon and three of oxygen, which is precisely the constitution of oxalic acid in an anhydrous state. But if we speak of ordinary oxalic acid, we shall find that it is combined with three equivalents of water (3HO), which would make the combination as follows:—

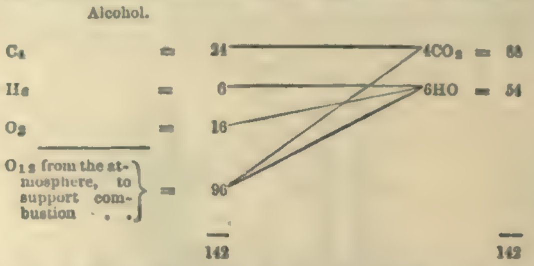
$$C_2 + O_3 + 3HO \text{ ; or, } C_2 + O_6 + H_3.$$

And in this formula we see how oxalic acid may be produced from starch or sugar (the usual source). Now, if we add concentrated sulphuric acid to oxalic acid, having the latter formula, decomposition ensues, its water is removed, and an equivalent, each of carbonic oxide and acid, is afforded.

As we proceed, we shall have to extend the number of elements in our formulæ, and include nitrogen. We shall, however, for the sake of simplicity, defer our remarks on this point till we have more fully described the simpler kinds of organic compounds.

The existence of carbon in vegetable bodies is constantly evidenced to our senses in the process of burning. Thus, in baking, toasting, roasting, and burning any vegetable body, a black mass is produced, which is owing to the carbon forming part of it being set free, as charcoal. In any of these processes, the hydrogen and part of the oxygen escape as water. The remaining portion of the oxygen combines with a portion of the carbon, and passes away as carbonic acid. Even the solid charcoal left, will gradually be converted into carbonic acid by combining with the atmospheric oxygen which surrounds it. The following formula shows the results of an entire combustion of a portion of absolute alcohol, which we shall take as a type of such results obtained during the combustion of other substances.

Results of the Combustion of an Equivalent of Alcohol.



We thus perceive, that by the combustion of one equivalent of alcohol with twelve of oxygen gained from the atmosphere, the oxidation of the spirit should produce four equivalents of carbonic acid and six of water.

In the early pages of this section, we have had frequent occasion to remark on the beautiful simplicity, and the value of the doctrine of chemical equivalents. But as we proceed in our investigation, we shall still further admire the sagacity of its discoverer. It is impossible to speak too highly of its use in this department of experimental science; in fact, organic chemistry has developed the nature of atomic values beyond the most sanguine expectations of the great Dalton.

The remarks and illustrations we have made, are, of course, only intended as introductory to our subject. We shall next speak of organic analysis, because it lays at the foundation of our investigations; and without its exercise it would be impossible to proceed a step in relating the natural history of the various substances we shall have to examine.

ORGANIC ANALYSIS.

In our previous pages* we gave extended directions for the qualitative and quantitative analysis of inorganic bodies. The principles and details we then explained, whilst incident to the analysis of organic bodies, are so, however, only to a limited extent, because our range over the nature of the elements with which we have to deal is also limited. In inorganic analysis we may happen to find any of about sixty different elements, and an almost interminable number of their compounds. In organic analysis we chiefly wish to detect the proportions of carbon, hydrogen, and oxygen present, and occasionally have to expect nitrogen. We do not trouble ourselves so much in reference to what we may call accidental substances, which are not absolutely essential to the typical constitution of

* See *ante*, pp. 394—407, inclusive.

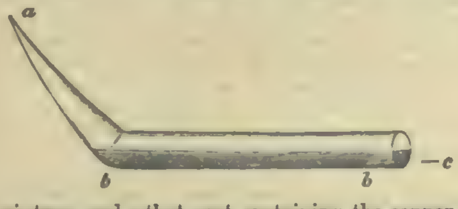
the bodies under examination, because we can almost always obtain vegetable products in a condition verging on absolute purity. Of course, if an analysis were required for commercial purposes we must be very exact in that respect also. Philosophically, we may consider flour, for instance, to be a compound of gluten and starch, and the analysis of it, and the detection of the elements present, would be restrained within the limits we have named. If, however, we have to conduct the analysis for agricultural purposes, we should pay far greater heed to what we have termed the "accidentals," such as silicious matter, phosphate of lime, &c., because the presence of such substances in the soil whence the wheat is produced is essential to its growth. If, therefore, we desired to analyse the wheat as a guide to the management of the soil, with respect to manure, &c., this matter then becomes of the highest importance. We shall, however, leave such till we enter upon the department of agricultural chemistry, to which they properly belong. Similar remarks are applicable to other technical applications of organic analysis.

We have already stated that the carbon, hydrogen, and oxygen existing in a vegetable product, are all resolvable into carbonic acid and water by the process of combustion, and the fact points out the course which must be adopted in conducting an analytical investigation. Many methods, both of a special and general nature, have been proposed; but the following is an outline of the plan usually adopted at the present time, and for which we are chiefly indebted to Dr. Liebig:—

(*a*). The substance to be analysed must, if solid, be reduced to as fine a powder as possible; this is best effected in a glazed Berlin porcelain mortar. After being powdered sufficiently fine, it may then be introduced into a tube, and exposed to a heat short of boiling water, if it will bear that without decomposition, which almost every substance will safely do.

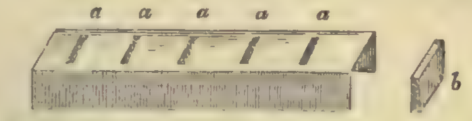
(*b*). It has then to be mixed with a considerable quantity of the black oxide of copper. This substance affords oxygen to any combustible mixed with it, when the two are exposed to a red heat. This is effected by introducing both into a German glass tube about eighteen inches long and an inch in diameter, which must have one end drawn out to a fine point. The substance to be analysed is to be mixed with the oxide whilst the latter is in a warm state, so as to prevent any danger of the absorption of moisture. A little clean oxide is first introduced into the tube, then the mixture of the substance and oxide; and some more oxide is then added, which, of course, will be at the open end of the tube. The following cut represents the tube as filled, *a* being the fine end, which is closed, *b b* the portion filled with the mixture, and *c* that part containing the copper turnings. When filled, the tube is to be laid horizontally, and gently tapped, by means of which the mixture will be spread evenly throughout the length. About three grains of the substance—which, of course, must be accurately weighed—is to be mixed with about an ounce to an ounce and a-half of the oxide.

Fig. 77.



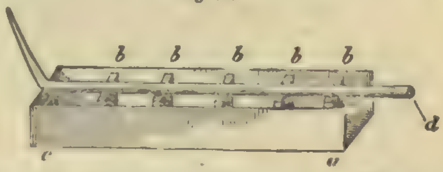
(*c*). This tube is then placed in a peculiar shaped furnace, so that the combustion may proceed in a gradual manner, commencing from the wide end of the tube, till it is completed at the narrow end, which is to be last heated. The wide end, however, projects beyond the furnace, for reasons we shall presently mention. The furnace is made of wrought iron plate, and should be about a foot long, and four inches wide and deep. At about two inches distance throughout its length, holes half an inch wide, and two inches long, are to be cut—*a*, *a*, *a*, *a*, *a*, *a*, as in the following figure, which represents the furnace, with the lower part uppermost (Fig. 78). Between each of these holes a small iron upright is placed (see *b* in Fig. 78), on which the tube is to rest during the process of combustion.

Fig. 78.



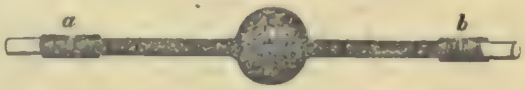
The fuel used is charcoal, which is first introduced in small quantities, at *a*, and gradually added, so as to carry on the combustion from *a* to *c* (Fig. 79). By these means a complete combination of the elements contained in the substance in the tube is effected, with the oxygen of the oxide of copper.

Fig. 79.



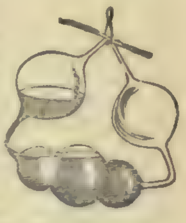
(*d*). At the end *d*, in the figure above, a tube is to be attached by means of an india-rubber connexion. This tube is to contain fused chloride of calcium, for the purpose of receiving the aqueous vapour generated during the combustion. By this, the amount of water produced is readily ascertained; and so the hydrogen and oxygen of the mixture are weighed away. A useful form of tube for this purpose is represented in the following cut (Fig. 80), in which is shown that part which is attached, by india rubber connexions, to the combustion tube, placed in the furnace; and *b*, that end attached to the potass apparatus, to be described immediately.

Fig. 80.



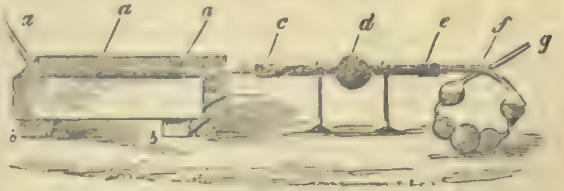
(*e*). The next piece of apparatus which is attached to the tube, shown above at *b*, is the potass bulb, represented in the annexed cut. The object of this is the absorption of carbonic acid, by means of pure liquid caustic potass, with which it is nearly filled; and by means of which the carbonic acid, produced during the combustion, becomes removed, and affords us the opportunity of ascertaining the amount of carbon in the body under examination. This potass bulb is attached, air-tight, to the end of the chloride of calcium tube, and so forms the end of the whole arrangement.

Fig. 81.



It will be perceived that we have only hitherto referred to the analyses of those substances containing carbon, hydrogen, and oxygen; and having described the different apparatus used, we subjoin a cut representing the whole in operation.

Fig. 82.



a a a, the combustion tube; *b b*, furnace resting on two bricks; *c*, connection of the combustion tube with the chloride of calcium tube, *d*; *e*, the connection between the chloride of calcium tube and, *f*, the potass apparatus; *g*, the open end of ditto.

The following particulars must be carefully attended to in a quantitative analysis conducted on the preceding plan.

If the article be a solid it must be most carefully weighed, and absence of hygrometric moisture should be carefully ensured. If, however, a liquid be examined, it should be inclosed in a glass tube, having a fine extremity. After the tube has been weighed, the liquid is to be introduced by expelling the air by heat, and holding the capillary opening beneath the surface of the liquid. A portion will thus be forced in by the pressure of the air. This tube is then to be let down to the closed end, marked *b*, in Fig. 77; and the remainder of the combustion tube is to be filled as before, with oxide of copper. The process is to be conducted as before, with the exception, that a gentle heat is to be applied to the end of the combustion tube holding the liquid. This will expel a portion of the liquid, which, passing as vapour to the heated portion of the oxide of copper, will be decomposed. Of course, this operation requires great care in manipulation; and but a little at a time of the liquid should be expelled, lest any portion might escape combustion.

The connections must all be as complete as possible, so as to be quite air-tight. The only open part will be the end of the potass apparatus. The latter should have its three lower bulbs *quite* full, and the two upper, *half* filled. At first a little air will pass off, which, of course, is owing to the expansion by heat of that contained in the combustion tube. The chloride of calcium tube must be accurately weighed when filled, each end being fitted with corks, which are to be weighed with it. These, of course, are to be removed on using the tube, but must be weighed again with it after the analysis is concluded, as their absence would of course introduce a source of error in the estimation of the increased weight due to the absorption of water, resulting from the combustion.

The same remarks hold good with the potass apparatus; for the amount of carbonic acid produced is known by the increase of weight, resulting from its absorption by the liquid. It must therefore be accurately weighed before and after the analysis, and the increase of weight indicates the amount of carbonic acid absorbed. At the moment of the analysis being concluded, which will be noticed when the liquid potass is not driven to and fro in the bulbs, the capillary end of the combustion tube is to be broken, and by the mouth—or, still better, the end of a syringe or air-pump attached by means of an india-rubber connection—air is to be drawn through the whole apparatus; and thus any water or carbonic acid unabsorbed is drawn through the calcium and potass tubes. It is true that a source of error may arise from the admission of air; but if this be not carried to any excess, the error will be but trifling.

When nitrogen is present in any substance to be analysed, a separate analysis must be effected to determine its presence. In place of filling the potass apparatus with that alkali, a solution of the chloride of platina is to be employed. The substance under examination is mixed with a portion of soda ash and lime, and heated as before. By this means the nitrogen produces ammonia, which, combining with the platina salt, forms the double chloride of ammonium and platina, in which form the nitrogen is estimated. The nature of the double salt has already been referred to under the head of Platina.[*]

The delicate nature of organic analysis requires long experience and great tact for its successful performance; and we should far exceed the limits imposed on us, were we to enter into every detail. Our object has been to point out general outlines; and we must refer our readers to works on the subject, in which full particulars are entered into, and every minutiæ of the processes which have been recommend are given in their proper order.

We may, however, just add, by way of illustration, the results of an analysis in which we shall suppose that the amount of carbon, hydrogen, and oxygen has been determined.

For instance, a combustible substance has been burned with oxide of copper, after the plans already recommended; and on weighing the chloride of calcium tube and contents, we find that its *increase* is 2·25 grains; and the *increase* in weight of the potass apparatus and contents, is 5·5 grains; how much hydrogen, carbon, and oxygen were present in the substance, supposing that it had weighed 3·75 grains?

1. We have 2·25 grains of water produced therefore. As the equiv. of water = 9 is to hydrogen = 1, so is 2·25 to ·25.

Or, As 9 : 1 : : 2·25 : $\frac{2{\cdot}25}{9}$ = ·25

Hence we have of hydrogen = ·25 grains.
And necessarily the rest is oxygen = 2·00 „
2·25 „

2. Now, we find that the contents of the potass apparatus sustained an increase of 5·5 grains. We therefore say—

As the equiv. of CO_2 = 22 is to C = 6, so is 5·5 to 1·5.

Or, As 22 : 6 : : 5·5 :
6

22) 33·0 (1·5
22

110
110

In other words, the substance analysed contained

Of hydrogen ·25 grains.
„ oxygen 2·00 „
„ carbon 1·50 „

Its original weight 3·75

If we wish to find the equivalents of each element present, we shall easily obtain them by multiplying each of the quantities in the above example by 4; thus—

H = ·25 × 4 = 1 = one equivalent.
O = 2·00 × 4 = 8 = „
C = 1·50 × 4 = 6 = „

Hence the supposititious substance is composed of one equivalent each, of hydrogen, oxygen, and carbon. We must here mention that we have invented a substance expressly for our purpose, so that it might contain only one equivalent of each element. This has been done only for the sake of simplicity; and our readers can easily extend our example to facts, by multiplying the proportion, as given above, by the formulæ for any chosen body, maintaining of course the relative proportions which exist therein.

Thus, if 3·75 grains of ether had been analysed, its formula being $C_4 + H_5 + O$, we should have had

Of hydrogen = ·507 grains.
„ oxygen = ·811 „
„ carbon = 2·432 „

3·750 „

Now, as the weight employed is nearly one-tenth of that of an equivalent of ether, which is 37, we shall nearly obtain the equivalent of each of the substances, by multiplying each of the above weights by ten. This result would be more exact if we used the factor $\frac{37}{3{\cdot}75}$; thus, the equivalent of the

Hydrogen $\frac{{\cdot}507 \times 37}{3{\cdot}75} = 5$

Oxygen $\frac{{\cdot}811 \times 37}{3{\cdot}75} = 8$

Carbon $\frac{2{\cdot}432 \times 37}{3{\cdot}75} = 24$

Or, ether = $C_4 + H_5 + O = 37$

---

[*] See *ante*, p. 372.

These illustrations will be sufficient to give our readers a general idea of the calculations involved in organic analysis, with the exception of that of the percentage, which is precisely similar to that explained already.*—We shall now proceed to investigate the properties of numerous organic substances—commencing with starch, sugar, &c.; and subsequently shall examine their chemical products, which are of a more complex character.

CHAPTER VII.

STARCH, SUGAR, ETC., AND THEIR PRODUCTS.

IN commencing the chemical history of vegetable products, we may observe that such must be to a large extent very cursory. The advance which chemical science has made during the last fifteen years in respect to the branch of organic products, has been so extensive, that were we to attempt to enter into it fully, we should require more space than has been devoted to all the subjects yet treated on in this volume. We are, therefore, compelled to select and indicate, rather than to define, all the divisions of this interesting department of experimental science.

The first substance to which we shall direct the attention of our readers is starch in its various forms. Starch is to be found in almost every plant, in some form or other. The most familiar instances which we can adduce of its presence, is that of its being found in wheat, potatoes, and other such plants as are used for common articles of food. If flour be carefully washed with *cold* water, a milky liquid passes off, which contains the starch of the wheat. If the liquid be allowed to settle, the starch will be deposited as a white powder, being separated from the gluten, which is the other component of the flour. If potatoes are broken up and pounded, the starch of which they are chiefly composed may be separated in a similar manner. During the existence of the potato disease, the fact that much starch may be obtained from potatoes, even in a diseased state, was utilised; and large quantities of that substance were thus obtained for the use of calico-printers, by which a considerable amount of wheat, previously used for that purpose, was saved. Starch forms, also, the chief part of arrow-root, sago, tapioca, and most other farinaceous foods.

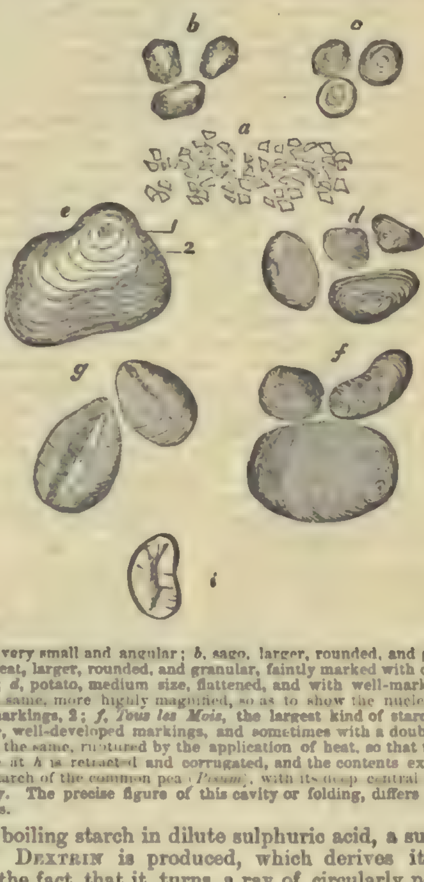
The physical characters of this substance vary with the sources whence it is obtained. To all external appearance, as viewed by the naked eye, it seems merely a granular powder; but if placed under a microscope, the various kinds of starch show cells, differing considerably in their external characteristics. The following engraving and description will assist our readers in this respect; and if they possess a microscope of ordinary power, they may readily make their own examinations of various forms of feculine products.

If starch be mixed with cold water, no notable change takes place; on mixing it with boiling water, however, the cells swell enormously, and eventually burst, as is familiarly known to be the case in cooking potatoes, making paste, and starch, for laundry use. By these means the real starch, which is enclosed in a membrane, is set free by the heat rupturing its covering.

We shall have eventually to notice the office which starch fulfils in reference to the propagation and growth of plants, and the simultaneous production of sugar. We shall now proceed to describe its chemical characters.

Starch is composed of carbon, hydrogen, and oxygen. Its symbol and proportions are $C_{12} H_{10} O_{10}$. It is precipitated by metallic oxides, and other substances in solution. Its proper test, however, is iodine, with which it forms a dark-blue colour, provided a cold solution of the test be employed. The simplest way of detecting its presence, is to add a solution of iodide of potassium to the substance supposed to contain starch; a few drops of sulphuric acid are then to be poured into the mixture; and if starch be present, a dark indigo colour is at once produced. A heated solution affords no such reaction. Starched paper dipped in a solution of iodide of potassium, is a test for the presence of free ozone, which sets the iodine free from the salt, and so produces a blue colour in proportion to its presence in a free state.

Fig. 83.—The more common forms of the Starch Cell.



a, rice, very small and angular; *b*, sago, larger, rounded, and granular; *c*, wheat, larger, rounded, and granular, faintly marked with concentric lines; *d*, potato, medium size, flattened, and with well-marked lines; *e*, the same, more highly magnified, so as to show the nucleus, 1, and the markings, 2; *f*, *Tous les Mois*, the largest kind of starch, of oval shape, well-developed markings, and sometimes with a double hilum, 1; *g*, the same, ruptured by the application of heat, so that the membrane at *h* is retracted and corrugated, and the contents exposed; *i*, the starch of the common pea (*Pisum*), with its deep central folding or cavity. The precise figure of this cavity or folding, differs in various grains.

By boiling starch in dilute sulphuric acid, a substance called DEXTRIN is produced, which derives its name from the fact that it turns a ray of circularly polarised light towards the right hand. LIGNIN is a substance forming a large proportion of cotton, and other fibrous materials; and these, by being boiled with diluted sulphuric acid, may be readily converted, by the change of their lignin, into grape-sugar. Of this singular fact we shall have to speak more fully hereafter.

GUMS proper, soluble in water, are a common product of plants. Soluble in cold water, they afford an adhesive solution, which is used for a variety of purposes. The ordinary gum-arabic may be taken as a type of the class; and from it a substance called *arabin* may be obtained, which is composed of $C_{12} H_{11} O_{11}$; and thus has a similar composition to sugar. The presence of gums in solution, is shown by their precipitation with the neutral or basic acetate of lead, also in solution.

INULIN is a substance analogous to starch, from which, however, it differs, in giving a brown colour when tested by iodine. It is insoluble in cold water, but dissolves in that liquid when heated.

PECTIN is somewhat analogous to starch. It is the jelly of fruits, such as is produced in the culinary process of preserving fruits. The red currant affords it in great abundance. It produces an acid called pectic acid, which combines with bases to form salts.

---

* See *ante*, p. 405.

We shall now pass on to consider a very important class of bodies, of which cane-sugar is the type, and from which a vast variety of articles of food and medicine may be obtained. The following, as well as the precedingly-named substances, are, as we shall observe, composed of oxygen, hydrogen, and carbon only.

SUGAR.—This important article of food may be obtained from various sources. That used in this country is the produce of the sugar-cane, so largely grown in tropical countries. The canes, when ripe, are cut down and conveyed to rolling-mills, between the rollers of which they are passed, so as to squeeze out the juice. This, when obtained in quantity, is heated; and slaked lime is added to clarify it. The clear liquid is then quickly evaporated and crystallised, being repeatedly stirred, to prevent the formation of large crystals. It is then drained to remove the molasses. Loaf-sugar is made from the product of the above process, purified by the addition of blood, &c., with which it is heated. The albumen separates all foreign matter; and thus sugar in a pure form may be obtained. In France, the beet-root is largely cultivated for the purpose of producing sugar; and in North America, large quantities are obtained from the maple-tree. The sap of this tree is obtained by "tapping," the juice being afterwards purified in a similar manner to that already described. Sugar, as we shall presently see, is produced from many sources, both of a vegetable and animal nature. Amongst the latter we may mention the sugar of goat, asses, and human milk.

Sugar, however, differs essentially in its chemical characters, according to the source whence it is obtained. From fruits—such as the grape—from honey and urine, during the disease of diabetes, the kind called *grape-sugar* is producible. This sort has not the sweetness of cane-sugar. It differs also in the form of its crystals, and in its less solubility in water.

The following table exhibits the chemical composition of various kinds of sugar:—

Cane-sugar	$C_{12}\ H_{11}\ O_{11}$
Grape "	$C_{12}\ H_{14}\ O_{14}$
Milk "	$C_{12}\ H_{12}\ O_{12}$

Cane-sugar may be converted into grape-sugar by means of dilute sulphuric acid.

A peculiar sugar, termed mannite, may be obtained from some plants, as the ash; it is the ordinary manna of commerce, and is composed of $C_{12}\ H_{14}\ O_{12}$.

Owing to the great demand for milk sugar in the homœopathic system of medicine, an immense quantity of this substance is now produced. Of this, some finely crystallised specimens were exhibited in the International Exhibition of 1862; they were produced in Switzerland, from the milk of goats.

We shall now proceed to speak of the various substances which may be obtained from sugar, by chemical and manufacturing processes.

OXALIC ACID.—If sugar be heated with dilute nitric acid, the well known oxalic acid is produced. The nitric acid parts with its oxygen, and so oxidises the sugar: crystals of the oxalic acid may thus be obtained, having a composition of $C_2\ O_3 + 3\ HO$, or a combination of one equivalent of acid with three of water. In this curious metamorphosis we have an astonishing change occurring between the material employed and the resulting product. The former, an article of food in universal request amongst all nations, may readily be converted into a most virulent poison, by comparatively simple means, affording another instance of the surprising changes which chemistry continually affords us.

Oxalic acid, if heated with sulphuric acid, undergoes decomposition, carbonic acid and carbonic oxide being produced. With bases, it forms the salts called oxalates, of which the binoxalate of potass and the oxalate of ammonia are the most important. The salt of potass exists in the plant called sorrel, and also in the English kind of rhubarb used as food, being the cause of its sour taste. It is sold in the shops as salts of sorrel, and is used for taking out ink-marks from linen, &c., having the power of forming a soluble salt with protoxide of iron. Oxalate of ammonia is chiefly used as a chemical test for lime, with which it forms an oxalate of lime, as an insoluble white powder. Oxalic acid unites also with oxides of metals, such as those of iron, copper, nickel, &c.

Saccharic acid may also be produced by the action of dilute nitric acid on sugar. It is composed of $C_{12}\ H_8\ O_{14} + 2\ HO$. Mucic acid is obtained by the action of nitric acid on gum, and the sugar of milk. Its composition is $C_{12}\ H_8\ O_{14} + 2\,HO$, and is therefore analogous to saccharic acid.

ALCOHOL.—This well-known liquid is the product of the vinous fermentation of grape-sugar. It is sold in commerce as spirits of wine. And to its presence in brandy, gin, rum, whiskey, wines and beer, their peculiar effects of producing intoxication are due. Alcohol is readily produced by adding yeast to a solution of sugar in water, at a temperature varying between 70° and 80° Fahrenheit. Carbonic acid is largely disengaged; and when fermentation is complete, and the liquid has become clear, it must be distilled in a retort, the first portions only being retained. The product is alcohol largely diluted with water. By repeated distillation with subcarbonate of potass, or dry lime, the water may be separated, until nearly absolute or pure alcohol is obtained. In its pure state, alcohol has a composition of $C_4\ H_6\ O_2$; compared with water = 1000, its specific gravity is 0·794. It boils at 173° Fahrenheit; and is converted into a vapour which is readily condensed, and which, like the liquid itself, is highly inflammable. "Proof spirit," such as is referred to in the excise laws, contains half pure alcohol, the remainder being water. Its specific gravity is 0·92 nearly. The uses of alcohol are very numerous in arts and manufactures. From its solvent powers it is used to make varnishes; but for this purpose, methylated spirits are now employed, of which we shall have to speak hereafter.

The most important use of alcohol is that of a beverage; and to this point we shall now direct the attention of our readers.

From our preceding remarks, it will be gathered that the fermentation of saccharine matter leads to the production of alcohol in all cases. This is strictly true; but the commercial products differ according to the source of the sugar. Thus, whiskey is obtained by the fermentation of the sugar of malt, as in beer. Rum is produced when coarse cane-sugar is employed. Brandy and wines, generally, are the produce of the juice of the grape. The differences of these liquids, then, are owing to the admixture of the alcohol they contain, with other substances dissolved and held in solution by it. In corn spirit, or that obtained from potatoes, a coarse offensive oil is found, which gives the peculiar smoky flavour of whiskey. In wines, the peculiar and distinguishing taste is due to the presence of an ether, which, at the same time, differs in each wine, and gives it its characteristic flavour—and so on. Again, the per-centage of pure alcohol varies greatly. In London porter, it does not exceed 3 or 4 per cent.; whilst in Spanish wines, such as sherry and port, as much as 20 to 30 per cent. is found; and brandy often contains as much as 50 per cent. of pure spirit. Although, therefore, the same chemical principles are involved in the manufacture of each kind of spirituous or fermented beverage, the modes of manufacture differ greatly. Beer, the favourite beverage of our own country, is produced from malt. Malt is produced from barley by a process which produces germination, and the simultaneous conversion of the starch of the seed into sugar. This is effected by moistening the seed, which should be kept together in masses; it thus heats, but is prevented from gaining too high a temperature by being repeatedly stirred on the malting-floor. It is then kiln-dried, which stops any further change. During this process a substance called *diastase* is produced, which, acting on the starch, converts it, eventually, into sugar.

The malt is crushed, and added to a proper proportion of water, at a temperature of 170° Fahrenheit. In this it is infused for some hours, and produces a sweet liquid, called wort. This is drawn off quite clear, and, being pumped up into coppers, is boiled with hops, which impart a bitter flavour, improve the beer, and assist in keeping it from any change which might deteriorate its flavour. If a considerable quantity of hops be used, bitter ale is produced, in which the flavour of the hop is predominant. In some beer, such as the Burton strong ale, more saccharine matter is left, and less hops used. Such ales have a highly feeding effect; whilst those of the bitter kind are excellent tonics.

After the boiling with hops is completed, the liquor is rapidly cooled, and yeast added to it, by which fermentation is effected. The difference of beer produced at the various breweries depends much on the management of this part of the process, and all the skill of the brewer is thereby called into exercise. When the fermentation has been carried on to a certain extent, it is stopped by drawing off the beer from the yeast into barrels. By long keeping, ale loses its sweetness, and acquires a strong taste; hence the difference between mild, or new, and old ale.

It has long been considered that the different flavour of ales is due to the water employed. But that such is not the case may be proved by the fact, that whilst each ale brewed by the great brewers in London, differs in its flavour from the rest, all the breweries are supplied by water from the same source, either Artesian wells, or the Thames, or New River water companies. Again, it cannot be owing to the softness of the water, for the presence of a little lime is advantageous. In respect to this, we may notice, that the water used by the Scotch brewers is generally very soft, and yet the class of ales they produce is quite different to that brewed in London, and the porter is vastly inferior.

Porter owes its dark colour to the addition of high-dried malt, which contains a substance termed *caramel;* and this may also be procured by strongly heating sugar, which becomes of a dark-brown colour. The high character which London porter holds as a beverage, is partly due to the care used in, and the extent of, its production. If it be required for export, an entirely different article is brewed, as that intended for London use would soon turn sour. Even if sent to other parts of the kingdom the same point is attended to; hence a Londoner will often find that the "London porter" he may drink in a provincial town, is much stronger than that he partakes of at home. We cannot here stop to notice the numerous adulterations which this beverage undergoes in its transit from the brewery, through the cellars of the publican, to the consumer. Sugar, copperas, tobacco, Spanish liquorice, treacle, *coculus Indicus, cum multis aliis,* &c., all join with water to make every two barrels of *genuine* porter into three of the Londoner's drink; and thus, more "porter" by far is drunk in London annually, than is really made at the breweries which profess to supply it. Stout is merely porter brewed of a greater strength and body.

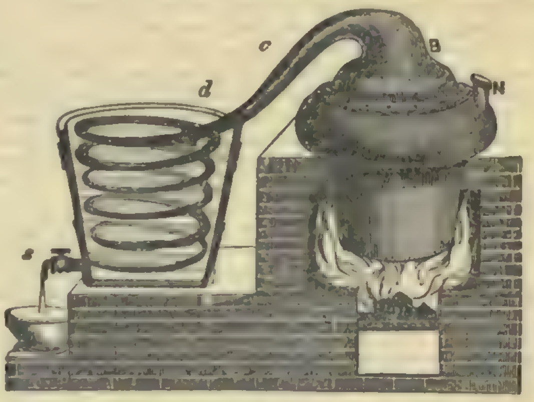
In this country, no wine, properly so called, is manufactured. The British wines owe their spirituous part to the addition of brandy to the fruits after which they are called. Foreign wines are the product of the grape, and vary greatly in their qualities. French and German wines contain from ten to eighteen per cent. of alcohol, whilst sherry and port have so much as twenty-five per cent.

In the south of France, Italy, Spain, Portugal, and many parts of Germany, the vine is extensively cultivated for the purpose of making wine; and the colour of the husks, or skins, of the grape, is the cause of the colour of the wine produced from them. The nature of the soil and the climate have a decided effect on the quality of wine produced; and hence a connoisseur will readily detect, not only the difference in the wines, but also of the vintage, some years being more favourable than others for the production of the grape.

When the grapes are ripe, they are carefully gathered, and the juice is pressed out and received in large vats. No addition of yeast is required for fermentation, as the grape itself contains a fermentable principle in its vegetable albumen, which absorbs oxygen, and so promotes the decomposition of the grape-sugar, and its subsequent conversion into alcohol. This is, however, a delicate and uncertain process, as the nature of the wine is materially influenced by it; and the result depends on the amount of vegetable fermentative matter the grapes may contain. After the wine has been bottled, a slight fermentation progresses in some kinds, and hence the production of carbonic acid, as in champagne and other sparkling wines. The gas escapes from the liquid in uncorking the bottle, just as a similar result takes place in opening a bottle of soda-water. Port, and some other wines, deposit a considerable quantity of tartrate of potass; and this, mixed with the colouring matter, forms the crust, so well known in old port wine, and which lines that side of the bottle which has been laid down. Many attempts have been made to deposit this substance rapidly by chemical means, but without success. During the last few years the production of wine has steadily increased, and the colonies of Great Britain, in Africa and Australia, are producing considerable quantities of this favourite beverage.

The production of spirituous liquors, commonly so called, depends on the processes we have already described; being supplemented by another—that of distillation. Brandy is procured from wine by distilling the spirit from that liquid. The following engraving will give a general idea of the form and uses of a still.

Fig. 84.



A represents the body of the still, containing the liquor to be distilled, which is introduced through an opening N. The still is built into a furnace, to the action of which it should expose as much surface as possible. B is the head of the still, which is connected by means of a pipe *c*, with a metallic worm *d*. This worm is placed in a vessel, which is kept filled with cold water. Heat being applied to the liquid in the still, the alcohol rises in vapour, and passing to the worm, it becomes condensed again into a liquid state, issuing from the cock *s* into any suitable receiver.

Now, by such means, alcohol may be readily distilled from any liquor containing it; and, as we have mentioned, brandy may thus be produced from wine.

Gin and whiskey are produced from malt in the following manner:—The malt is infused in hot water, and then immediately fermented as far as possible, so as to convert all the sugar into alcohol. Generally speaking, the malt is mixed with a considerable proportion of raw grain, and hence the cost of the spirit is lessened, and its quantity increased. The "wort," thus fermented, is transferred to the still, and thus whiskey is produced. For making gin, the whiskey, or raw spirit, has to be rectified;-that is, its fusel oil, which gives the flavour to it, must be removed, and other oils substituted for it. This is effected by a second distillation of the raw spirit, to which salts of potass are added. Gin *should* be a mixture of alcohol and the oil obtained from juniper berries; but, generally speaking, oil of turpentine is largely substituted, and hence arise some highly prejudicial effects on the system of the habitual gin-drinker.

Liqueurs are procured by dissolving various essential oils in alcohol of various strengths. Perfumes are manufactured in a similar manner; and occasionally both are subjected to another distillation, so as to ensure complete mixture.

We must now pass on to consider the effect produced on sugar when the fermentation is pushed on to what has been termed the acetous state, or that in which the spirit becomes converted into an acid.

If the wort of the brewer, or wash of the distiller be left, after fermentation, to the free action of the atmosphere, an acid, called the acetous, is eventually produced. Indeed, this is the method often adopted for the production of the common vinegar of commerce, and results from the atmospheric oxidation of the alcohol. On similar principles, but by different means, alcohol diluted with a little water may be converted into acetic acid. This is effected by dropping it on some finely divided platina,* when the smell of acid produced will be abundantly evident. Another arrangement, in which the oxidation and slow combustion of alcohol is produced, is described at the page to which we have just referred. Acetal ($C_{12} H_{14} O_4$) is a colourless liquid, and may be produced by the slow oxidation of alcohol through the action of finely divided platina.

Acetic acid combines with several bases forming salts, called acetates. The acetates of lead have already been referred to at a previous page;† the acetate of iron is employed as a mordaunt in dyeing, and for this purpose is largely manufactured in the North of England.

Acetate of alumina is similarly employed.

Of late years, acetic acid has been extensively used in photography, as a developing agent. That of the strongest kind is generally preferred for the purpose, and is sold under the name of "Glacial Acetic Acid." It is prepared from the acetate of soda, by distilling that salt with sulphuric acid; and from the liquid distilled over, crystals may be readily obtained at a temperature less than 60° Fahrenheit. A considerable quantity of vinegar, containing a portion of acetic acid, with many impurities, has lately been manufactured by the agency of the "vinegar plant." This is a species of fungus, which produces the acetous fermentation in solutions of saccharine matter. The chief source, however, of the vinegar of commerce is ale, which, from having been kept too long, has become "hard" and sour.

Various combinations analogous to acetic acid are producible from alcohol, but these are of special interest to the professional chemist only.

ETHERS.

An interesting group of substances, which has of late years received much attention, is found in the ethers which are producible from alcohol by distillation with acids. And we must here call attention to a singular phenomenon, in the fact that a substance called *Ethyl* ($C_4 H_5$), symbol Ae, can assume all the properties of a base, just as a metal might do with oxygen and acid. In fact, this substance, ethyl, may replace such bases; form haloid salts, with chlorine, iodine, &c.; analogously to sodium or other metals, it may be oxidised; and thus it opens out a very curious range of organic compounds to our investigation.

Adopting the "Ethyl theory," as it is termed, we shall view ethyl as the base of a system of compounds; and from its various combinations the following substances are obtained, which, with the symbols, we have arranged in a tabular form:—

Base—Ethyl	$C_4 H_5$
Oxide of base—Ether . .	$C_4 H_5 O$
Hydrate of Oxide . . .	$C_4 H_5 O + HO$

Confining our attention, for the present, to the above compounds, we may state that ethyl has been isolated from its iodide ($C_4 H_5 I$) by the action of zinc and heat. It is, when condensed, a colourless fluid. Its oxide ($C_4 H_5 O$) is the ordinary "sulphuric ether" of the shops, which is obtained by distilling rectified spirits of wine with sulphuric acid. The vapour should be received in a vessel surrounded with pounded ice. Its specific gravity is less than alcohol, being 0·720 (water = 1·000). It is a very volatile fluid; boils in the air at 96°, and under freezing-point in the vacuum of an air-pump; is highly combustible, and burns with a bright flame. This ether is employed in medicine as a stimulant. If its vapour be breathed, which may be done by pouring a little of the liquid into a bladder fitted with a mouthpiece, it produces very similar effects to those of the "laughing gas." And it was for some time used, before the discovery of chloroform, in surgical operations, to destroy the sense of pain.

On passing the vapour of ether through a red-hot tube it undergoes decomposition, and "aldehyde" is produced. This substance is a hydrated oxide of "acetyl" ($C_4 H_3$), and hence its composition is $C_4 H_3 O + HO$. A connection with the ethyl series, and that to which acetic acid belongs, is thus established. And the products of the decomposition of alcohol and ether are respectively homologated.

By using hydrochloric instead of sulphuric acid, in distillation with spirits of wine, as just described, the chloride of ethyl is produced ($C_4 H_5 Cl$), commonly known as chloric ether. Nitric ether ($C_4 H_5 NO_6$) is similarly produced, by the action of nitric acid on rectified spirits of wine.

We have confined our attention, chiefly, to those forms of the combinations of ethyl which are more generally known. A large number of others, however, has been discovered; and as they have no special interest we shall only give the symbols showing their constitution.

Ethyl Compounds, in addition to those already named.

Bromide of	Ethyl . .	$\overline{C_4 H_5} + Br$
Sulphide „	„ . .	$\overline{C_4 H_5} + S$
Cyanide „	„ . .	$\overline{C_4 H_5} + Cy$
Sulphate of Oxide of	„ .	$O + \overline{C_4 H_5} + SO_3$
Nitrate „	„	$O + \overline{C_4 H_5} + NO_5$
Carbonate of	„	$O + \overline{C_4 H_5} + CO_2$
Oxalate „	„	$O + \overline{C_4 H_5} + C_2 O_3$
Acetate „	„	$O + \overline{C_4 H_5} + C_4 H_3 O_3$

An inspection of the above table will at once convince the student how completely ethyl replaces a metallic base, in its haloids and salts. And this fact has formed the basis of an entirely new doctrine in chemical science, namely, that of substitution. We shall have again to refer to this point as we proceed.

With other substances than those we have referred to, ethyl forms interesting compounds. Wine, for instance, owes its *bouquet*, or rich flavour, to the presence of what is termed "*Œnanthic*" ether. Butyric, valerianic, magaric, and stearic ether are compounds of ethyl, with the acids bearing their names.

The other derivatives of alcohol possess, with one exception, less interest than those to which we have directed attention. And we shall, therefore, conclude with some account of chloroform, to which great attention has been directed, owing to its employment in connection with surgical operations.

Chloral is produced by passing dry chlorine through alcohol, free from water. If, to the product, soda or potass be added in solution, a decomposition ensues, and chloroform is produced. But the plan usually adopted is, to distil alcohol with chloride of lime. The liquid thus afforded is chloroform; it has a pleasant smell, and, if inhaled, has the peculiar property of so far influencing the nervous system as to produce almost total insensibility to pain. Its effects depend, however, very materially, on the temperament of the person inhaling it. In some instances, we have noticed great cerebral excitement, leading to violent acts. In a case which came under our notice, some years ago, a lad, 12 years of age, part of whose finger had to be amputated, was placed under the influence of the agent. To all appearance he was perfectly insensible to pain; he was yet able to describe each step of the operation, which he did as each was finished, with an amazing exactness. On being restored (if we may so say) to consciousness, he was perfectly unaware that the top joint had been removed, and would not believe the fact until he saw his finger, on the next day, when it was uncovered for the purpose of dressing it. In several cases, the administration of chloroform has been attended with fatal consequences, in which, however, its action could scarcely be properly assumed as the sole cause of death.

---

* See ante, p. 372.

† See ante, p 379.

It may be as well for us to give a general glance over the subject to which attention has been drawn in this chapter, before proceeding further, inasmuch as it will, to a large extent, form a basis on which we shall hereafter have to build. Starch, sugar, and their products, were the subjects on which we were to treat. We have found that, from these vegetable products, a vast variety of substances, having no physical similarity to them, can be obtained. Alcohol, ethers, acids, each having their own peculiarity of constitution, are readily producible from the well-known articles of our daily food. Even a cursory glance over the different substances we have mentioned, or referred to, will be sufficient to lead every thoughtful mind to reflect on the astonishing multiplicity of compounds which may arise from the combination of three elements, in variable proportions. We have, hitherto, noticed that, from sugar alone, deadly poisons, favourite beverages of all classes, medicines, condiments, and interesting philosophical results, are easily obtained. Wonderful as may be such discoveries, they are but an index to the innumerable instances of a similar kind which organic chemistry presents to our view. Perhaps, in no branch of scientific inquiry can we find an instance in which so few agents are, by the fiat of the Creator, employed in so great a variety of ways and purposes. This fact has rendered the study of this portion of our subject a matter of the deepest interest to most living chemists. But, to the sagacity and researches of Liebig every civilised nation is indebted, in a commercial and social point of view; his labours, chiefly, have opened out a valuable and extensive field of inquiry, and have made popular a subject of great difficulty.

CHAPTER VIII.

METHYL, AMYL, ETC., AND THEIR PRODUCTS.

In the last chapter, we remarked, that the substance called ethyl, had the peculiar property of acting as a base, and of forming certain definite compounds with oxygen, chlorine, &c., and acids. We now shall show that other substances exist, having analogous properties, equally capable of acting as bases, and of producing compounds having very similar constitution to those produced by ethyl.

The base of the first of the series is called Methyl—symbol, Me—and it is composed of $C_2\ H_3$. It is contained in ordinary wood-spirit, which is a hydrated oxide of methyl. The latter is obtained by the distillation of wood. The acid liquor produced is neutralised by lime, and the spirit is produced therefrom. The product is a limpid liquid, having an unpleasant smell; it readily burns on being inflamed; and is largely employed for a variety of purposes in the arts; by cabinet-makers, as a solvent for varnishes; and to burn in lamps. Its specific gravity varies with its purity, but should be about 0·795 (water = 1·000).

Oxide of methyl is the analogue of ether, and may be produced by distilling wood-spirit, just described, with sulphuric acid. The chloride, iodide, bromide, sulphide, and cyanide of methyl, are similar in constitution to the compounds of the different substances with ethyl, and have the same formula, excepting that that of methyl is substituted. Similar observations apply to the combination of sulphuric and other acids with methyl.

During the slow combustion of wood-spirit a peculiar acid is produced, which has also been obtained from the well-known insect, the ant. It has, therefore, been called formic acid. Combined with one equivalent of water, its constitution is $C_2\ HO_3\ HO$. Formic acid readily unites with bases forming the salts called formates. It has a pungent smell, and readily blisters the skin if applied to it.

AMYL has a composition analogous to the substance we have already described; for, like ethyl and methyl, it contains carbon and hydrogen only. Its general symbol is Ayl, and it consists of $C_{10}\ H_{11}$. Common fused oil is a hydrate of its oxide. This liquid was long treated as a waste product in distilleries. It is readily produced in the distillation of spirit from potatoes; has a strong smell, and is combustible.

Amyl forms a similar series of compounds to ethyl; hence we have its oxide, or amyl-ether, the chloride, bromide, iodide, &c.

Benzoyl—symbol Bz—is, to some extent, analogous in its basic properties to ethyl, &c. Bitter-almond oil, which is a combination of benzoyl ($C_{14}\ H_5\ O_2$) with hydrogen, is a substance well known as an article in general use for the purpose of perfumery, &c.; and is a product of the distillation of water in which bitter-almonds have been steeped. This substance, which is a hydrate of benzoyl, becomes converted into benzoic acid by oxidation.

Benzoic acid is chiefly obtained, for ordinary use, by the sublimation of gum-benzoin. When the latter substance is heated, the acid rises in vapour, and condenses in fine crystals. During its volatilisation, the acid has a very powerful smell; it is hence used as an ingredient in pastiles, incense, &c. It readily forms salts with bases, called benzoates.

Benzoyl forms numerous compounds besides those we have mentioned, but they are not generally of interest. The constitution of some of them is given below, in tabular order, with which we shall content ourselves, without entering into any further description of them:—

Chloride of benzoyl . . .	Bz Cl
Iodide ,, ,, . . .	Bz I
Sulphide ,, ,, . . .	Bz S

A peculiar acid, having some connection with the benzoyl series, may here be named. It is found in the urine of domestic animals, and is termed hippuric acid. It is scarcely soluble in water; is decomposed into benzoic acid, &c., by heat, and forms salts with alkalies. This acid contains a portion of nitrogen as a constituent.

We shall include with the series two other bases, analogous to those we have described—namely, kakodyl and salicyl; although the latter appears to have some analogy to the vegetable alkalies, which we shall have to speak of presently.

Kakodyl—symbol Kd—is a peculiarly offensive, and fearfully poisonous compound, composed of $C_4\ H_6\ As$, thus including an equivalent of a metal, arsenic, in its composition. Its oxide is obtained by distillation, from a mixture of acetate of potass and arsenious acid; the product is to be condensed in a cold vessel, when a dense liquid will be obtained, which is the impure oxide. To obtain it in a pure state it must be re-distilled with potass, in a retort, filled with hydrogen. This operation is of the most dangerous character, from the poisonous nature of the substance produced.

Like ethyl, &c., kakodyl produces a chloride, iodide, &c. It is also susceptible of oxidation, producing the kakodylic acid, having a constitution of $C_4\ H_6\ O_3$.

The whole of the combinations of kakodyl are curious, from the intensely powerful effects they have on the animal system. And we should strongly urge on our readers the prudence of being content with their brief description, rather than to attempt their production.

Salicyl, to which we now direct attention, is obtained from a product of vegetable life, salicin, and derives its name from the willow tree, in the bark of which it may be found. The crystals of salicin have a beautifully silken appearance. It is prepared by infusing the bark of the willow, poplar, &c., in hot water, and heating with the protoxide of lead. Hydrosulphuric acid* is then to be passed through the solution, to remove the lead as sulphide. Salicyl is the base of this substance.

There are other compounds analogous to ethyl, &c., which we shall omit to notice altogether, or refer to them in a more convenient place.

In the perusal of this chapter, our readers will have perceived that we have entered into a novel branch of organic chemistry, in which we find fresh analogies, and a very interesting series of compounds. As we may have again to refer to the substances we have described, we shall, for the present, end our remarks by presenting the symbols of the constitution of each, in a tabular form, so as to be convenient for future reference; and shall then proceed to give a description of the alkaloids and vegetable acids.

Table showing the constitution of Ethyl, Methyl, Amyl, Benzoyl, and some of their Compounds.

Name.			Symbol.	Composition.
	ETHYL	....	Ae	$C_4 H_5$
Ether	,,	Oxide of	Ae O	$C_4 H_5 O$
Alcohol	,,	Hydrate of Oxide of	Ae O + HO	$C_4 H_5 O + HO$
	METHYL	....	Me	$C_2 H_3$

Benzoic acid	,,	Hydrate of Oxide of	Bz O + HO	$C_{14} H_5 O_2 O + HO$

CHAPTER IX.

VEGETABLE ALKALIES OR ALKALOIDS, AND ACIDS.

In our last chapter we included a description of salicyl, because its analogies are in accordance with those of ethyl, &c. Salicin, which contains it, would appear to belong to the alkaloids. We have accordingly chosen it as the last of the basic series, before commencing an account of the vegeto-alkalies.

These substances differ materially from all other organic matters with which we have yet been engaged, in the fact of their containing nitrogen as an element of their composition. They are, generally speaking, principles existing in minute quantities in the plants from which they are obtained. They are but slightly soluble in water, their proper menstrum of solution being alcohol. With acids they act as bases, and in their specific character resemble the alkalies; hence they have received the title of alkaloids. Some of them are extremely poisonous, whilst others exert a highly beneficial influence on the human system. After giving a general description of the alkaloids, we shall proceed to describe some of the leading vegetable acids.

STRYCHNINE.—This alkaloid is obtained from the *nux vomica*, which also contains another substance called BRUCINE: in fact, these two alkaloids are often mistaken for each other, in unskilful hands. Strychnine, in the pure state, has a crystalline form, an intensely bitter taste, is barely soluble in water, but dissolves easily in boiling spirits of wine. Brucine may be separated from strychnine by its solubility in *cold* alcohol. It is also more soluble by far, in water, than strychnine.

A sulphate of strychnine is readily produced, as is the acetate, by the action of the corresponding acids on the alkaloid. Brucine forms analogous salts with the same acids.

Of late years, strychnine, or, as it is often called, strychnia, has obtained a painful notoriety in connection with cases of poisoning; more especially in that of the celebrated Palmer's case. It is, perhaps, the most dreadful poison which can be administered to a human being. In quantities of a fraction of a grain to one grain, according to the constitution of the victim, its effects are fatal. Rigid contortions of the muscles of the body are its symptoms of poisoning. The sufferer retains his mental powers undiminished, although he is racked with pain; and, at last, he is put out of misery by convulsions, which are truly horrible to behold.

The tests for the presence of strychnine are twofold—chemical and physiological; the latter having been first introduced to notice by the late lamented Dr. Marshall Hall.

If a grain of strychnine be placed on a plate with a little powdered bichromate of potass near it, and a drop of concentrated sulphuric acid be let fall between them, a rich purple colour is instantly produced when all three are stirred together, but which speedily changes to a red tint, which is permanent. The same colour is produced by using the red ferri-cyanide of potass in place of the bi-chromate.

The physiological test is more satisfactory, and may be illustrated as follows:—Dissolve $\frac{1}{4}$th of a grain of the acetate of strychnine in a little boiling alcohol, and add thereto two ounces of cold water. Place in the solution two small frogs. For some time no effect will be apparent. This is best conducted in a tall glass jar, the top of which should be covered, for reasons which will be presently seen.

After a time the poison will be absorbed into the system of the animals. If the glass which contains them be then shaken, the poor creatures will instantly suffer from convulsions—stretching out each limb, which will become rigid; they will utter piercing shrieks, and show all the usual effects of strychnine poisoning. After a time the eyeballs will swell, and death ends their sufferings.

---

* See *ante*, p. 376.

During the trial of Palmer, we were requested to undertake a series of experiments, in order to discover whether strychnine suffered decomposition simultaneously with that of an animal body. For the purpose of ascertaining this, we tried the following :—

Six young frogs were poisoned by means of a grain of strychnine dissolved in the manner already indicated. When quite dead, the bodies were carefully washed, to remove all traces of strychnine not absorbed into the animal textures. They were then cut to pieces, and exposed for a fortnight (in summer-time), till the mass was completely putrid. Copious washing with distilled water was then employed, and the mass boiled for some hours in alcohol. The liquid was filtered, and evaporated to dryness, sulphuric acid being then added to form the sulphate. The product was then dissolved, and administered to two frogs, who speedily passed into convulsions and died. Now these experiments were conducted with the full expectation and hope that the decomposition of the strychnine would have resulted, but it was shown that such did not take place. Every possible care was taken to insure accuracy of result, and therefore the experiments may be depended upon.

There seems to be no remedy for strychnine as a poison. We may, however, mention, that on attempting to put some of the numerous frogs we experimented on, during the time named, out of their misery, we gave them a very large dose of cyanide of potassium, in solution. This, instead of killing them, prolonged their lives. Other substances were also tried, which we cannot now name from memory, but as deadly poisons in general. This would seem to indicate, that some substances having, in the normal state of the animal, a fatal effect, are positively antidotal when it suffers from poisoning by strychnine. On this point, however, we can offer no decided opinion, as our experiments were only carried on in reference to the hopes of some, that their result might induce a reprieve of the criminal under sentence of death. The results we have named, however, deserve further and careful investigation. During the above course of experiments, we may further mention, that exceedingly small doses of strychnine seemed to produce a tonic effect. This was noticed through occasionally tasting the ends of the fingers, to ascertain that all accidentally adhering strychnine had been washed away, and so to prevent its introduction into any opening of the skin—a circumstance which sometimes occurs in investigations of bodies containing poisons, &c. The formula for strychnine has been stated as $C_{42}\ H_{22}\ N_2\ O_4$. And of Brucine, $C_{46}\ H_{26}\ N_2\ O_8$.

Quinine and **Cinchonine**.—These are obtained from the well-known Peruvian bark, which, from their presence, has been used so much in medicine, as tonic. Quinine, however, as a disulphate, has been generally substituted. Both these substances assume a crystallised form, and neither are readily soluble in water ; but in this respect quinine has the advantage of cinchonine. They are both very bitter. The sulphate of quinine is generally sold in minute crystals, and, for medicinal purposes, is dissolved in dilute sulphuric acid. An acid called Kinic acid may be obtained from the Peruvian bark, which unites with bases, and also affords, with other substances, a curious range of compounds.

Morphine.—This alkaloid is obtained from opium, by a somewhat tedious process. It is soluble in boiling alcohol, and but sparingly so in water. With sulphuric, nitric, hydrochloric, and phosphoric acids, it forms salts. The sulphate and acetate are used as medicines.

Narcotine and **Codeine** are also obtainable from opium ; and, in some respects, they resemble morphine. The sedative effects of opium are due to the presence of the alkaloids. And morphine salts are now chiefly employed in place of the vegetable substance, which always contains a host of impurities. A peculiar acid, the meconic, which forms salts with bases, is also found in the opium of commerce.

Nicotine, is found in tobacco, and is a deadly poison. Like **Conine**, which is produced from hemlock, it forms salts with acids, which may be obtained in a crystallised state. Similar remarks apply to **Hyoscyamine**, from the *hyoscyamus;* **Atropine**, from the *atropa belladonna;* and **Aconitine**, which is the active principle of the *aconitum napellus.* There are many other vegetable substances which afford similar principles, all of which possess a bitter taste, and are generally poisonous when taken internally.

Theine.—This principle, which is identical with that called **Caffeine**—the names varying according to the source of the substances—is found respectively in the tea and coffee so much used as beverages ; and it is to the presence of these alkaloids that is owing the refreshing and exhilarating effect of those drinks.—**Theobromine** is similarly contained in the cacao-nut. Caffeine, or Theine, is soluble in cold water, but much more so in the heated liquid ; hence the use of boiling-water in making the infusion of either tea or coffee. Salts of this substance have been obtained, and also a double one with the chloride of platina.

It will be noticed, generally, that each of the alkaloids is but slightly soluble in water, however they may be dissolved in boiling alcohol. They form salts with many of the acids, and are distinguished from other organic substances, having a vegetable origin, by containing nitrogen. They are mostly deadly poisons, and exist in minute quantities in the vegetable from which they are obtained.

The general method of obtaining them is to steep the plant or bark in hot water, or to make a strong decoction. Sulphuric or acetic acid is added, to form a salt; and, in some cases, these are decomposed by hydrate of lime. The alkaloid is thus set free, and may be dissolved out by boiling alcohol, from which it is afterwards obtained by evaporation and crystallisation. Generally speaking, the chemical constitution of their substances has not been satisfactorily obtained; and we shall not attempt to guide our readers by giving hypothetical formulæ, in which entire dependence cannot be placed, more especially when no particular necessity exists, or advantage can arise from such a course.

VEGETABLE ACIDS.

Having described the chemical character of the leading alkaloids, we shall now add some remarks on those acids which are obtained from some plants, omitting such as the oxalic, &c., to which allusion has already been made at page 412, in connection with sugar, &c.

Generally speaking, the vegetable acids are freely soluble in both hot and cold water ; gallic acid, however, forms an exception in the latter case. They have all a sour taste ; generally affect blue litmus paper ; form soluble salts with alkalies and metallic oxides ; and are decomposed into other acids by the aid of heat.

Tartaric Acid may be obtained from the ordinary cream of tartar. An impure tartrate of potass is found in wines,* which is the chief source of the acid. From this salt an insoluble tartrate of lime is produced, which is subsequently decomposed by sulphuric acid. From this the tartaric acid may be crystallised. The chief salts of this acid are those of potass and soda. It, however, forms salts with the earths. With antimony and potass it forms the tartar-emetic used in medicine. By being heated, tartaric acid becomes changed into a variety of other substances having an acid character: and an anhydrous acid may be obtained, freed from two equivalents of water, which the commercial product always possesses. Racemic acid has a definite relation to tartaric acid, and is obtained also from some kinds of wine. It is frequently termed Paratartaric acid. The formula for anhydrous tartaric acid is $C_8\ H_4\ O_{10}$: and that of the commercial substance is the same, with the addition of two equivalents of water, or $C_8\ H_4\ O_{10} + 2HO$.

Malic Acid—$C_8\ H_4\ O_8 + 2HO$—is found in apples and other fruit, and is also united with oxalic acid in the common rhubarb stalks. It is also present in the berries of the mountain-ash. This acid unites with bases forming salts called malates, of which the malate of lead is of the most interest, as being the salt from which the acid is obtained.

---

* *See ante*, p. 413.

Citric Acid is found in lemons, in great abundance, from the juice of which it may be obtained by adding chalk, which affords a citrate of lime. Dilute sulphuric acid is to be added to the precipitate, which will then be decomposed. The citric acid may be crystallised from the remaining liquid. In the anhydrous state, the formula for citric acid is $C_{12}\ H_5\ O_{11}$, but it is in a crystallised state united with five equivalents of water, as produced above. Its proper constitution, however, may be represented by the addition of three equivalents (3HO) to the above formula. Citric acid unites with bases, forming citrates, of which the alkalies are soluble, whilst those of the earths are insoluble in water.

Gallic Acid.—The ordinary oak-bark, gall-nuts, catechu, sumac, &c., contain two acids, the gallic and tannic, which have considerable commercial importance, inasmuch as the tanning of leather, the manufacture of ink, and photographic processes, depend on them.

Gallic acid may be procured by allowing an infusion of powdered nut-galls to be exposed to the air, until the whole solution, &c., has become completely mouldy: from this, gallic acid may be dissolved out and crystallised. It is now prepared in large quantities as a photographic agent, being much used in developing pictures by various processes.

When gallic acid is heated, another acid, the pyrogallic, is produced, which is also largely used in photography. The formula for gallic acid is $C_7\ HO_3 + 2HO$; whilst that of the pyrogallic is $C_6\ H_3\ O_3$.

Tannic Acid—$C_{18}\ H_5\ O_9 + 3HO$—is the active agent in oak-bark, nut-galls, sumac, &c., which renders them so valuable in the manufacture of leather and ink. It has the property of precipitating gelatine, &c., as found in skins, as an insoluble substance. In the process of tanning, the gelatine of the skins is thus transformed, and they are thereby rendered not liable to further change. With the oxide of iron a black colour is produced; and hence the usual method of making ink, and of dyeing textile fabrics of a black colour, is that of employing solutions of iron, and infusions of substances containing tannic acid. The acid is generally obtained by means of the action of ether on nut-galls. The liquid is added to the powdered nut, and the solution of acid is allowed to evaporate spontaneously, when it will afford crystals of the acid.

With the exception of the tannates of iron, as in ink, and dye products, the tannates and gallates are of no importance.

We have thus presented descriptions of the chief vegetable acids to which the attention of the student need be directed. Some of them, as we have seen, are of considerable commercial importance. Their salts are all decomposible by the mineral acids, by means of which the organic acids themselves may generally be set free, and obtained in an isolated form. In almost every case they may be had in crystals.

CHAPTER X.

MISCELLANEOUS VEGETABLE SUBSTANCES.

OILS, RESINS, COAL AND ITS PRODUCTS, PARAFFINE, ROCK-OIL, PETROLEUM, VEGETABLE COLOURING MATTER, ANILINE, ETC.

We shall now briefly describe a variety of vegetable products, of considerable use for numerous purposes, and obtained from various sources, either during the growth or from the decay of plants.

Oils.—Vegetable oils much resemble those obtained from animals in many respects. They give a greasy stain; if of the "fixed" kind, are inflammable, of light specific gravity, and consist chiefly of carbon and hydrogen; hence their use for illuminating purposes.

The *fixed* oils—such as that of the olive or almond, &c.—are distinguished from the *volatile* by many qualities. They cannot be distilled except at a high temperature, and then they are generally decomposed. The volatile, such as oil of lavender, or otto of roses, readily evaporate, even at ordinary temperatures. If a drop of otto of roses and one of olive oil be placed on blotting-paper, the essential oil will speedily evaporate by a gentle heat, whilst the fixed oil stains the paper with an unctuous mark. It is customary to adulterate the otto with spermaceti; and the above plan affords a ready means of detecting the imposition; for, if any of the spermaceti be present in a specimen of the otto, the volatile oil will pass off, whilst the fatty matter remains on the paper.

Generally speaking, the oils derive their names from the plant producing them; and the following gives a description of the best known substances of each class.

Fixed Oils.—These oils consist chiefly of two distinct substances: one a fluid, to which the name *oleine* is applied; and the other a solid matter, termed *stearine* and *margarine*, when obtained from animal substances, or *palmitine* or *cocine*, when produced from vegetable, as the palm or cocoa-nut. Vegetable oils are generally obtained from the fruit or seeds of the plant. Thus, olive oil is expressed from the fruit; whilst rape, linseed, castor, &c., afford oil from the seed. Their chemical composition varies considerably. Generally speaking, they contain about equal proportions of carbon and hydrogen, a little oxygen, and an equivalent of water. Some are nearly solid, as palm oil, at ordinary temperatures; but even the most fluid become semi-solid on exposure to a temperature of 32°, as is familiarly known in the case of salad oil, the most fluid, which "freezes" in winter-time. Some oils, by the absorption of oxygen, become what are termed "drying oils," such as linseed, which, if boiled with litharge, affords the drying oil used by house-painters. All fixed oils are insoluble in water; most form soap with that fluid, or emulsions, by the agencies of alkalies; and some are soluble in alcohol and ether.

Vegetable wax is obtained from some plants belonging to the family *Myricaceæ*, &c., and large quantities of this substance are now imported from Japan, South America, and the Cape.

The following table gives the specific gravity of some vegetable oils, water = 1,000:—

Rape oil	913
Colza	914
Olive	916
Almond (sweet)	917
Poppy	922
Sunflower	926
Cocoa	926
Linseed	930 to 960
Castor	965

Although the specific gravity of the fixed oils is the method of distinguishing them, the action of sulphuric acid in a concentrated state has been proposed. One drop of the acid is added to a few of the oil to be examined, and the reaction may be carefully noticed. Each oil presents a distinct effect, at once characteristic of its nature. The subject, however, is one into which we cannot here enter in detail.*

Olive oil is the produce of the *Olea Europæa*, and is obtained from the fruit by pressure and fermentation.

---

* See Article, *Artificial Illumination*, Sect. II.

Almond oil is afforded by the almond tree, the nuts of which give the oil, on the kernels being crushed or pressed.

Linseed oil is afforded by the seeds of the flax plant; and the seeds of the Indian hemp also contain abundance of oil. The cake left after the extraction of oil from linseed, is largely used as food for fattening cattle.

Rape and *Colza oil* are the produce of seeds of the *Brassica* family. The latter oil has been much employed of late for lamps. That of the rape-seed is much used for the same purpose, but both require refining from various substances with which they are mixed in the raw state.

Nut, Poppy, Cotton, Mustard, Sunflower, &c., oils, are obtained from the seeds of the plants bearing their names, and have different uses, depending on their specific qualities. They are employed in the manufacture of soap, for illuminating and lubricating purposes; and, generally speaking, the solid refuse left after extracting the oil, may be employed as food for cattle. There are numerous other vegetable fixed oils, to which we need not allude separately.

VOLATILE OILS.—These oils are the produce, in most cases, of the flowers of plants, which owe their fragrance to them. In some cases, however—as oil of turpentine—the oil is obtained from the wood of a tree. Volatile oils are generally soluble in alcohol, and hence are largely used as perfumes.

Perfumes have for ages been highly esteemed; and in the earliest records of biblical and general history, we read of various productions of that class. This will be a matter of no surprise, when we remark that the climate of Greece, Turkey, and Egypt, countries in which the early history of the world is involved, is such as to be most favourable for the production of flowers affording the best perfumes. At the present day, we are indebted to those countries for many of our best essential oils; and the otto or attar of roses is indigenous to Damascus and its neighbourhood.

In England many places are devoted to the cultivation of flowers intended for the use of the perfumer. Mitcham and its neighbourhood, and other places in Surrey, are especially noted for the cultivation of flowers for perfumery and medical uses. In Germany and on the banks of the Rhine, as at Vierlander, the cultivation of flowers is an object of importance to the farmer and landholder.

There are many ways of obtaining the perfumes contained in flowers. Some yield their essential oil readily; others part with it more slowly. The following methods may be tried, and they serve as illustrations of the various modes adopted according to circumstances:—

1st.—Dip some fine cotton lamp-wick in the purest olive oil, and lay the petals of the flowers on these threads. Place these over each other in layers, and after some time loosen the threads, and soak them in a glass of warm water. The oil will gradually ooze out, and, with the water, may then be transferred to a still. As distillation proceeds, the more volatile oil will separate from the fixed one, and, passing over, may be condensed in the worm, together with a portion of the vapour of water. As the oil and water condense, the two will separate, and the essential oil will float on the water surface, from which it may easily be removed. For this purpose it is better to receive the condensed liquids in a glass vessel, because in that they will be more readily distinguished.

2nd.—The flowers may be rubbed together with dry chalk or loaf sugar in a mortar, and water is then to be added. The mixture, so obtained, is to be transferred to the still, and the usual process of distillation being carried out, the oil is readily separated. The essential oil of lemons is obtained very easily by rubbing the outside of the peel with loaf sugar, which, on being dissolved in water in the body of the still, soon yields up the oil by distillation.

3rd.—The leaves of the flowers may be soaked for some time in a strong solution of common salt in water. This extracts the oil, and the liquid can then be distilled.

4th.—But the readiest way in most cases is to steep the flowers for some time in strong spirits of wine. The spirituous solution so obtained is then to be transferred to the body of the still, and the vapour being condensed in the worm, will be found to contain the essential oil in union with the spirit.

We have already pointed out other properties of essential oils. They consist chiefly of carbon, hydrogen, and oxygen; but in some nitrogen is found; and in the oil of the onion, &c., sulphur is also present. It will be unnecessary for us to describe such oils as those of roses, lavender, neroli, lemons, bergamot, &c., as their general qualities are so well known. We shall therefore confine our remarks to the following:—

Turpentine and *Camphor.*—These substances are both the produce of the wood of trees. Oil of turpentine is obtained from the pine, larch, and fir. The tree is "tapped;" that is, a hole is cut into it a little above the ground, and the resin exudes, and is collected in suitable vessels. The oil is obtained from the crude product by distillation. Its specific gravity is 870—water = 1000, and it is highly inflammable. Common turpentine is an impure form of the liquid.

Camphor is obtained from a plant, the *Laurus Camphora*, by distillation of the wood. This well-known substance is highly inflammable, can be sublimed by a moderate heat, is but slightly soluble in water, but readily in alcohol, and has numerous medicinal and other uses. A peculiar acid, the camphoric, is obtained by the action of nitric acid and heat on camphor. A substance resembling camphor may be produced by passing hydrochloric acid gas through oil of turpentine.

Cedar and sandal-wood, and valerian root, each afford an essential oil from the solid portion of their substance, having distinctive chemical and odoriferous properties. The preceding oils have carbon, hydrogen, and oxygen solely as their constituents. The oils obtained from mustard seed, onion, garlic, eschalots, horse-radish, and assafœtida, contain also sulphur and nitrogen. The presence of sulphur in mustard is readily noticed by its well-known action on the silver of mustard-spoons. These articles of domestic use should, therefore, be gilt, so as to prevent the production of the black sulphide of silver, which so frequently covers the unprotected silver surface. Mustard also affords a fixed oil, to which allusion has already been made.

RESINS.—Under this head some very interesting products range. They are generally obtained from the tree affording them, by the process of "tapping," and the juice which exudes soon acquires solidity. Ordinary resin is thus a product of the pine, fir, larch, &c.

Caoutchouc, or India-rubber, is one of the most valuable of these products. It is obtained by making a hole in the stem of the *Ficus Elastica*. A milky juice passes out, which gradually becomes solid. The natural colour of caoutchouc is nearly white; its dark tint is acquired by the bottles into which it is made being smoked over a fire. Caoutchouc is soluble in ether, some kinds of naptha, and petroleum; and, in this state, is used as a varnish for waterproofing purposes. It is composed of carbon and hydrogen, and is highly elastic and inflammable. Mixed or worked up with sulphur, it loses a portion of elasticity, but acquires other useful properties. Its varied applications are well known; and, with the exception of gutta-percha, few vegetable products have been so extensively employed in making articles of comfort and luxury.

Gutta-percha is also the product of a tree, but differs from India-rubber in many important respects. It is less elastic, but does not lose its elasticity by being heated to a high temperature, as is the case with India-rubber. In their chemical characteristics they also differ, and in their solubility in menstrua. Both are non-conductors of electricity, and have therefore been extensively used for insulating telegraph wires. Electrical machines have been made of each of these materials, and they present great advantages to the electrician, owing to the very slight deposition of moisture on their surface in damp weather. The non-conducting power of heat possessed by gutta-percha is of great value, when that substance is employed in making water-pipes, as the enclosed liquid rarely freezes.

Lac, amber, mastic, dragon's-blood, &c , are resins, some of which are soluble in alcohol, and thus afford varnishes of different kinds. We may include pitch under this head, as it is a product of vegetable life, being obtained from the fir tribe of trees, in a similar manner to that already described

COAL AND ITS PRODUCTS.

Under this head we should be tempted to enlarge very considerably if space permitted ; but as the subject has been fully entered into in Section II., under the head of *Artificial Illumination*, we need do no more than present, in some respects, a general outline of the subject.

Coal is unquestionably of vegetable origin, and seems to have resulted from the decomposition of plants nearly allied to the ferns of our time. Indeed, the fossils of the coal measures afford every indication of that kind. *Lignite* and jet seem to be wood in a state of transition towards coal. Several years ago, we picked up at Tynemouth, near Newcastle, on the coast, a nut, which contained decomposed or rotten wood, charcoal, coal, and iron pyrites, all in one solid piece ; and this specimen well illustrates the agencies of heat and chemical decomposition, which have been active in producing the valuable fuel to which we are so much indebted for our position as a manufacturing nation. It would seem that the plants were first converted into peat ; that, subsequently, the land bearing them subsided ; and, being covered by strata, the pressure on the surface, and terrestrial heat, changed these plants into the forms we now recognise as coal.

Other minerals afford products analogous to those of coal. We merely mention this for the present, as we shall shortly have to describe such at some length.

Coal is chiefly composed of carbon and hydrogen, with some oxygen, and a slight per-centage of nitrogen, in certain kinds. When exposed to the action of heat, a vast variety of compounds of these substances is produced, many of which can be resolved into other substances. Indeed, a mass of coal may produce so many compounds that it would be impossible to describe all in a volume of moderate size Supposing considerable heat to be applied, the residue consists of a black mass called coke, which is nearly pure carbon.

The volatile products consist of olefiant gas, carburetted hydrogen, ammonia, carbonic oxide, carbonic acid, bisulphide of carbon, tarry matter, &c., &c., some of which we shall now describe.

Light Carburetted Hydrogen, or *Marsh gas*, so called from its frequency in districts containing pools of stagnant water, is a compound of CH_2, and may be obtained from various sources. It is highly inflammable ; and hence is partly the cause of the illuminating power of coal gas. It escapes from its natural source, the coal mine, in large quantities, occasioning those fearful accidents in mines of that material.—*Olefiant gas*, so called from its producing an oily fluid, by the agency of chlorine, is composed of $C_4 H_4$, and may be obtained by the action of concentrated sulphuric acid on alcohol. This gas is also inflammable, and burns with a rich yellow flame. The other volatile products to which we have alluded, have already been mentioned, under the heads of Nitrogen, Carbon, and Sulphur, respectively.

The manufacture of gas from coal is carried on to an enormous extent in this country ; but however interesting the subject may be, we must pass it over for others of greater importance in a scientific point of view. Besides, the article on Artificial Illumination, in the section on Light, affords every theoretical and practical particular. But one product of the distillation of coal or wood demands some notice, on account of the curious chemical products it affords. We refer to what is usually called tar.

Tar may be obtained by distilling wood or coal in close vessels, and condensing the products ; some of them we have already considered at page 415, to which we must refer our readers.

Creosote is a product of the destructive distillation of resinous wood. Its smell may be recognised in cured fish, smoked hams, &c. ; and its name is derived from the antiseptic power it possesses. Its preparation is somewhat complex : it is separated from wood-tar by distillation, and is composed of $C_{14} H_8 O_2$.—*Eupione* is another product of wood-tar. It differs from creosote in being readily inflammable, of less density, and also in its chemical composition, its formula being $C_5 H_6$. From some kinds of wood, a kind of paraffine is produced, to which, as obtained from another source, we shall have to direct attention hereafter.

Carbolic acid is a product of coal-tar, and is, or is nearly, identical with creosote in most of its properties. Its formula is $C_{12} H_5 O + HO$. It has been much used of late years as a powerful disinfectant. This product of coal introduces us to an interesting series of substances, ranged under the generic term, phenyl—$C_{12} H_5$—of which carbolic acid is a hydrated oxide. Connected with this series is aniline, a product alike of coal and indigo. We here meet with one of those extraordinary discoveries in chemistry which for many years may lie hid, only noticed by the scientific chemist, and yet may suddenly expand into the most useful form of applied science. For a long time, aniline was recognised as a principle of the colouring matter of indigo ; but it is only lately that, by the teachings of chemical science, we have been able to produce precisely the same substance from coal. At the present time, aniline, as obtained from coal-tar, is exclusively used in many dyeing establishments, for affording the colours—blue, mauve, Magenta, Solferino, &c.—which far exceed, in brilliancy, those produced from vegetable sources. Aniline is manufactured to a large extent from tar, by a patent process, and the philosophy of the subject we shall investigate when speaking of indigo.

Phenyl is perfectly analogous to ethyl, methyl, amyl, &c., which we have described at page 414, and subsequently ; and affords an oxide (the hydrate of which is carbolic acid), a chloride, &c.

Coal Naphtha.—This liquid is also obtained from coal-tar, being one of the last products of its distillation. After being removed from the tar in a crude state, it is redistilled, and becomes what is termed *light naphtha* It is an extremely mobile fluid, has a strong smell, a density of 890, water = 1000, and has been much used as an illuminating agent in what are called naphtha lamps. Benzole, which has already been described, may be produced from this naphtha by careful distillation, and subsequent agitation with sulphuric and nitric acids. Benzole thus procured is a liquid of a density of 850, water = 1000 ; is highly inflammable, and has lately been much used for naphthalising gas, and as a detergent for articles of clothing.

Rock Oil, or Petroleum.—In many parts of the world, a large quantity of oil spontaneously exudes from the minerals of some rocks which are adjacent, either to the coal measures, or in rocks containing lignite, &c. The oil wells of Birma, Baku, Syria, and at Colebrookdale, are instances of the kind ; but they all sink into insignificance in comparison with the wells lately discovered in Canada. As these have excited the deepest interest in all circles, we shall give somewhat extended particulars, and in the words of eye witnesses.

The oil deposits at present known seem confined to districts in the counties of Enniskillen, Brooke, and Sombra, in which parts the oil wells were first discovered. One of the largest yields a supply of no less than seven thousand barrels of oil daily, which flows out spontaneously, just like water. Immense quantities of the oil are wasted for want of casks to store it up.

As first afforded, this oil is highly inflammable; so much so, indeed, that serious accidents have been caused through its ignition. It has, however, been stated that it may be so refined as not to ignite under a temperature of 130°. It can be used as a lubricant, and affords naphtha, benzine, paraffine, and many other useful products. The following remarks are from a paper by Professor Hind, of Toronto University :—

"The extraordinary cheapness of petroleum, as an illuminator, is too well known in Canada to require any special notice. Notwithstanding the comparative dearness, in this country and the United States, of the chemicals (sulphuric acid and alkalies) which are required to purify, deodorise, and fit it for burning in lamps, yet it is, at 45 cents a gallon, incomparably the cheapest illuminator which has yet been manufactured; and it threatens, for domestic purposes, to drive all other means of illumination out of the field. But in Britain, France, and Germany, where acid and alkalies are abundant and cheap, and where various products, such as benzole, tar, &c., can be utilised with profit, the preparation of purified petroleum can be effected at so much cheaper a rate than on this continent, as to nearly make up the difference in the cost of the raw material which freight and insurance would add to it. Petroleum has arrested the production of coal oil or keroline on this continent; it will soon arrest, if proper steps are taken, the production of shale oil in France and Germany."

The following Table shows the comparative advantage of this Petroleum, or Rock Oil, over all other burning oils :—

Description of Oil.	Price per Gallon.		Intensity of Light by the Photometer.	Amount of Light from equal Quantity.	Cost of an equal Quantity of Light in Decimals.
	s.	d.			
Petroleum, or Rock Oil.	2	0	13·70	2·60	2·00
Sperm	7	6	2·00	·95	20·00
Camphine	5	0	5·00	1·30	10·00
Rape or Colza	4	0	2·10	1·50	6·50
Lard	4	0	1·50	·70	14·50
Whale	2	9	2·40	·85	8·25

Paraffine.—We have already alluded to a substance called paraffine, as obtained from wood-tar, and which is so named on account of its weak affinity, or slight inclination to combine with other bodies. Of late years, a large quantity of paraffine and paraffine oil has been obtained from Boghead coal, or Torbane-hill mineral, under a patent taken out by Mr. James Young, of Bathgate, near Edinburgh. The substance whence it is produced has been the "chameleon" of chemistry; for almost all kinds of differing opinions have been pronounced respecting it: the point to decide being, as to whether it is a mineral proper, or a coal—a question yet unsatisfactorily determined. The following is an account of Mr. Young's process :—

The raw material is heated in an iron retort; then exposed to hot steam, by which the oil, tar, and paraffine are volatilised. After being condensed, the product is distilled, and subsequently purified by means of sulphuric acid and oxide of manganese, or bi-chromate of potash. The residue having been washed, is distilled a second time, and subsequently cooled, strained, and pressed. It is then heated to 400° with concentrated sulphuric acid; and having been washed in hot water and soda, it is afforded as a solid body, semi-transparent, and presenting an appearance of bleached wax, but of a more pearly hue. In this form it is made into candles, which burn brilliantly, and without smoke. The oil produced from the raw material is employed almost universally in this country in lamps, and also as a lubricant for machinery.

Paraffine and its oil are prepared from various other substances; and lately it has been proposed to employ bog-peat in Ireland for the purpose; but we believe that the process has not been commercially successful.

Bitumen or Asphaltum is a solid substance, obtained chiefly from the neighbourhood of places abounding in other hydro-carbon products. The Dead Sea has long been noted for its adjacent bitumen pits. This substance is also found in India, America, and other places. It is of a black colour, inflammable, and being easily melted and moulded, is much used as a paving material when mixed with sand. In this form it is employed for rendering arches and railway tunnels waterproof, also as a basement flooring in warehouses.

Many substances analogous to coal, lignite, bitumen, &c., are found in various countries; but such are more conveniently described in the sections on *Mineralogy* and *Geology*.

VEGETABLE COLOURING MATTER.

Until within a recent period, most colours used in calico-printing, paper-staining, dyeing, &c., were chiefly obtained from vegetable sources. Mineral dyes, however, have been lately much in favour, and have the advantage, where they can be used, of being lasting, and easily applied. Some of these thus used, and also as pigments, have been described in our previous pages; we shall, therefore, here chiefly direct attention to colours of a vegetable origin.

The natural colours of leaves and flowers are due to a peculiar principle which is subject to the action of heat, light, and chemical action, but which is lost on the death of the plant. It is there a vital principle only. Colours employed for dyeing, &c., are extracted from the plant after its vitality has ceased, and are resident in the leaves, stems, roots, and flowers. Red dyes are obtained from madder, or rubia tinctorum, safflower, or carthamus, Brazil wood, logwood, sapan wood, the cochineal insect, &c.; blue colours are afforded by indigo, orchil, litmus, &c.; and yellow dyes are produced from fustic, turmeric, saffron, &c.

But all these colours *per se* are fugitive, and require a *mordaunt* to fix them in the fabrics to which they are applied. The action of a mordaunt is readily illustrated by that of iron and an infusion of logwood used in dyeing black. If a piece of cotton were simply dipped in the infusion of logwood, it would only acquire a dirty red-brown colour; but if it be first soaked in a solution of sulphate of iron, the oxide of the metal attaches itself to the fibres of the material, and, on being introduced into the logwood infusion, a black and permanent colour is produced. The mordaunts usually employed are salts of iron, alumina, and tin, others being used only to a limited extent.

Madder is chiefly employed in dyeing red. It is the root of a plant, and is imported into this country from the continent in a state of powder, having a dark-red colour. From it a peculiar principle, called *garancine*, is produced by means of sulphuric acid. This preparation is superseding the use of the raw madder, because it is more economical, cleanly, and effective. Other principles may be extracted from madder, such as *purpurine*, *alizarine*, *xanthine*, &c., of which the alizarine is the most important, because it is really the colouring principle of the rest, and is the chief constituent of the garancine of commerce. The celebrated Turkey red dye, which withstands the action of most chemical substances, is obtained by means of madder. The process is long and troublesome; and we may refer our readers to a late edition of Berthollet's *Bleaching and Dyeing*, for a full account of all its details.

Cochineal is properly an animal dye, but its colouring powers are due to the cactus, on which it feeds. With alumina, a decoction of the insect affords a rich red colour, used in dyeing silk, and in producing "carmine." We have succeeded in producing some rich red precipitates from a cold infusion of the cactus-flower and solutions of carbonate of soda and citric acid, employed in the manner we are about to describe in connection with safflower.

Safflower is a kind of saffron, and affords two colouring principles—a yellow and a red—the former being abundant and useless, whilst the latter is obtained only in small quantities, and is very valuable as a dye for silks, producing reds of the purest colour and of every shade, from pink to deep poppy.

The safflower must be washed in *cold* water, until all the yellow colour is removed. The residue of solid matter is then to be steeped in a solution of carbonate of soda, also cold; and, after some time, cotton wool is to be introduced so as to absorb the colour. It will appear of a muddy red tint; but on the addition of a solution of citric acid, or lemon juice, a magnificent red colour is afforded. By a repetition of this process the cotton may be filled with colour, which can afterwards be removed by the same means as those just employed. The colour is thus obtained isolated. A large quantity of the colour is manufactured on the banks of the Lea, near London; and also near Paris. The winter months are chosen for the purpose, as the heat of summer spoils the tint. From the small quantity of colour produced from the raw material, it is very expensive, and its use is chiefly confined to dyeing silks, and making "carmine saucers."

Decoctions made by boiling the chips of Japan, Brazil, and logwood, afford a red colour, with tin and alum as a mordaunt; and a black with salts of iron. These substances are chiefly used for dyeing wool and cotton yarn. Each of them contains some tannic acid, as do sumac, gall-nuts, oak-bark, walnut-peels, &c.; and such, with iron, afford black dyes of various depths.

Yellow colours are produced by the action of alumina, as a mordaunt on infusions of turmeric, &c.; but these colours are generally fugitive. Intermediate tints of brown, maroon, &c., are produced by successively dyeing the stuffs a yellow and red colour, until the desired tint be arrived at.

Blue vegetable colours are obtained from some lichens, amongst which the *rocella tinctoria* is that most commonly used. All the lichens, however, afford colours of some kind, and even those of a yellow and red tint. Orchil, used in dyeing silk, is obtained from the *rocella*, by means of ammonia, or more economically, urine, which has so far undergone decomposition as to afford ammonia. From these plants, peculiar colouring principles, such as *orcine*, &c., may be obtained, which are analogous to garancine, alizarine, &c.

Indigo has, till the discovery of the production of aniline from coal-tar,* been the chief source of the permanent blue of the dyer. The colour from indigo is not obtained, as in most other cases, by infusion or decoction in water, but by means of the strongest sulphuric acid. The raw material, as imported, is in blue-coloured cakes; these are powdered, and to them the strongest sulphuric acid is added. By this, the real principle of indigo is dissolved out. The principle of dyeing with this substance is that of first deoxidising it, which is done by means of the proto-sulphate of iron. This renders the indigo in a state fitted for absorption by the fabric, which, after being dipped into the solution, becomes of a deep blue colour on exposure to the oxygen of the air, and the colour then becomes permanent. In the process, the alkaline earth, lime, is used with the proto-salt of iron. And this introduces us to the production of aniline from a vegetable, as we have shown its production already from coal-tar.

If indigo be acted on by a hot solution of potass, and then distilled, aniline is produced as a nearly colourless liquor. It is highly volatile, soluble in water, and on being oxidised by chromic acid, affords a rich purple tint. It matters not what it is produced from, for it is equally obtainable from indigo, nitro-benzole, and coal-tar. And this is a matter of not only deep philosophical interest, but, in the uses to which it is applied, has become a most important article of commerce.†

Into the varied treatment which this substance undergoes, we of course cannot enter; and we have made our remarks more extended on it than we should have done, solely because it affords an instance of a most remarkable practical application of purely scientific research, and which we are glad to say has been the means of enriching those to whose perseverance we have been indebted for its manufacture in quantities.

Aniline forms numerous combinations with other bodies; its chemical formula has been stated as $C_{12}H_7N$, and thus it contains one equivalent of nitrogen. Stating it in its relation to the phenyl series,‡ we may use the formula—Pyl H_2N, or, $C_{12}H_5 + H_2N$.

In this chapter we have selected some of the chief of the many miscellaneous products of vegetable life, and have endeavoured to arrange them in such connection as would most conduce to their being understood by our readers. With them we shall dismiss the subject of vegetable chemistry, advising those who desire to prosecute the subject still further, to peruse the works of Fownes, Graham, Miller, Odling, and others, to whom we have ourselves been indebted for some of the facts which have been adduced.

CHAPTER XI.

ANIMAL SUBSTANCES.

ALBUMEN—FIBRINE—CASEINE—GELATINE—PROTEINE—KREATINE—BLOOD—OIL AND FATS—URINE AND UREA—BONES, ETC.—MANUFACTURES FROM ANIMAL SUBSTANCES—MANURES, CANDLES, SOAP, TANNING, ETC.

THE department of chemistry devoted to the consideration of animal matter in general, has already been the subject of an elaborate paper in our previous pages; we shall, therefore, here confine ourselves to a mere outline of facts.

The elementary constituents of animal life are, like those of vegetable existence, but comparatively few in number. Carbon, hydrogen, oxygen, and nitrogen, are, if we may so call them, the essentials; whilst sulphur, phosphorus, lime, and metallic oxides, in exceedingly small proportions, are the accidentals of animal matter. And yet, without a due proportion of each, the animal would be incomplete; for phosphorus is essential to the brain, lime to the bones. And thus the entirety is made up of parts, having definite ratios, which cannot be interfered with, lessened, or increased, without producing great changes in the being which may be their subject.

We need not here enter into any description of the individual elements; that has already been done in our previous pages: we shall, therefore, call attention to a few substances which either are part of, are secreted, or excreted, by the animal system.

ALBUMEN.—This substance is best typified in the white of a hen's egg, which contains the yolk suspended in nearly pure albumen. At a temperature of 160°, it becomes solid, as is well known in the domestic operation of boiling eggs. It then ceases to be soluble in water; and if exposed to a high temperature, it affords ammonia, and impure charcoal. Albumen is found in the blood, and in many secretions of the animal. It also exists in the juice, fruit, and seeds of plants. When in solution, it is precipitated by metallic salts, those of mercury being eligible, and by some acids, as the tannic, &c. Its chemical composition is stated by Mulder, as—

Carbon	53·5
Hydrogen	7·0
Nitrogen	15·5
Oxygen	22·0
Phosphorus	·4
Sulphur	1·6
	100·0

FIBRINE, so named from its fibrous appearance, is a constituent of blood, from which it may be removed by beating up that liquid with twigs, to which the febrine adheres. In a solid state it exists in flesh, in the gluten of flour, and in grasses. The chemical composition of fibrine is—

---

* See *ante*, p. 420.

† See *ante*, p. 420.

‡ See *ante*, p. 420.

Carbon	52·7
Hydrogen	6·9
Nitrogen	15·4
Oxygen	23·5
Phosphorus	·3
Sulphur	1·2
	100·0

From this we observe, that it scarcely differs from albumen, and in many of its characteristics it resembles that substance.

Caseine is found in milk; and, in fact, cheese is nearly pure caseine. A vegetable substance, legumine, much resembles caseine, and is found in cabbage and other plants. Pure caseine is insoluble in water and alcohol, but readily dissolves in alkaline solutions. In making cheese, the caseine is coagulated by means of an acid, obtained from the stomach of the calf. This is called rennet, and hydrochloric acid may be substituted for it, having, to some extent, a like effect. Caseine contains carbon, hydrogen, nitrogen, oxygen, and sulphur.

Gelatine and **Chondrine** contain the same elementary bodies. They are easily extracted from tissues, bones, &c., by means of hot water; and calf's-foot jelly is an instance of the former substance; whilst isinglass, glue, and size, represent it in a more solid state. In manufacturing bone manure, much chondrine is often produced. This substance differs from gelatine in not assuming what is generally termed a *gelatinous* state, and is not precipitable by tannic acid, which precipitates gelatine readily.

Proteine is obtainable from albumen, fibrine, &c., through their decomposition by an alkali, and subsequent precipitation by acetic acid. It seems to be a proximate principle of albumen, fibrine, and caseine.

Kreatine is a principle existing in flesh, from which it may be extracted by aqueous infusion. It is composed of carbon, hydrogen, oxygen, and nitrogen. It is soluble in hot water, and is extracted from heat in the process of stewing, &c.

Blood.—This liquid is essential to animal existence, and consists of water and organic matter. Its specific gravity varies, but may be stated at 1·05, water = 1·00. The red particles, which owe their colour to *hæmatosine*, are the heaviest portion of the liquid. The blood corpuscles vary in size in different animals; and lately M. Duboscq, of Paris, has rendered great service to physiology by the photographs he has produced of these globules. Their general appearance is accordingly characteristic of their origin. The following cuts will illustrate the fact: Fig. 85 representing the blood globules of man; Fig. 86, those of fishes.

Fig. 85.

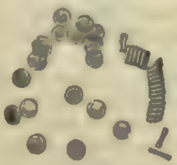

Fig. 86.

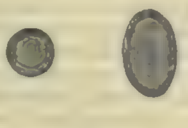

We need scarcely state, that by means of the blood every part of the body is nourished; hence it must contain every substance required in the animal from which it has been obtained for analysis. The following gives the proportions of proximate principles in human blood in a thousand parts:—

	Male.	Female.
Water	779·0	791·0
Red particles	141·0	127·0
Albumen	69·4	70·5
Earthy salts, &c.	6·8	7·4
Fatty particles	1·6	1·6

The above proportions differ from those given by other authors; but we need scarcely state that the composition of the blood incessantly varies in the same individual, owing to change of diet, disease, and other causes.

Oils and Fats.—At a previous page we have drawn attention to the oily matters produced by vegetables. To these the animal fats present much resemblance. Generally speaking, fat may be resolved by the action of alkalies and acids into oleine, stearine, margarine, and glycerine, each of which afford acids, theoleic, stearic, &c.; and such unite with alkalies and other bases. Thus soap is a stearate of soda; and by the addition to it of a dilute acid, the stearic acid is set free. Stearine is thus manufactured for making candles. The fat is made into an earth-soap by means of lime; to this dilute sulphuric acid is added, which sets the stearine, or stearic acid, free. By pressure and purification, it is eventually presented in a solid form. Margarine, oleine, and glycerine are simultaneously produced by the above process.

Spermaceti is a solid obtained from a species of whale, and is analogous to stearine in most of its characters. Butter is an animal fat, obtained from the milk of the female.

Amongst the secretions, such as bile, milk, urine, &c., we need only single out urea, which is a constituent of urine, and is interesting, as it may be produced artificially. For this purpose cyanate of potash is dissolved, together with sulphate of ammonia. The solution is evaporated to dryness; and the urea so formed, is extracted by means of alcohol. From this solution crystallised urea may be obtained, affording a rare instance of an animal product being imitable by the direct combination of its elements, apart from vital action. Its composition is $C_2\ H_4\ N_2\ O_2$. Uric acid is a component of urine, and is afforded in a solid state in guano, and the urine of serpents. Hippuric acid exists in the urine of gramnivorous animals.

Bones.—The framework or bones of animals consists of earthy matter, united by means of organic substances. The composition of bone varies, not only in different animals, but in the sexes of each. The following table affords an analysis of human bones:—

Animal matter	33·30
Phosphate of lime and fluoride of calcium	53·04
Carbonate of lime	11·30
Phosphate of magnesia	1·16
Soda and common salt	1·20
	100·00

In the crustacea, and marine animals generally, the carbonate of lime chiefly abounds; and thus the shells of mollusca are readily dissolved away, and engraved on, by means of hydrochloric acid.

Skin, nails, and horns may be considered as nearly identical in their constitution and production; the same may be remarked of hair and wool. In hair, both manganese and sulphur have been found.

Into the philosophy of nutrition, the production of bone, flesh, muscle, nerve, the secretions, &c., we cannot enter, as such will be fully considered in the section on *Comparative Physiology*, at the commencement of Vol. II. Our design has been to simply refer to those parts of the animal, the consideration of which is confined to the chemical details, and not to trench on subjects on which our space and arrangement forbid us to enlarge.

We may, however, add a few remarks on the manufactures connected with animal chemistry. Of late years, much attention has been paid to the production of animal manures. The bone, after being calcined, is drenched with dilute sulphuric acid, by which a superphosphate of lime is produced, which is of great value to the farmer. Blood, and other animal waste, have similarly been applied; and scarcely any substance of an animal nature exists, that is not now used for the purpose.

Hoofs, horns, blood, &c., are used in the manufacture of prussiate of potass, and in the process of cementation. Skins are, as is well known, converted into leather, by the process of tanning, in which the tannic acid* converts the soluble into insoluble substances.

---

* See *ante*, p. 415.

Fat, oils, wax, &c., are largely used in the manufacture of soap and candles by means of the process described in connection with stearine. This branch of manufacture has enormously increased of late years, owing to the stimulus which chemical discoveries have afforded.

Bones and urine are employed in the manufacture of phosphorus, a substance which, a few years ago, was only a chemical curiosity, but which, at the present day, is an absolute necessity (in the lucifer-match) to, perhaps, every civilised home in the world. Glue, size, isinglass, patent gelatine, are each produced from skins or bone; and the latter substance has become of considerable commercial importance in the manufacture of portable soups. We decline, for the sake of our readers, to indicate its possible sources in many cases.

Space fails us to name all the uses to which animal substances are now applied. Chemistry helps us, not only to use up what would otherwise be waste, but actually converts, in some cases, substances, literally as "cheap as dirt," and real dirt, into others as valuable as gold. Indeed, its chief object, at the present day, is to turn to profit that which has been cast away as useless in former times. Aniline, aluminum, and a host of other products, afford us instances of the kind, and prove, alike to the philosopher and the artisan, that nothing was made in vain, or without its definite object and use.

Whilst it is the province of science to discover and indicate, the natural energy and instinct of man tend to utilise; and thus each succeeding age builds its monument on the *débris* of that which preceded it, only to afford materials for that which has to follow.

CHAPTER XII.

CHEMISTRY APPLIED TO AGRICULTURE.

WITHIN the last few years chemistry has been extensively employed in connection with agricultural pursuits. For centuries, agriculture had been little else than a system of conjecture and chance, in which the experience or opinion of each farmer was followed, without reference to principles or experiment. At the present time, on the contrary, science becomes the guide of every homestead —the aid of chemistry is everywhere sought, and agricultural societies and colleges are the means of disseminating its teachings amongst the masses.

At first sight it would seem that agricultural chemistry is a subject so extensive, that an acquaintance with it would involve almost a lifetime of research and experience; but such is not the case. We have simply to learn the constituents of any plant, and we shall at once perceive the nature of the soil required for its production. The question of climate, period of sowing and reaping, drainage, and similar matters, do not fall within the scope of chemistry. Such are purely matters of judgment and experience, for which no science can be substituted, except the knowledge acquired by repeated and long-continued observation.

The chemist has to decide on the question of the component parts of soils actually present, and the nature of such which, whilst absent, may be supplied in the form of manure. To do this, he carefully analyses the grain which is to be sown, and the soil in which it is intended to sow it; and whatever the latter is deficient in, his result should tend to point out, and to suggest a supply.

Let us first examine into the most important of all kinds of food, the cereals, such as wheat, rye, &c. The ear of wheat consists of seed, which is composed of gluten and starch. The latter substance is abundant in most plants, especially in cereals, potatoes, &c. It consists entirely of carbon, hydrogen, and oxygen,* whilst gluten has an additional element in the form of nitrogen. But besides the starch and gluten, earthy matter of various kinds is found in the seed and stem, such as silex, lime, &c.; and these, whilst they act as the bone to the plant during its vitality, become bone in the animal through the absorption of those substances in the system from the vegetable food on which it subsists. It matters not whether animal or vegetable food be used by man, exclusively, or mixed together. In either case he acquires the mineral matter of which his bones, teeth, &c., stand in need;—from the plant directly, in a crude state; or from the animal, as the ox and sheep, in a form more readily adapted for assimilation. Indeed, the domestic animals and plants used as food are simply channels, by which the elements of the soil are changed from inanimate dust to the constituents of sentient humanity. In this process, for a time only, inanimate nature is robbed of part of her own; but this occurs only for a brief space. Daily we give back, as excreta, portions of earthy and saline matter; and, at last, when we return "dust to dust, ashes to ashes," we repay the debt we have incurred during the brief period of our existence; and our mortal bodies, in their decay, literally and truly return to the earth from which they were first made. Nothing is lost; but, on the contrary, the particles of matter undergo an incessant change of combination—flitting at one moment as dust in the sunbeam, and anon forming the material of man, made in God's own image.

If we carefully examine the constituents of an average soil, we shall find that their number is comparatively few. The following is an analysis of one of the best soils found in the grazing pastures of Devonshire and Cheshire. It contains of

Silica	per cent.	70·2
Alumina	,,	19·2
Carbonate of lime	,,	0·4
Oxide of iron	,,	6·0
Water and organic matter . .	,,	4·1
Chloride of sodium (common salt)	,,	·1
		100.0

Now the whole of the above ingredients go to form the solid matter of a plant, but only in part; for the great proportion of flour, potatoes, &c., consists of carbon and water, derived, not from the soil, but from the atmosphere which surrounds the plant.

When a seed commences to germinate it produces two organs—the root, or radicle, which is to inhabit the soil; and the plumule, which, rising beyond the soil into the atmosphere, is to become the means by which the carbonic acid floating in the air is to be absorbed, and its carbon assimilated to the body of the plant. With this part of the growth the farmer has nothing to do; he must leave all to nature. With the root, however, he has everything to engage his attention; because that supplies the plant with the stamina which enables it to acquire a living and productive form.

Now, as soils differ in their nature, they are accordingly fit for the growth of corresponding plants, and every plant, as is well known, will not flourish equally in every soil. Clay consists chiefly of silica and alumina; and when it contains about forty per cent. of sand, it affords a clay-loam. The colour of clay is caused by the presence of oxide of iron. If a soil contain from ten to twenty per cent. of lime, it becomes a marl; and with a greater proportion, as in the chalky soils of Kent and Sussex, a calcareous, or lime soil is afforded.

When a soil is too close, inferior crops are produced; and some plants, as the potato, will not grow, or will produce inferior crops. Hence, in travelling over extensive ranges of country, we find great diversity of crops. In Kent, Essex, Suffolk, &c., we find cereal produce prevailing, with rotations of turnips and potatoes. In the Midland Counties grass is chiefly cultivated, for grazing purposes. In Lincolnshire and Cambridgeshire we see heavy corn crops, owing to the land containing the essential constituents in the soil.

---

* See *ante*, p. 411.

Soils differ greatly, not only in their chemical constitution, but also in respect to their physical characteristics. A solid clay will not permit water to pass through it, whilst sand allows that fluid to percolate most readily. Now, generally speaking, the clay is rich in all the substances which are required to produce the plant, whilst sand is comparatively deficient; and yet a better crop shall be produced from sand soil than from heavy clay. This fact shows that we must not depend solely in the results of a chemical analysis to direct us in the choice of a soil. Indeed, we have seen in Invernesshire and Nairnshire, in the north of Scotland, soils (if they deserve the name) consisting of nothing but unmixed sea-sand, in their natural state, but which, by means of manures, afford excellent crops of wheat, barley, and oats. An excess of moisture in soils checks vitality equally with droughts; therefore, not only is a clay improved, in a chemical point of view, by admixture with sand and lime, but its physical character is altered, and it becomes more readily drained, "warmer," and therefore fitter for the production of any kind of crops.

After one kind of plant has been grown in a soil, it will be found to have abstracted such parts of that soil as have been required to afford it nourishment; and thus the soil has become deteriorated. Now, it is a remarkable fact, that the absence of an ingredient will entirely prevent the production of seeds and fruit. Lime is essentially necessary for this purpose; in fact, pea and bean plants will bear flowers but not seed in its absence. We have at this moment before us a luxuriant crop of beans, grown in a soil in which the same kind of seed was sown last year, but, in the absence of lime, was absolutely unproductive. At the early part of the present year, the soil was well dug up and limed, and now every stem is loaded with pods. On another soil, we tried precisely the same experiment some years ago; half was limed, and the other half was exhausted: the latter bore plenty of leaves, but not a pod; while the former afforded abundant crops, the same kind of seed being sown in each. It is true that such are extraordinary examples; but the farmer has plenty of them, although not so distinctly marked as these. Poor crops generally indicate that their producer has failed in his duty and practical knowledge. This is the great secret of the success which attends farming in the north of England and in Scotland. There the *climate* is everything that can be against the farmer, but his practical experience overcomes the natural deficiencies of the soil and climate; and thus he can produce crops on land which, in the south of England, farmers would only compare to those of a stone wall, as to its probabilities of producing power. We have seen oats growing on a limestone rock, on which the soil rarely exceeded four inches in depth. There the soil had to be brought to the rock; whilst in the southern counties, rich loam, extending many feet in depth, may be found. When a deep soil is superficially exhausted, it may be improved by being deeply ploughed. By this means the subsoil is brought to the surface, and so mixes with and replaces that which had been exhausted by the crops that had grown on it. In a similar manner, the rotation of crops benefits a soil; for if turnips, for instance, be grown where wheat has been reaped, they merely take up water; whilst the cereal has withdrawn silex, alumina, lime, &c. The atmosphere then has time to break up and decompose such elements into a soluble state, and so fit the soil, by a kind of reproductive process, for a repetition of the cereal growth after a lapse of time. Herein consists the advantage of allowing the fallowing of land. The soil is left to itself for a year or two; the atmosphere and moisture decompose the felspar and other minerals of which it is composed, and thus render it fit for growing various crops in succession.

Another point of great importance is the degree of pulverisation of land. As a plant grows it shoots out from the main root a vast number of radicles, by means of which it absorbs, from a thousand sources, its mineral food. If these radicles are confined by a close soil, the plant droops and dies; whilst if the soil be porous, and finely divided, these little roots can extend in all directions, and so become feeders for the main root and the plant. Ploughing, digging, harrowing, the burrowing of animals, as moles, worms, &c., the decay of vegetable fibres, all make such channels in the soil, and also assist in its drainage; and many manures, such as straw, and the like, thus effect a physical as well as a chemical improvement in land. This is a matter of great importance; although we feel sure that it is systematically neglected, and generally by pure accident only obtained. Burning clay has lately been much resorted to for this purpose; and, where coal is cheap, is an excellent practice. The retention and close character of the clay is destroyed, and the soil rendered into a finer state of division, and therefore more porous.

MANURES—ANALYSIS OF SOILS.—An experienced farmer will readily guess as to the nature of the substances abstracted from a soil by any crop; but chemical analysis more certainly points out this, and also suggests what kind of manure may be required to restore fertility. We shall not enter into minute details of the plan of analysis, as that has already been done at page 394, and succeeding pages. We shall only give directions as to the preliminary part of the process.

It will generally happen that more than one kind of soil is contained in a field, or many fields may consist of the same kind. An average of the soil should, therefore, be gathered, and the various samples mixed together. The first point to ascertain will be the amount of moisture which the soil contains. For this purpose all stones should be removed, and the earth may be weighed. It is then to be exposed for some hours to a temperature not exceeding 212° Fah. This will drive off all absorbed water, and the loss of weight will indicate the amount present.

The absorbing power of a soil may be learned by drying and weighing samples as above. They may then be well wetted, and left till all loose water has drained off. Their comparative weights being then ascertained, their absorptive power will also be learned.

After the amount of water in the soil has been ascertained, the next step will be to find out how much soluble matter it contains. This may be done by agitating the specimen for some time with cold water, when the soluble parts may be removed and tested, in the way directed at page 398. The insoluble portion may then be digested with hydrochloric acid, to remove iron, &c., and the remainder of the analysis carried out in the way suggested at the page referred to, *et seq.* By such a method, and following the instructions already given, any one of ordinary intelligence may gain sufficient knowledge of the constituents of a soil, and distinguish the earths and metallic oxides it contains. A quantitative analysis requires considerable knowledge and experience, and is better left to the professional chemist.

Having discovered what substance the soil is deficient of, the next step is to supply the required material. This is done by manures; and the choice of the proper one is decided by the results of the analysis. Such a multitude of these preparations is offered at the present day, and each is stated to be the "very best," that a farmer will, in many cases, be in a state of perplexity as to what he should choose. We shall not increase his difficulties by giving directions, which, at the best, would be but suggestive, if of use at all. So much depends on drainage, climate, and other physical circumstances, besides those of a chemical character, that it would be impossible for us to specify a universal panacea for all the ills that earth is heir to. We shall, therefore, simply name the proximate elements essential, and the manures which contain them, and leave to practical experience their choice and application. In purchasing any kind of manure, we may warn the farmer that he may be greatly deceived. The practice of adulterating guano with sand, &c., is very common; and, in every case, a certificate of analysis should be insisted on at the time of purchase. Many respectable houses always furnish this.

Substances required for Soils.

Silex	As in	Sand.
Alumina	„	Clay.
Lime	„	Chalk and limestone.
Oxide of iron . .	„	Sand and clay.
Phosphorus . . .	„	Phosphate of lime.
Sulphur	„	Plaster of Paris (sulphate of lime).
Nitrogen	„	Ammonia.
Carbon	„	Chalk, carbonic acid, vegetable matter, &c.

The following supply some or all of these substances :—

1. *Sewage.*—This abounds in every town, and has frequently been utilised to a great extent. Near Edinburgh there are fields which, from being comparatively worthless, now produce several crops of grass annually, owing to the sewage of the city being allowed to flow over them. Generally speaking, however, sewage matter is far too much diluted with water to be of much value, except in places where it can be readily applied by pumping, or the natural fall of the land. Of course it contains *every* substance required on the land, because it is the product of all that has been taken from the land in the shape of corn, grass, and the flesh of oxen, sheep, &c., fed on it. When it can be economically applied, it is highly valuable; but on clayey grounds, the immense amount of moisture deposited may prove hurtful. On sandy soils it becomes a most eligible manure.

2. *Guano.*—This substance is in high repute. It contains nitrogen (as ammonia), phosphorus (as phosphate of lime), silex, lime, &c. Indeed, we may consider it as the concentrated equivalent of town sewage. It is composed of the decomposed excreta, feathers, bones, &c., of birds.

3. *Artificial Manures.*—Next to the above come a legion of manures prepared artificially, all resembling sewage matter and guano, and containing the elements to which we have referred. To enumerate such would be impossible. Some are of great value; and in many we are inclined to believe that the only thing of value about them is the cask in which they are contained. Of such, we say to the farmer *Caveat Emptor.*

4. *Super-phosphates.*—These manures are made by calcining bones, and adding sulphuric acid thereto. A super-phosphate of lime with sulphate of lime is produced, affording phosphorus, sulphur, and lime. These are generally sold as bone manures, and are of great value to most soils.

5. *Lime, Chalk, Limestone.*—Some lands require the destruction of vegetable matter, which is effected by the addition of—

6. *Caustic Lime.*—This may be readily obtained by burning chalk, which drives off the carbonic acid. Chalk gives soft, and limestone hard, lime. Chalk or limestone is eligible for lands deficient of lime, but not requiring that substance for the purposes just named. They gradually become soluble, by the absorption of carbonic acid from the atmosphere.

7. *Fish, Seaweed, &c.*—These are readily procurable at the sea-side, and contain lime, common salt, and many other substances. They are each spread broad-cast on the land, or heaped up that they may putrefy. In Kent this manure is largely used; and sometimes sprats are so plentiful on the south coast of England, that they are employed to a very great extent by the farmers.

In the above epitome of manures, we have not included stable dung, human excreta, &c. The latter is used almost exclusively in China, and we need scarcely say is highly valuable. It is dried and made into cakes, in which form it is sold to the agriculturist in that country.

We have, in these observations on the subject of Agricultural Chemistry, confined ourselves solely to the results of personal experience in most parts of Great Britain and Ireland. We have met and conversed with farmers of every degree of intelligence and experience, and must say, that to depend on the dicta of any one or any class, would be to go counter to the rules of sound farming. What would be excellent as a plan in the south of England, would bring starvation to the doors of a northern farmer. In Ireland things spring up despite human intelligence; in Scotland, in despite of nature; and in England, these extremes meet. But the progress of science and railroads is effecting immense revolutions. Agricultural societies present to their members the results of extended experience and observation; the sons of farmers are now almost universally acquainted with, or are being instructed in chemistry; and the "dark ages" of agriculture are passing away into the things that were.

Of course we have only given a sketch of the application of chemical science; we shall conclude by recommending the perusal, by such of our readers as may need greater detail, of the works of Davy, Liebig, Johnston, and other eminent men, to whom humanity will ever owe a lasting debt of gratitude. The Proceedings of the Royal Agricultural Societies also afford much valuable information to the practical farmer on all the points we have named.

CHAPTER XIII.

THE SANITARY APPLICATIONS OF CHEMISTRY.

NOTHING is more gratifying to the true philosopher than to find that the facts and laws he has discovered may be applied for the social benefit of mankind; and just in proportion as this is successful, so he gains the reward of his labours.

Of late years, the subject of Social Science has been extensively ventilated; and, under the able and active superintendence of Lord Brougham, an association has been formed, with the object of discussing all questions relating to the moral, mental, and physical well-being of our nation. It is with the last department, in its relation to chemical science, that we shall briefly deal.

Health, individually and socially, depends chiefly on an abundant supply of fresh air, good (not "pure") water, and wholesome food. The latter is assimilated with the animal system; the water assists in diluting the food, in its assimilation, and in the formation of the blood, flesh, bones, &c., conveying the soluble matters to their proper destination; whilst the air, acting on the carbon of the food, causes its slow combustion, and this affords heat to the animal.

We, however, necessarily give off, in our most healthy condition, various excreta, consisting of gases, liquids, and solids; of which the chief are, carbonic acid from the breath and skin, other gases the product of digestion, &c., urine, and fæces; all of which, whilst decidedly poisonous to humanity, are extremely valuable as food for plants. In other words, what we have done with and must get rid of, is exactly that which the vegetable kingdom must have, and hence arises a compensating process between animal and vegetable life and their exigencies. The subject has already been entered into in the last chapter; we shall, therefore, not require to describe the uses of animal products. In dealing with this subject, we shall confine our remarks almost solely to the question of pure air; for the supply of water and the adulteration of food have already become subjects of government interference, and may be safely left to public management. Our supply of air, on the contrary, is purely a *personal* question, and so deserves the most careful consideration.

During the process of respiration, carbonic acid is abundantly produced in the lungs, and is, of course, exhaled as the breath is exspired. With this, a considerable amount of fœtid animal matter is also exhaled, which adds to the impurities of the surrounding air. If a person sit in a room destitute of arrangements for ventilation, he must, after a time, re-breathe these poisonous exhalations, and by so doing vitiate the blood, which depends on the supply of pure air for its oxygenation. The close smell of bedrooms in the morning, after one or more persons have slept in them, is caused by these exhalations; and the fœtor of alleys and courts, inhabited by the poorer classes, is due to the same cause, aided, however, by imperfect sewers, closets, &c.

Now the atmosphere, in its normal condition, contains only from four to six parts of carbonic acid in ten thousand of air. In unventilated rooms this proportion enormously increases; and an idea of this may be gained from the following example of a boys' school, extracted from a Parliamentary Report:—

Capacity of room . . .	22,140 cubic feet.
Number of boys present . .	164
Carbonic acid present in the air of the room after having been occupied 2½ hours .	$\frac{23 \cdot 71}{10000}$

Thus we see that the proportion of carbonic acid to that of air had increased from 5 to nearly 24 parts per 10,000, or nearly five times its normal quantity. How can we wonder, then, that fevers abound in crowded localities when such palpable facts are presented to us. It must be borne in mind, also, that besides the carbonic acid afforded, animal matter, other gases, and impure aqueous vapour are produced in such cases. The presence of these soon become evident from the languor into which the children fall; and then the physical evils resulting from breathing impure air, exert a visible and undeniable influence.

Defective drainage is another cause of impure air, and in many cases a most fatal one. The sewers, of course, carry off every species of excreta and waste from our houses. These substances all mix together, and mutually decompose, giving off many hydro-carbons, sulphuretted hydrogen, and other deleterious substances. When the connection between the house-drain and the main sewers is defective, these gases will enter the house, especially when the barometrical column is falling; hence arises the "smell of drains" just previous to wet weather. Defective drainage and typhoid diseases are always to be found concomitant; and the only effective remedy lies in removing the cause of the evil.

Disinfectants.—We may here conveniently refer to substances which have been used as disinfectants, omitting such as pastiles, perfumes, &c., which merely mask, but do not remove, pernicious exhalations. Chloride of lime, chloride of zinc, carbolic acid, caustic lime, and charcoal, are the most effective that can be used, consistent with abundance of supply, and consequent cheapness.

The two chlorides are of great value, because they decompose, sooner or later, most of the hydro-carbons in sewage gases; they are easily applied, and are very cheap. Carbolic acid and lime are not so fit for domestic use as those we have named, but can be employed on the large scale. The former may be cast down sewers; whilst the lime is suitable for covering graveyards, and any places whence effluvia are given off. Of late years, immense quantities of lime have been thrown into that great common sewer, the River Thames, during the summer months, and with the most beneficial effect.

Charcoal, whether as obtained from peat or other substances, is of great value. It is readily applied, and is of slight cost. Some years ago it was proposed, by Drs. Stenhouse and Watson, to purify the air supplied to hospitals, by passing it over trays of charcoal, or charcoal containing platina in a minute state of division. The following extract from Dr. Watson's remarks, gives the *rationale* of the method, and also affords some instances in which charcoal may be usefully applied:—

"Charcoal, as is well known, has the power of absorbing various gases in large quantities, and, perhaps, few more readily than those which arise during the decay of dead animal and vegetable substances. But charcoal does something more than simply absorb; for it is evident that, if it possessed no other property, a point would shortly be reached, when, having become quite saturated, it would cease to act. Charcoal, then, has another power in addition to that of absorption; and for the illustration of this I would refer to the following striking experiment:—Certain dead animals were placed in an open box, and covered with a layer of roughly-pounded wood charcoal, rather less than three inches in thickness, and all the decomposible portions disappeared more rapidly than if they had been buried in the ordinary way. Moreover, the boxes containing these dead animals were kept for many months in a room in which several persons were employed during the day, but still no disagreeable effluvia were detected, and health remained unaffected.

"All decaying animal and vegetable matters give off, during decomposition, fœtid and deleterious gases, which, in the end, tell as fatally upon the human constitution as does the bite of a viper, or the most insidious poison known to the chemist; and the animals referred to in these experiments formed no exception to this rule—a fact which could be readily ascertained by removing a portion of the charcoal so as to get nearer to the putrid mass below. From this, therefore, it follows, that not only does the charcoal hasten decomposition, but that those deadly gases that are constantly being given off, become, in their passage through the charcoal, converted into inodorous and comparatively harmless ones.

"The explanation of this peculiar result is simple and very beautiful. Charcoal is an extremely porous substance, presenting through its mass an almost incredible amount of surface; and upon this depends its power of absorbing various gases in large quantities. The oxygen of the air is the great vivifier of nature. The deadly emanations given off by decomposing matters are in what is called a 'low state of oxidation;' that is, they contain a comparatively small proportion of oxygen. Combine them with, or force them to take up, more of this purifying element, and the point is gained: that which, perhaps, an instant before would have proved most hurtful if breathed, becomes now almost entirely resolved into comparatively harmless combinations.

"Now charcoal contains within its pores a very large proportion of oxygen, amounting to rather more than eight times its bulk. As already shown, it absorbs the various putrid gases with avidity, and in this way they are brought into intimate contact with the condensed oxygen existing in the charcoal, and the result is as has been described.

"Such, then, is the action of common charcoal in dealing with the fœtid gases of decomposition. It not only absorbs but destroys them; that done, it gives out the resulting comparatively harmless products; room is made for more oxygen from the air, and more of these bad gases from whatever source, and thus the process ceaselessly goes on. In this manner the charcoal is, so to speak, constantly purifying itself; and, under ordinary circumstances, with occasional exposure in front of a large fire, or to the sun's rays, its powers remain intact for an almost indefinite period."

For domestic purposes, as the above extract will show, charcoal is of great use. It may be employed either in powder or in pieces of about the size of a pea, and, in that state, should be thrown over the object to be disinfected.

Ventilation.—This subject, although its end is of a purely chemical character, more properly appertains to the Laws of Heat;* we shall, therefore, confine our remarks to general principles only.

The gases given off from the lungs, are nitrogen and carbonic acid, in a heated state. The former has a specific gravity of 0·97, whilst the latter has that of 1·524. We should hence suppose, at first, that the nitrogen would rise in the air of a room, and the carbonic acid would fall to the lower parts; but this never happens, unless either gas is present in great excess. On the contrary, by the action of gaseous diffusion they intermingle, and so form a homogeneous combination in all ordinary circumstances. In a *closed* room, therefore, every part will soon arrive at a literally stagnant state. The only motion of the impure air will be produced by the animal heat, which causes it to rise, and the cooling effect of the windows and walls, which has a contrary influence. On opening a door, however, a fresh series of physical causes comes into operation. A draught of cool, and therefore heavy, air *sets into* the room at the lower part, whilst one of hot and light air *escapes outwards*, at the top. This may be readily noticed by holding a lighted candle successively at the bottom, middle, and top of an open doorway, when these currents will be noticed ; the middle part, however, affording no current. This simple experiment teaches us the philosophy of ventilation in the most effective manner ; and every ventilating arrangement which has yet been, or is likely to be proposed, rests for its basis on this fact.

---

* In the section on *Heat*, this subject is treated on in considerable practical detail.

When open fires are found in a room, of course a constant draught is maintained ; and this, doubtless, diminishes the unhealthy character of apartments in which we often see men, women, children, cats, dogs, &c., &c., herding together. A fire must be kept for cooking purposes ; and *all* the animals we have named generally sleep on the floor, or but little removed above it. They then, to some extent, enjoy a constant change of air when at rest ; whilst to a person entering such a room the effluvia would be intolerable, because *his head* would be much above the chimney opening, through which the lower stratum of impure air passes away. On these vital and interesting subjects, however, we must not enlarge. We commend them to the study of all our readers, as a matter of duty on their part. A little sound practical advice to a poor man, earning his weekly wages and supporting a large family, is of much greater pecuniary value than a liberal donation of money. The last he will soon spend ; the former will save him, in medicine and loss of time (his money) by illness, some pounds perchance in the year. Indeed, we never see a broken pane of glass in the window of a working man's room, without being thankful that the brittle nature of the material most mercifully provides for him one of the greatest blessings of nature—free air, and also ventilation —both of which he wilfully denies himself, to his own loss of health and resources. Well would it be if the city missionaries, so usefully employed in our large towns, would, in such a manner of giving sanitary advice, *completely* follow the pattern of the Great Physician, who "went about doing good," not to the souls alone, but generally *first* to the bodies of men. However much we may endeavour to raise the moral condition of man, we must not neglect his physical state. Our relationship, as beings, is threefold—moral, mental, and physical. At no instant in this life do they exceed each other in their exigencies. They have been united by the Creator from the moment man was created, and they are not put asunder until He commands, and death becomes the means of their dissolution.

Distantly connected with the subject of ventilation is that of clothing, in so far as it concerns the removal of those gases which pass from the skin. It is a remarkable fact, that animals may be as readily poisoned by the absorption of poisonous gases through the skin as if such were inhaled by the lungs. Some years ago, when the Niger expedition was first proposed, an inquiry was made into the causes of the unhealthiness that prevails in regions surrounding the Niger and other tropical rivers. After much dispute on the subject, it was considered that the presence of free sulphuretted hydrogen was the proximate cause ; and that not only would danger arise from inspiring the tainted air, but that the entire surface of the body was also predisposed to absorb the fatal exhalations. To prove this, rabbits were enclosed in air-tight vessels, filled with sulphuretted hydrogen, in such a manner that the heads of the animals were left free in the open air ; so that the poisonous gases could not pass into the system by means of the lungs. It was found that a rapid absorption took place through the skin, which soon proved fatal. If, however, the bodies were well oiled, then the pores of the skin being filled up, absorption did not take place ; and so the animals, placed in the circumstances referred to, were comparatively uninjured. Applying, to some extent, such principles to the question of the human subject, we shall see that, unless the clothing permits a certain amount of ventilation of the body, either by its being porous, or only covering the skin loosely, the animal exhalations will be retained on the surface of the skin, and will be reabsorbed, to the manifest detriment of the individual. Hence the danger which arises in part from the use of what is termed "water-proof" clothing. The gaseous and liquid secretions are kept in contact with the skin, and are thus productive of serious consequences. The use of water-proof shoes hence frequently causes "tender feet;" for the ammonia or acetic acid secreted, according to the physical constitution of the person, acts as an irritant of the skin ; and thus, for the same reason, the nonporosity of the leather—new shoes always hurt the feet, preventing, as they do, the escape of the perspiration.

It is thus found that flannel worn next the skin, and woollen clothes generally, are the most healthy. They retain, through their non-conducting power, the heat of the body ; and yet, by their porosity, permit of a constant circulation of the air they inclose, into which the excreted gases, &c., pass off. They have also another advantage, which is that of acting as an irritant to the skin. They stimulate the nerves on its surface, and thus the pores are kept continually open.

CLEANLINESS.—The remarks just made bring us to another subject of great importance—that of personal cleanliness ; and in this, chemistry and chemical manufactures play a most important part. It is well known that the body of a human being contains some millions of outlets, through which water, &c., continually pass out. The liquid and gaseous substances escape, or else are absorbed by the clothing ; whilst some portion of the solid is retained in the skin and in the pores. This solid matter consists of animal fat, common salt, acids, and other substances, which, if not removed, will close the perspiratory pores, and prevent that relief to the system which those pores are intended to afford. In removing the matter, water alone is not sufficient. This may be readily noticed on any one taking a bath, either hot or cold, after violent exercise. The water will flow from the skin without really wetting it, simply because the fatty matter, deposited on the surface, intervenes between the skin and the liquid. If, however, an alkali, either free or in the form of soap, be used, then the fatty substances are easily removed. Soap, indeed, is simply a convenient method of applying an alkaline solution in such a way that, whilst its detergent properties may be employed, its caustic effects, which would destroy the skin, are avoided. Washing powders, and other substances of the class, are those generally containing either potass, or soda in a free state ; and from their known power of combining with the animal fatty acids, their value as detergents arises. Of course, what is required to cleanse the skin, is equally useful in the operation of washing articles of clothing. If such are not cleansed from the impurities which they have absorbed from the skin, they soon not only acquire a fœtid smell, but become positively dangerous. Kept near the absorbing pores, they afford a constant supply of impure matter, which, if reabsorbed, is productive of any kind of disorder of the typhoid class. We are, perhaps, not wrong in applying a similar observation to ragged clothes as we have done to broken windows ; for what one does to ventilate the room of the poor man, the other does to his body—each allowing an unwelcome, but necessary supply of fresh air.

WATER.—We have already stated that we do not intend to enter into the question of the supply of water, but we may make a few remarks respecting its chemical relations to sanitary questions. Pure water, in the chemical sense, never occurs in Nature. The nearest approach to it is rain ; which, however, is always contaminated with gaseous exhalations, if collected on land; and with saline matter if it fall near the sea-shore. Absorbed by the earth, and percolating the interstices of sand, rocks, &c., it acquires a variety of substances, which dissolve in it. When these are in excess, the water is termed "mineral water;" and usually contains lime, magnesia, oxide of iron, and alkaline salts. Such water can neither be used for washing, drinking, or culinary purposes, owing to its hardness. When such saline ingredients are in less proportion, we have a liquid resembling river water; and such partakes of the character of that supplied to most of the large cities and towns in the kingdom. Generally speaking, such water contains from fifteen to twenty-five grains of inorganic, and from one to four grains of organic matter to the imperial gallon; besides a small proportion of oxygen, carbonic acid, and other gases in a dissolved state.

Confining our attention solely to the organic matter (for the other questions have been frequently inquired into in our previous pages), we may observe that both vegetable organisms and animalcules are its constituents. It has been noticed that, in seasons when diarrhœa is most prevalent, the presence of putrefied or putrefying organic matter is always in excess in most sources of our water-supply; and so universally is this the case, that no competent authority doubts the direct connection between the disease and this circumstance.

If there be one subject in which we are most at fault with respect to chemical science, it is that of the operation of poison on the human system; especially that of vegetable and animal poisons. Their action is so subtle, and frequently the external physical effects of it so speedily pass away, that nothing but rough conjecture is left us in respect to that action.

The most careful chemical analysis has failed us in attempting to detect the details of poisoning by putrefied matter, whatever may be its origin. It has been ingeniously suggested that the result is due to a kind of inoculation; for it has been found, that if the matter of putrefied sausages be introduced into the system, in a manner similar to that adopted in vaccination, the blood soon becomes vitiated, and the death of the subject speedily ensues. However, to extend such a theory to all cases of death arising from the use of impure water, would hardly be permissible; we can only point out the evils which may arise, advise that they be carefully avoided, and hope that, eventually, we may gain some deeper insight into this painful, but deeply interesting subject.

It is a remarkable fact that some kinds of water really become purer after undergoing a kind of fermenting process. The animal and vegetable matter they contain, undergoes decomposition; and assuming, by the rearrangement of their elements, new forms of combination, the water itself is left in an almost pure state. The water supplied from the Thames to shipping, affords a notable example of this; and is, therefore, preferable to any other kind, when required for long voyages. Of late years, the general adoption of steam as a method of propulsion, and the invention of various forms of apparatus for distilling sea-water, have been of great advantage to persons undertaking long voyages, and have greatly conduced to the health and comfort of the passengers.

As remarked at page 426, water acts as a solvent and diluent to the human system. Whatever we take in the water we drink, must travel through the system, and be assimilated to its structure, or be rejected as urine, together with other substances which it has dissolved during its progress. This will show of what extreme importance it is that the water of which we partake should be of good quality. As we have before observed, it must not be chemically pure, for then it would be almost valueless; but it should only contain such substances as shall be beneficial, or, at all events, not prejudicial to health. Let us for a moment glance at what the office of water is to our system; and in the term we shall include such liquids as milk, broth, infusion of tea, &c., which are almost entirely composed of water.

First, as a diluent, water moistens and lubricates all the surfaces of our internal organs. The nose, eyes, ears, mouth, larynx, lungs, stomach, joints, &c., constantly require it; and when, in febrile attacks, we suffer from its comparative absence, the consequences are sufficiently well known to all. Then, as a solvent, it conveys albumen, fibrine, caseine, &c., to the surface of the stomach, in such a form as that organ can readily assimilate them; and it carries those proximate principles in the blood to each part of the human frame. In the body it produces the muscles, fat, fibre, nerves, &c., by this power of conveyance. On suitable parts it deposits its saline substances to form bone. Externally, it is essential to the production of hair, nails, &c.; and it is constantly employed in conveying to the skin the materials of which that substance is composed, and by which it is constantly renewed as it is worn away or injured. After having performed this, and many other functions, it returns to other parts of the system, bearing with it all the valueless and waste products of the entire system, till it arrives at those organs by means of which the body is relieved of the excretions.

From this hasty glance, our readers will at once perceive how essential water is to us as an active chemical agent in our system. But we may go still further, and remind them that a great proportion of our bodies consists of water. This is constantly passing off by the lungs and the skin; and the liquids we drink have, therefore, another office than those we have referred to, in that of maintaining the mass of the body of a uniform size.

We, however, cannot further enlarge by such details. Our object has been to show, in a general manner, the chemical relationship which water has on the health; and we must leave our readers to make such practical applications as the subject is capable of.

Chemical Manufactures and Sanitary Laws.—It is a most unfortunate circumstance, that many of our manufactories are not only the causes of disease to those engaged in them, but spread their evil influence for considerable distances around them as a centre. According to late legal definitions, such manufactories may be deemed "nuisances," if carried on to the prejudice of the health of the surrounding neighbourhood. It is equally unfortunate that such manufactories must necessarily be surrounded by workpeople, who, as they are engaged in the factories, must reside near their work.

It would be impossible for us here to enumerate the various occupations in which chemistry is involved, and which may be really dangerous in a sanitary point of view. The manufacture of chemical products, bone-boiling, artificial manure-making, and the like, come under the category; and, from the fact that they, generally speaking, require a great bulk of cheap material to afford but a comparatively small amount of commercial and valuable product, they cannot be carried on at a profit unless they are situated near the places from which the raw material is obtained. If even they were removed from the neighbourhood of large towns, still their exigencies would soon tend to produce almost a town of workpeople around them; and hence a temporary delay, but not a cure, of the evil would result.

It would thus seem, at first sight, that such manufactories must necessarily exist as a source of constant injury to health, and that either the people who subsist on them must die of disease, or, in their absence, of starvation. But such need not be the case, for, in almost every instance, an improved system of drainage, and the erection of tall chimneys for the purpose of carrying away smoke, vapours, &c., will mitigate all the evils which exist at the present time. The astonishing improvement which has taken place in the city of London, since the "Smoke Act" has been enforced, proves that where there is the will there is also the way; and, in the absence of the will, the strong arm of the law can soon effect every desirable result.

It is true that some manufactures must always be unhealthy; such as those of the production of white lead, arsenic, steel grinding, and the like. In such cases, however, much may be done by scientific means, urged by humane endeavours. At all events, we may rest quite assured that no manufacture can be legitimately carried on which must necessarily cause the death of its labourers; and we may equally be certain, that as, in manufacturing, we merely avail ourselves of the laws of nature applied for special purposes, there are such methods of conducting our processes as shall render them quite consistent with sanitary requirements, if our prejudices and ignorance do not stand in the way.

Much foolish prejudice, however, exists in the mind of the public against all places in which chemical substances are produced; and hence sulphuric acid and soda manufacturers have been the subjects of considerable persecution. In many cases, positive benefit may arise from the purification and disinfectation of the sewers, by the waste running from such factories. We have met with several instances of the kind in London, and other large cities, presenting cases in which whole streets have been protected from disease by this cause. The erection of tall chimneys for carrying off the fumes and vapours, and an abundant supply of water, will generally remove all sources of danger. It is, however, extremely desirable that competent inspectors should be appointed, whose duties should not be confined to the prevention of nuisance *outside* the factory, but who should also have a judicious control over the internal arrangements, and thus be enabled to keep a watchful eye on the health of the work-folks *inside* the gates. It will frequently be found that the ill-health of labourers in chemical works, does not so much arise from the inhalation of fumes, &c., as from their constant exposure to changes of temperature, and from the fact that most of the processes are carried on in open sheds, affording little or no protection from draughts of air, and wet weather. By these the strongest man must soon be reduced to a state of disease, through checked perspiration, &c.

Two singular instances, in which the production of disease seems at first sight unavoidable, are those of glass-silvering, and lucifer match-making. In both of these, the vapour of the substances used seems to be absorbed by the worker, until his entire frame is permeated. In silvering glasses, large quantities of quicksilver are used. The progress of disease is noted by the salivation produced; and at last the individual becomes almost a complete carious mass. In making lucifer-matches, the phosphorus is similarly absorbed by the system, affecting the bones of the face and palate until these are completely eat away. But in this extreme case a remedy has been discovered; for if amorphous phosphorus be employed,[*] all danger vanishes, and the work people suffer no inconvenience of any kind. On the continent, the use of the ordinary phosphorus is forbidden, for the foregoing reason, and thus a most painful and incurable disease is prevented.

Our space will not permit us to enlarge further on this interesting subject, or we might point out several instances in which the employment of poisonous substances is not only dangerous, but positively wicked. The manufacture of green artificial leaves, &c., is carried on by the use of the arseniate of copper. Scores of young females are hourly exposed to the pernicious dust of the compound in close rooms, for no other purpose than to administer to the vanity of others.[†] No one can hesitate to pronounce against such occupations, whether in respect to the evil resulting to the workers, or to the danger which most certainly arises from wearing the product of their labours. In many a ball-room, the ladies carry, in their ornaments and dress, as much arsenic as would suffice to poison all present; and, generally, the arsenical dust is wafted from their dresses and head-dresses, in quantities of which they have but little idea. This is one out of many similar employments in which females are engaged; and may thus serve as a type of manufactures, which less devotion to fashion would at once cause to be abolished; and in being carried on, serve no useful end.

The following Tables of WEIGHTS AND MEASURES will be found useful by the student. A more extended series will be given in connection with Applied Mechanics.

ENGLISH WEIGHTS.

	Grains.		Ounces.		Pound.
Troy weight . . .	480	=	1		—
	5760	=	12	=	1
Avoirdupois weight	437½	=	1		—
	7000	=	16	=	1

FRENCH WEIGHTS.

The standard is the gramme = 15·434 troy grains; and the decimal system is adopted. Thus the

Milligramme . . = ·015434
Centigramme . . = ·154340
Decigramme . . . = 1·543400
Gramme . . . = 15·434000
Decagramme . . = 154·340000
Hectogramme . . = 1543·400000
Kilogramme . . . = 15434·000000 = 2¼ pounds avoirdupois weight, English.

ADDENDA.

THE NEW METAL, THALLIUM.

In the chapter treating on Metals,[*] we have mentioned the discovery of two, by means of the spectrum analysis; and an extended use of the same agency has resulted in the addition of a third to that class of elementary bodies. In the Great Exhibition of 1862, a few grains of this metal were exhibited, which had been obtained from the residue of a process for making sulphuric acid. Its discovery arose from a rich green spectral band being produced, when a portion of the material above named was submitted to the spectrum examination; and the name *Thallium* was applied to it, on account of the colour of the flame. Since that time Mr. Crookes has devoted his attention to the production of the metal on a larger scale; and has so far succeeded as to have prepared several ounces. In its physical character it resembles lead, being very soft, marking paper like that metal, and having a specific gravity of 11·4. Its chemical equivalent is 203. It forms two or three oxides; and unites with acids, affording salts, which crystallise in beautiful forms. The chief sources have hitherto been substances united with sulphur—such as native sulphur—ores of copper, &c. The small quantities, comparatively speaking, yet procured, have not enabled Mr. Crookes to give a probable estimate of its commercial value and application; but, as it seems pretty widely disseminated in mineral bodies, it may possibly become of some importance in the arts and manufactures.

SECTION VII.

MATHEMATICS.

CHAPTER I.

ARITHMETIC.

In the previous pages, the attention of our readers has been chiefly directed to the forces which operate on every kind of matter, and to the different qualities of those substances of which material bodies are formed. We have hitherto scarcely required more than the ordinary rules of arithmetic in the calculations of quantities, time, and space; but we shall now proceed to an entirely different range of subjects. These will afford a full exposition of the different branches of mathematical science, the rules of which enable us to express the relative value of both the forces acting on, and the quantities of, matter, together with every other particular involving the use of numbers, symbols, &c. As each subject will have a special introduction, it is not necessary that we should here occupy any considerable space in discussing their nature. We shall rather confine ourselves to advising our readers as to the best method of studying. We may first impress on their minds the necessity of proceeding *step by step*. If any person were to glance at a page in trigonometry, or the differential calculus, it would be a matter of no surprise if he were to hopelessly despair of ever mastering the subject. On the other hand, an acquaintance with the common rules of arithmetic and algebra, and the elements of geometry having been once acquired, little or no difficulty will be experienced in the investigation of the higher branches of those subjects, provided the student makes himself thoroughly acquainted with every rule, *successively*, as he proceeds. It is incumbent, therefore, that the old Greek motto, "Hasten slowly," should become the rule of every tyro in mathematical science, if success and proficiency are to be obtained. We must add, that the entire work, both in the preceding and succeeding pages, has been so arranged as to *gradually* inure the mind to close reasoning. When we have to investigate the laws of astronomical science, all the rules of each branch of mathematics will be involved; and it is therefore essential to those who would penetrate into the depths of that science, that they should have become tolerably proficient in each branch of mathematics. Without this, the study of astronomy is little better than "star-gazing;" which, while it may afford excitement to our imagination, has but little effect in increasing our knowledge and expanding our mental powers.

Many of our readers may have no desire to become deep mathematicians. On such we would urge that mathematics may not only be studied for the sake of their applications, but may be used as a mental gymnasium. In every other branch of science, truth is veiled under theories; whilst, in mathematics, she appears unclouded by a single doubt. Each proposition of geometry is absolutely demonstrable. No doubt can be left of their truth; and in such investigations the mind undergoes an exact although severe training, which fits it for exercise in the daily affairs of life, as much as for the accurate study of nature and nature's laws.

The articles on each of the following subjects have been written by different authors, whose names have been already mentioned in the table of contents. The editor has ventured on such alterations in the original papers as he deemed would assist the reader or student in cases of apparent difficulty, which often occur to those unused to the phraseology and technicalities of mathematical science. The arrangement of each paper has been made so that the preceding shall be introductory to those which follow; and thus the student may progress from one subject to another, until he has become fully acquainted with each branch of the science.

Introductory.—The present section is to be devoted to that branch of study implied in the term Mathematics—a term which comprehends one of the most extensive and important departments of human knowledge. By most people, it is considered also as one of the most *difficult* departments; and many, with time and talents for the task, are deterred from entering upon a study which would amply repay the expenditure of both, by this mistaken prejudice. Every science, no doubt, has its hard and knotty points; and in no intellectual pursuit can distinction be attained without labour, thought, and perseverance; yet if there be one subject of scientific inquiry which, more than any other, is distinguished by the simplicity, certainty, and obviousness of its fundamental principles—by the irresistible evidence by which position after position is established—and by the systematic gradations by which layer after layer of the intellectual structure is completed—that subject is Mathematics.

In other topics of research, there is generally more or less of hypothesis or conjecture: there are obscure recesses, into which the light of truth and demonstration cannot penetrate, and where fancy and imagination are sometimes permitted to guide our steps. But there are no perplexities of this kind in mathematics—no ingenious theories to mislead, and no conflicting opinions to bewilder; our progress here is exclusively under the unerring direction of Truth herself; and it is her torch alone that lights up the path.

Whatever, therefore, may be the difficulties connected with the study of mathematics, it is plain that they do not arise from our having to grope our way in darkness and uncertainty; the asperities of the road are as clearly revealed before us as the level and unobstructed track; and all that the earnest student requires, is some friendly hand to aid him in surmounting these in the earlier stages of his progress.

It is this sort of aid that we here propose to supply. We do not undertake to conduct the scientific inquirer through the entire regions of mathematical research—ours is a far less ambitious aim: we write for the young—for the self-dependent—the solitary—and, perchance, the unfriended student. The office we here take upon ourselves will be performed, if we succeed in the endeavour to assist *him*. This is the only object at which we now aim; and we think it right thus explicitly to declare it, in order to forewarn those who may desire information on the more recondite researches of science.

It may be proper to mention, however, that although we now propose to limit our labours to an exposition of the elementary principles of mathematical learning, and to economise space as much as possible; yet, within the bounds prescribed, we shall take care that every subject receive a full and fair elucidation, and that it be discussed to an extent amply sufficient for the purposes of general education. We hope, too, by avoiding all attempts at magisterial dignity of style, and addressing our readers in the familiar language of social intercourse, to secure their attention, and win their confidence. That we may be fortunate enough, by clearness and simplicity of explanation, to awaken in some a genuine love for science, and a desire to prosecute their researches in writings of wider scope and higher pretensions, is our earnest desire.

We have thought it advisable to commence our work on elementary Mathematics with a preliminary treatise on Arithmetic—the groundwork upon which the entire system, with the exception of pure geometry, ultimately rests. Books on arithmetic, however, are so numerous, and so easily accessible, that we might have been held excused from introducing so hackneyed a subject into a work which, though confessedly of an elementary character, is, nevertheless, intended to embrace a range of topics beyond the ordinary limits of a schoolboy course. But it unfortunately so happens, that books on arithmetic, with few exceptions, are little more than mere depositories of practical rules and mechanical operations; and are, therefore, but ill-suited to prepare the young for that higher kind of exertion—higher, because more intellectual—which science, properly so called, always demands.

A boy who has gone through his "Walkingame," and who, generally speaking, is then introduced to "Euclid," is naturally enough bewildered by the total dissimilarity of the two authors—not from difference of subject, but of manner of exposition. The former has abundantly supplied him with *rules*, but no reasons; the latter gives him *reasons*, but no rules: the one has loaded his memory, and employed his fingers; while the other appeals to his judgment, and exercises his understanding.

To make, in this way, the passage from arithmetic to geometry an abrupt transition from the mechanical to the intellectual, we conceive to be a serious defect in educational training. Arithmetic is as much a science as geometry: there is not a rule in the one, any more than there is a theorem in the other, that is not founded on reason, and demonstrably true. And even viewing arithmetic merely in reference to its practical utility in commercial affairs, to the demands upon it in the counting-house and the shop—we still contend that its principles should be rationally taught—not authoritatively declared, inasmuch as that which has engaged the understanding, and been received from a conviction of its truth, is more securely retained in the memory than what is committed to it by rote. Rules, unsupported by reasons, are hard to learn, and hard to remember; but, when the practical precept is associated in the mind with the theoretical principle on which it depends, we learn and remember with ease and satisfaction; for, instead of words, we get knowledge.

These considerations have prevailed with us; and have determined us to render this course of elementary mathematics complete, by commencing at the very foundation. It must be borne in mind, however, that our design is not to exhaust here any subject of which we treat: it is rather to excite an appetite for knowledge, than to satiate it. It will not be expected, therefore, that our treatise on arithmetic is to be co-extensive with what, under that name, is usually put into a schoolboy's hands; the bulk of such books arises, in a great measure, from the system of instruction condemned in the preceding observations; the object of which system seems to be to inculcate a knack of readily applying *rules*, by experimenting upon numerous examples, under the guidance of the prescribed directions. This, as the reader has already been made aware, is not our object; we propose to explain *principles*, and to furnish the reasons that justify the rules; persuaded, that if the former be thoroughly apprehended, there need be but little anxiety felt about the mere verbal memory of the latter.

It would extend these introductory remarks far beyond the space that can be allotted to them, to enter into any detailed account here of the several particulars to be introduced in this division of the work; but we cannot conclude them without a few words more especially addressed to those who have resolved to place themselves under our instructions.

It is a common thing with students in science to be frequently making inquiries as to the *use* of what they are learning. "What is the *use* of this?" is a question put at every turn; generally to the annoyance of the teacher, and often to the discredit of the learner.

The use of any intellectual pursuit—employing the term *use* in its higher and more honourable signification—is to be realised in the mental satisfaction and the mental elevation it communicates. You do wrong to estimate science solely and exclusively in proportion as it visibly contributes to our animal wants and enjoyments: there is an intellectual pleasure in the very process of acquiring knowledge; while the conscious possession of it raises the human being in the scale of creation, and thus enables him to contemplate its wonders from a more exalted position. It is in this way that knowledge, like virtue, to which indeed it is allied, is said to be its own reward; for the study of science is accompanied with gratifications of the purest and loftiest kind; and is productive of advantages to the student altogether distinct from the benefits conferred by its applications to the practical purposes of life. It invigorates and enlarges the faculties—refines and elevates the desires—and adorns and dignifies the entire character, withdrawing our thoughts from what is mean and degrading, and inclining them to the noblest and worthiest of objects—to the love and veneration, and therefore to the practice, of TRUTH.

These advantages, though unconnected with outward and tangible results, are surely too precious to be entirely overlooked in any correct estimate of the value of scientific pursuits. When, in the course of these, you find yourself engaged in an inquiry that may seem to have but little relation to the things of sense, and are, on this account, disposed to ask—what is the *use* of it? just reflect whether the intellectual exercise has not been combined with intellectual gratification; and whether there be not an abstract beauty in the result arrived at, that awakens pleasurable feelings, practically realised, though hard to be described. We think the reflection will, in general, suggest an answer to the inquiry in some measure satisfactory.

These tranquil and purely intellectual enjoyments have prompted and encouraged the efforts of the wisest of men—have cheered and sustained them amidst penury and neglect; and, under the persecutions of power, wielded by ignorance, have supplied a consolation second only to that which Divine revelation affords; and they have finally been regarded as no mean reward for a life thus tried, and toils thus endured. They were considered as compensation sufficient for the labours even of NEWTON—many of whose discoveries in science would, in all probability, never have been given to the world but for the urgent interference of private friends.

We are anxious that you should be influenced by considerations such as these; and that you should regard science as something more than a ministering agent to our animal comforts, or even to our social gratification and convenience. The practical benefits of science—and more especially of those departments of it connected with the subjects of the present volume—are in little danger of being overlooked or undervalued; they are spread profusely around us; and are felt and enjoyed by all. And there thus seemed to be all the more need for directing your attention to collateral advantages—less palpable and striking, and therefore less likely to be duly appreciated.

We shall now proceed to the business before us: we shall assume no knowledge at all on your part in reference to the topics to be discussed; and, in even so simple a subject as ARITHMETIC, we shall begin at the beginning.

Arithmetic.—Arithmetic is that branch of knowledge that teaches us how to perform calculations by means of numbers. The rules which direct the various operations constitute the *art* of arithmetic: the reasons and principles on which these are founded belong to the *theory* of arithmetic; and the theory and practice united, form the *science* of arithmetic. It is this that we are now going to explain. You are aware that the symbols, or marks, employed in this subject are called *figures*, and that they are as follow:—1, 2, 3, 4, 5, 6, 7, 8, 9, together with the mark 0, called *nought*, or *cipher*, or *zero*, and which stands for *nothing*. This 0 is also called a *figure*, so that there are *ten* figures in arithmetic: the number of *units*, or *ones*, which each stands for, is here written—

nothing,	one,	two,	three,	four,	five,	six,	seven,	eight,	nine.
0	1	2	3	4	5	6	7	8	9

Each of these figures is also called a *number:* but the word number has a wider meaning. Thus 26, 43, 57, &c., are all numbers, each of which consists of *two figures*; the first number is *twenty-six*, the second *forty-three*, the third *fifty-seven*, and so on; so, that you see, the 2 in the first stands for *two tens*, the 4 in the second for *four tens*, and the 5 in the third for *five tens*. In like manner, 368 is a number of *three figures*. The first figure, 3, stands for *three hundred;* the second, 6, for *six tens*, or *sixty;* and the third, 8, for *eight ones*, or *units:* the number itself standing for *three hundred and sixty-eight*.

You thus perceive that a figure which, when written singly, stands merely for so many *units*, changes its meaning, or value, according to the *place* it occupies in a number of several figures. If it occupy the last, or right-hand place, it still stands for units; but if it be in the next place, to the left, it stands for so many *tens;* if in the place next to that, for so many *hundreds;* and if it occupy the fourth place from the end, it stands for so many *thousands:* the number 7352, for instance, is seven thousand three hundred and fifty-two.

Figures thus have a *local* value; that is, a value depending upon the places they occupy in a number. The following is a number of *twelve* figures; and when the local values, of these figures are written against them, it supplies what is usually called the

NUMERATION TABLE.

2	4	6	8	7	3	1	5	9	4	3	8
hundreds of thousands of millions.	tens of thousands of millions.	thousands of millions.	hundreds of millions.	tens of millions.	millions.	hundreds of thousands.	tens of thousands.	thousands.	hundreds.	tens.	units.

And this number is read thus:—two hundred and forty-six thousand eight hundred and seventy-three MILLION, one hundred and fifty-nine THOUSAND, four hundred and thirty-eight.

A person beginning to learn arithmetic will be enabled, by means of the above table, to *read* any number—that is, to express its value *in words*. In a large number like that here given, the easiest way to proceed is this. Cut off the *last three* figures, then the next three, then the next, and so on; thus dividing the figures into sets of three as far as possible. A glance at the *table* shows that the leading figure of each set is *hundreds* of something; that of the first set, on the right, is *hundreds* of *units*, or simply *hundreds;* that of the next set is *hundreds* of thousands; that of the next, *hundreds* of millions; and so on. And by thus finding out the *local* value of the leading figure in each *period*, as it is called, you may read the number with ease. For example, the number 68547329, when divided into periods, as here proposed, is 68,547,329: pointing to the 3, you say *hundreds*, and passing to the 5, *hundreds* of thousands; the incomplete period, 68, must therefore be 68 *millions;* and the entire number 68 million, 547 thousand, 329; or, expressing the value wholly in words, it is sixty-eight million, five hundred and forty-seven thousand, three hundred and twenty-nine. In a similar way we find the number 42638572613, or 42,638,572,613, to be 42 thousand 638 million, 572 thousand 613. If you wished to put this wholly into words, all you would have to do would be to write forty-two for 42, six hundred and thirty-eight for 638, five hundred and seventy-two for 572, and six hundred and thirteen for 613. The leading figure of a complete period, you know, is always *hundreds*, according to the plan we have proposed; and when you have found by the table *what* these hundreds are, or from practice can recollect what they are, you can have no difficulty in reading the number. When any of the figures are *noughts*, a little extra care is, however, necessary. Thus, the number 460305007, which, divided into periods, is 460,305,007, is read four hundred and sixty million, three hundred and five thousand, and seven.

From what has now been said, you clearly see what is meant by the *local* value of a figure. If it occupy the place of *units*, its value is so many *ones;* if it be in the place of *tens*, its value is *ten times* as many ones—that is, it represents so many *tens;* if it be in the place of *hundreds*, its value is *ten times* as many *tens;* if in the place of *thousands*, it is *ten times* as many *hundreds;* and so on. So that, as you advance a figure, place after place, towards the left, you increase its value *tenfold* at every remove: thus, 8 is simply eight *ones;* 80, where the 8 is now in the *second* place, and *nothing*, or *nought*, in the first place, is *eighty*, or *ten times* eight; 800, where the 8 is in the *third* place, and *noughts* in the first and second places, is *eight hundred*, or *ten times* eighty; and so on. This tenfold increase in the value of a figure, when it is removed one place from right to left, explains why our system of numeration is called the *decimal system;* the word *decimal* being derived from a Latin word, meaning *ten*. It was a beautiful contrivance thus to give a *local*, as well as an absolute value, to the symbols, or figures, used in the *notation* of arithmetic.[*] You see that by this happy idea we are enabled to express all numbers whatever by the help of only *ten* different marks, or symbols: whether we owe it to the Arabs, to the Greeks, or Romans, is a question on which there is still some doubt.

It ought, perhaps, to be mentioned, that although the numbers considered above do not extend beyond twelve figures, numbers with more figures than these may occur, and that there are words to express the additional periods. If the number have *thirteen* figures, the leading figure on the left would stand for so many *billions;* and if a complete additional period were joined to a number of twelve figures, making a number of *fifteen* figures, then the leading figure on the left would, of course, be *hundreds* of billions. But *billions*, *trillions*, *quadrillions*, &c., are names so seldom employed or wanted, that the numeration table need not be encumbered with them. It may be worth a passing notice, too, that no distinct ideas are conveyed by any of these terms: beyond a very moderate extent our notions of the value of numbers become confused. The number of *ones* in a million, even, is hard to conceive: it is a thousand thousand, and would take more than twenty-three days to count, though you kept at it for twelve hours a-day, and counted one every second. Our ten figures, or *digits*, as they are often called (*digitus* being Latin for finger, and our ten fingers suggesting the word[†])—our ten figures thus enable us accurately to express on paper, without the error of a single unit, numbers too great to be even conceived or imagined.

---

[*] The marks, or symbols, made use of in any science, constitute the *notation* of that science.

[†] *Names* frequently throw light on the origin of *things:* it is interesting to notice, that the name *digit* is plainly significant of the early rude method of counting on the *fingers;* and that the name *calculation* as plainly refers to the primitive practice of reckoning with *pebbles* (*calculus*, a pebble). In a similar way *electricity* derives its name from *electron*—amber; *magnetism*, from *magnesia*, &c.

Before concluding these remarks on numeration, it may be as well to show the beginner how a number expressed in *words* may be translated into *figures*. This is not quite so easy as to translate figures into words; the plan is as follows:—

Write down a row of *noughts*, or *ciphers*, and, as if these blanks were numbers, mark off the *periods:* then, commencing at the first cipher on the left, put under each the proper *figure* in the number proposed, taking care that it be in its proper *place:* if any *vacancies* appear under the corresponding ciphers, fill them up with *noughts*. Thus, let it be required to put into figures the number five hundred and six million, thirty-four thousand, and forty-eight. We know that the place of *millions* has *six* places to the right of it; we therefore put a nought for the millions, and write six noughts after it, and, as we see, from *hundreds* being the leading word in the written expression, that the first period will be a *complete* period, we *prefix* two noughts more. The requisite row of noughts, divided as proposed, is as in the margin; and under these we now have to write, in their proper places, the figures 5, 6, 3, 4, 4, 8, and then to fill up the gaps with noughts; we thus find the number, when written in figures, to be 506,034,048. The learner will be able to do without such helps as these after a little practice; he should accustom himself to express in words the numbers he uses, when these are of moderate extent, and not content himself with merely looking at them.

000 000 000
506 034 048

We shall now proceed to the four fundamental operations of arithmetic: these are *addition*, *subtraction*, *multiplication*, and *division*. There are no calculations, however long and intricate, that are not composed of one or more of these four.

Simple Addition.—Addition teaches us how to add numbers together, and so to find the *sum* of all. It is called *simple* addition, when the numbers to be added either have no reference to particular *things* or *objects*, or when the things referred to are *all of the same denomination:* thus, if 24 pounds, 37 pounds, 82 pounds, &c., were all to be added together, the operation would be that of simple addition; but if 24 pounds 7 shillings, 37 pounds 2 shillings, 82 pounds 12 shillings, &c., were to be added, then, as pounds and shillings are different things, the operation would not be *simple*, but *compound* addition; one of the first set of things being called a *simple* quantity, and one of the other set a *compound* quantity. The rule for performing simple addition is as follows:—

RULE.—Arrange the numbers to be added one under another, so that the first column of figures on the right may be *units*, the next column on its left *tens*, the next *hundreds*, and so on. This is nothing more than preserving each figure in its proper place. Add up the units' column: if it amount to a sum expressed by only *one* figure, put this figure down under the units' column. But if it be a number of more than one figure, the *last* figure only of that number—the *units'* figure—is to be put down, and the number expressed by what is left, after rubbing out the figure thus put down, is to be *carried* to the next, or tens' column, and added in with that column.

If the sum of the tens' column be a number of a single figure, it is to be put down under that column; but if it be a number of more than one figure, then, as before, only the last, or units' figure, of that number, is to be put down, and the number which is expressed, after the figure put down is rubbed out, is to be carried to, and added in with, the figures in the next column, and so on; observing, that when the last column is reached, the entire sum of that column is to be put down. Suppose, for example, the following numbers are to be added together—namely, 246, 357, 26, 148, and 6; then, writing the numbers, one under another, as in the margin, so that the *first* column on the right may be a column of *units*, the next a column of *tens*, and the next a column of *hundreds*, we proceed, under the direction of the rule, as follows: 6 and 8 are 14, and 6 are 20, and 7 are 27, and 6 are 33; there are, therefore, in the first column, 33 units; that is to say, 3 *tens*, and 3 *units:* the 3 units we put, of course, under the column of units, but we carry the 3 *tens* to the next, or tens' column, and say—3 and 4 are 7, and 2 are 9, and 5 are 14, and 4 are 18; that is 18 *tens:* the 8 we put down, but the number left, after rubbing this out, namely 1, we carry to the next column, as it is clear we ought to do; for this 1 is one more place to the left; it stands for *one hundred*, and therefore belongs to the hundreds' column: any figure next, on the left, to a figure that stands for *tens*, must, from the principles of numeration, stand for *hundreds*. Carrying, therefore, the 1 to the hundreds' column, we say, 1 and 1 are 2, and 3 are 5, and 2 are 7; that is, 7 *hundreds:* so that the sum of the proposed numbers is 783; that is, seven hundred and eighty-three. From this operation you see that the figures of the *sum* are all carefully put in their proper places, so that each has its own *local* value; the numbers *carried* from one column to the next, are so carried because they really *belong* to the place, one in advance, to the left. Arranging these numbers one under another, as before, taking care not to disturb their local positions, we proceed thus: 3 and 2 are 5, and 8 are 13, and 3 are 16, and 2 are 18; 8 and carry 1: 1 and 5 are 6, and 7 are 13, and 6 are 19; 9 and carry 1: 1 and 7 are 8, and 7 are 15, and 8 are 23, and 4 are 27; 7 and carry 2: 2 and 7 are 9, and 4 are 13, and 8 are 21; therefore the sum is 21798: that is, twenty-one thousand seven hundred and ninety-eight. It is plain from the foregoing illustrations, that the rule for addition is in strict accordance with the system of notation and numeration already explained, and that it must always lead to the correct result. There is no *figure* higher than 9: *ten*, of any denomination (*hundreds*, *thousands*, &c.), is *one* of the next higher denomination; so that in adding up any column of figures, all of the same denomination, for every *ten* in the sum, *one* must be carried to the next column; and, therefore, as many *ones* as *tens*.

21798

You have already seen that the marks used in the *notation* of arithmetic are *figures:* besides these, other marks are frequently employed to *indicate operations* with these figures, and to express relations among them: thus, instead of saying 2 *and* 5 *are equal to* 7, the form $2+5=7$, is used to express the same thing: the mark $+$ being the *sign for addition*, and the mark $=$ the *sign for equality:* this must be borne in mind: $+$ is called *plus;* so that $2+5=7$, may be read 2 *plus* 5 *equals* 7, or 2 *plus* 5 *are equal to* 7. The following, therefore, are statements in symbols, instead of in words, which you will at once understand: $2+5+1=8$; $3+4+2=9$; $6+5+3+1=15$. A few examples in addition are here given under this form. You will have to arrange the numbers in them in columns, as in the two examples worked above; and, if the results of your addition be correct, they will be found to agree with the numbers to the right of the sign of equality:—

(1.) $324+643+201+46=1214$.
(2.) $36+320+708+17+3=1084$.
(3.) $5684+340+7006+309+824=14163$.
(4.) $20065+8473+751+92083+564+92=122028$.

Simple Subtraction.—Subtraction teaches us how to subtract the smaller of two numbers from the greater, or to find their difference, which is called the *remainder*. The operation is called *simple* subtraction when the numbers refer to things of the same denomination, as in *simple* addition. The rule for simple subtraction is as follows:—

RULE.—Put the smaller number under the greater, taking care, as in addition, that units shall be under units, tens under tens, and so on.

Then, beginning at the *units*, subtract each figure in the lower row from the figure above it, if the lower figure be not the *greater* of the two, and put the remainder underneath (see the operation in the margin, where 34572 is subtracted from 68594, and the remainder found to be 34022).

From 68594
Subt. 34572
Rem. 34022

But if you come to a lower figure, which is *greater* than the figure above it, add 10 to the upper figure, and then subtract, putting down the remainder as before, and taking care to *carry* 1 to the next figure of the lower row.

From 64927
Subt. 27385
Rem. 37542

For example: let it be required to subtract 27385 from 64927; then, placing the former number below the latter (as in the margin), we proceed thus: 5 from 7, and 2 remain: 8 from—not 2—but 12, and 4 remain; carry 1: 4 from 9, and 5 remain; 7 from 14, and 7 remain; carry 1: 3 from 6, and 3 remain.

All that requires explanation here is the *carrying*, as in the former rule. In the preceding example we see that the 8 cannot be taken from the figure above it, because *this* is only 2: we, therefore, add 10 to the 2, converting it into 12; but the adding 10 to any figure is simply putting 1 before it; that is, it is adding 1 to the *preceding* figure, which 1, by carrying it to the next lower or subtractive figure, is taken away again at the next step. In like manner the 4, in the upper row, is converted into 14, and the one thus prefixed to it is afterwards taken away, by 1 being carried to the next lower figure, and 3 subtracted instead of 2. It is plain that in *subtraction* the carrying can never amount to more than 1.

From 130741392
Subt. 86025704
Rem. 44715688

As another example, let 86025704 be subtracted from 130741392: then, having arranged the numbers as in the margin, we proceed thus: 4 from 12, 8; carry 1: 1 from 9, 8: 7 from 13, 6; carry 1: 6 from 11, 5; carry 1: 3 from 4, 1: 0 from 7, 7: 6 from 10, 4; carry 1: 9 from 13, 4: therefore the remainder is 44715688.

There is a *sign for subtraction* as well as one for addition: it is the little mark — placed before the number to be subtracted; it is called *minus:* 5—2 is therefore 5 *minus* 2, that is, 5 *diminished* by 2; the remainder, or difference, is of course 3: so that 5—2=3. By help of the plus and minus signs, we can easily connect together in a single row a set of numbers, of which some are to be added, and others to be subtracted; thus, 4+6—3—2 means that 4 and 6 are to be *added*, and 3 and 2 are to be *subtracted;* so that 4+6—3—2=5. Instead of subtracting first 3 and then 2, we may, of course, subtract 5 at once; so that the above is the same as 10—5=5; and whenever addition and subtraction operations are indicated in this way, it will always be best to find first the sum of the *additive* quantities, then the sum of the *subtractive* quantities, and then, as in the foregoing example, to find the *difference* of the two results: in this manner the result of 125+427—684+237—15, is computed as in the margin, and found to be 90. So that 125+427—684+237—15=90.

125 684
427 15
237 ——
—— 699
789
699
——
90 result.

We shall here add a few examples to be worked in a similar manner:—

(1.) 361+483—246—179=419.
(2.) 573—184+602—67=924.
(3.) 86243+721—649—70+13—9=86249.
(4.) 12064+700628—109641+637—2604=601084.
(5.) 23596—625+72311075—13758—3506285+6879=68820882.

In order to *prove* whether subtraction is correctly performed, *add* the remainder to the number which has been subtracted—that is, to the *lower* of the two proposed numbers; the *sum* will be the *upper* number, if the work be correct: thus, in each of the two examples above, we have—

Subtractive number	27385	86025704
Remainder . . .	37542	44715688
Upper number .	64927	130741392

Simple Multiplication.—Multiplication is the method of finding the *sum* of any number of *equal* quantities, without the trouble of repeating them, one under another, and adding them up; it is a short way of obtaining the *results of addition*, when the numbers or quantities to be added are all *equal.* When the quantities are not only equal, but all of one denomination, the operation is called *simple* multiplication.

To perform this operation readily, a *table*, called the *multiplication table*, must first be learnt; and the result which arises from multiplying one number by another, provided neither be greater than 12, must be committed to memory; it is one of the few operations in arithmetic where the memory of rules is indispensable.

The number by which another is to be multiplied, is called the *multiplier;* the number which is multiplied, the *multiplicand;* and the result obtained—which, as just stated, is the same as would be got by writing down the multiplicand as often as there are units in the multiplier, and adding all up, is called the *product.* The multiplication table shows what the product is in every case in which neither multiplicand nor multiplier exceeds 12; and, by knowing this table, the product may always be found, whatever numbers be proposed as multiplicand and multiplier. It may be as well to mention here, that the numbers called by these names, when spoken of together, are generally called *factors* of the product, as they *make* or produce it: thus, 2 and 3 are *factors* of 6, since 3 taken twice, or 2 taken three times, make or produce 6.

MULTIPLICATION TABLE.

Twice		3 times		4 times		5 times		6 times		7 times		8 times		9 times		10 times		11 times		12 times	
1 are	2	1 are	3	1 are	4	1 are	5	1 are	6	1 are	7	1 are	8	1 are	9	1 are	10	1 are	11	1 are	12
2	4	2	[illegible]	2	[illegible]	2	10	2	12	2	14	2	16	2	18	2	20	2	22	2	24
3	6	3	9	3	12	3	15	[illegible]	18	3	21	3	24	3	27	3	30	3	33	3	[illegible]
4	8	4	12	4	16	4	20	[illegible]	24	4	28	4	32	4	36	4	40	4	44	4	48
5	10	5	15	5	20	5	25	5	30	5	35	5	40	5	45	5	50	5	55	5	60
6	12	6	18	6	24	6	30	6	36	6	42	6	48	6	54	6	60	6	66	6	72

8	16	8	24	8	32	8	40	8	48	8	56	8	64	8	72	8	80	8	88	8	96
9	18	9	27	9	36	9	45	9	54	9	63	9	72	9	81	9	[illegible]	9	99	9	108
10	20	10	30	10	40	10	50	10	60	10	70	10	80	10	90	10	100	10	110	10	120
11	22	11	33	11	44	11	55	11	66	11	77	11	88	11	99	11	110	11	121	11	132
12	24	12	36	12	48	12	60	12	72	12	84	12	96	12	108	12	120	12	132	12	144

That the product in any case is really what the table states it to be, the learner can easily prove for himself; he has only to take the multiplicand as often as there are units in the multiplier, and, by addition, to find the sum of all; thus, the table states that 8 times 6 are 48, which is true, because 6, written eight times, and all added, produce 48, that is,

6 + 6 + 6 + 6 + 6 + 6 + 6 + 6 = 48.

and so of any other pair of *factors* within the limits of the table.

I. *When the Multiplier is not greater than* 12.

RULE.—Put the multiplier under the multiplicand, units under units; and, by aid of the table, multiply each figure of the multiplicand, commencing at the units' figure, by the multiplier. Set down the right-hand figure only of the product when it is a number of more than one figure, and carry as in addition.

For example: multiply 6432 by 4. The multiplier 4 being placed under the multiplicand 6432, as in the margin, we proceed thus: 4 times 2 are 8: 4 times 3 are 12; 2 and carry 1: 4 times 4 are 16, and 1 are 17; 7 and carry 1: 4 times 6 are 24, and 1 are 25.

```
Multiplicand  6432
Multiplier       4
              ————
Product . .  25728
```

A beginner, with the table before him, can easily perform operations of this kind; but he must learn to work them without looking at the table. It is as well to show him the time and trouble saved, by actually exhibiting the work of such examples by addition, as here annexed. The following, worked like the example above, require no further explanation:—

```
 6432
 6432
 6432
 6432
 ————
25728
```

```
 78326    9073214    57387    264135
     8          9       10        12
——————   ————————   ——————   ———————
626608   81658926   573870   3169620
```

The multiplication by 10, as in the third of these examples, requires, in fact, no actual work, or reference to the table. You know that a number becomes ten times as great by simply putting a 0 after the figures; this causes each figure to advance a place to the *left*, so that its local value is increased tenfold. In like manner, a number becomes multiplied by 100 when *two* 0's are added to it; by 1000 when *three* are added, and so on, as is evident from *numeration*. The *cipher*, though in itself of no value, thus plays an important part in our notation; by filling up what would otherwise be gaps between figures, it keeps them in their proper places, and preserves their local values; and by being put after a number, it has the effect of multiplying that number by 10, 100, &c., according as it is written once, twice, &c.

The *sign* for multiplication is × placed between the *factors*, thus:—(1.) 346×7=2422. (2.) 6047×5=30235. (3.) 246053×6=1476318. (4.) 53274×800=42619200. In working this fourth example, the plan is to consider 8 only as the multiplier, and to put the ciphers to the right of it, as in the margin, annexing them afterwards to the product by 8. (5.) 470329×11=5173619. (6.) 375842×12=4510104.

```
   53274
     800
————————
42619200
```

II. *When the Multiplier is greater than* 12.

RULE.—Place the multiplier under the multiplicand, units under units, tens under tens, &c.

Commencing with the units' figure, multiply by *each* in succession, and arrange the several rows of results, so that the first figure on the right in each row may be *directly under* the multiplying figure that produced it. Add up all these products, and the sum will be the complete product.

For example, if we have to multiply 426 by 34, we place the 34 under the 26, and proceed thus:—4 times 6 are 24; 4 and carry 2: 4 times 2 are 8, and 2 are 10; 0 and carry 1: 4 times 4 are 16, and 1 are 17. The first row is now completed, and we begin anew, with the next figure, 3, as multiplier, taking care to put the first figure we get in the new row directly under this 3. 3 times 6 are 18; 8 and carry 1: 3 times 2 are 6, and 1 are 7: 3 times 4 are 12. The rows are now completed, so that, drawing a line and adding up, we find the product to be 14484.

```
  426
   34
 ————
 1704
1278
—————
14484
```

You see, from the local position of our second multiplier, 3, that it is in reality 30, and 426×30=12780: adding this product to the former product, that given by the 4, as in the margin, the whole product by 34 must necessarily be the result; and you see that it agrees with that in the example.

```
 1704
12780
—————
14484
```

If our multiplier had been a number of *three* figures, as 534, then, to the *partial* products obtained we must have added the product due to the 5; which, having regard to its local value, is 500; and if we retain the noughts, the whole operation would be as here annexed. And it is plain that we may always omit the noughts, provided we take care, as the rule directs, to put the first figure of each partial product directly under the multiplying figure, which supplies that product. It is worthy of notice, too, that the product will always be the same, whichever of the two numbers be regarded as the multiplier: you may easily satisfy yourself that 426 multiplied by 534, is the same as 534 multiplied by 426. To be convinced that this principle is perfectly general, you have only to assure yourself of the fact within the limits of the multiplication table, which you may do by replacing multiplication by addition, as shown in a previous example; that is, proving to yourself that 3 times 7 is the same as 7 times 3; that 5 times 8 is the same as 8 times 5, and so on, as the table declares: because, whatever be the two factors, the multiplication of one by the other is made up only of multiplications within the limits of the table. It is in general most convenient to take that for the multiplier which gives the fewer partial products, or rows of figures. (See the operations in the margin.)

```

7941     2136
——————   712
942332   ——————
         942332
```

The learner may now exercise himself in the process, by showing that the following statements are true:—

(1.) 4214×24=101136.
(2.) 658×243=159894.
(3.) 3264×2300=7507200.
(4.) 15607×3094=48288058.
(5.) Show that 243×616=9×9×11×8×7×3.
(6.) Show that 2048×1936=64×121×32×16.

When the multiplier consists of two figures, forming a number greater than 12, there are two partial products, or rows of figures, to add up; but, with a little address, the product may be written down at once, whenever the multiplier does not exceed 20. Suppose, for instance, it were 16, then, if we multiply by the 6, and, as we go on, add in not only what we *carry* from any figure of the multiplicand, but also the immediately *preceding* figure of the multiplicand, the complete product will be obtained in one line, as in the margin; the operation being carried on thus: 6 times 8 are 48, 8 and carry 4: 6 times 7 are 42 and 4 are 46 and 8 are 54; 4 and carry 5: 6 times 3 are 18 and 5 are 23 and 7 are 30; 0 and carry 3: 6 times 2 are 12 and 3 are 15 and 3 are 18; 8 and carry 1: 1 and 2 are 3. It will be advisable for the learner to practise this short way with the multipliers, 13, 14, 15, 16, 17, 18, 19. Multiplication which is thus performed in one line, is called *short* multiplication: when there are more lines, it is *long* multiplication.

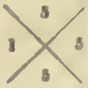
Method of proving multiplication by casting out nines.

We shall here mention a useful method of trying whether the product of two numbers is correct; but must postpone the explanation of the *principle* of the method till you arrive at *Algebra*. We can only mention here, that if any number be divided by 9, the remainder will be the same as would arise from dividing the *sum* of the figures in that number by 9: for 10 is equal to *once* 9+1; 100 is equal to 11 times 9+1; 1000 to 111 times 9+1; and so on: that is, the remainder arising from dividing 1, followed by any number of *noughts*, by 9, is always 1. Consequently the remainder arising from dividing 2, or 3, or 4, &c., followed by any number of noughts, is 2, or 3, or 4—the same as the figure preceding the noughts. It therefore follows, that whether we divide a number, such as 4326, which is of course 4000+300+20+6, by 9, or simply divide 4+3+2+6, that is 15—the sum of the figures—by 9, we must, in each case, get the same remainder. This property, taken in connection with the principle referred to above, and to be proved in Algebra (see the multiplication of compound quantities in Algebra), suggests the following rule:—

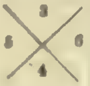
Rule.—Add together the figures of the multiplicand, not counting any 9 that may occur, rejecting also 9, whenever, in adding up, the sum amounts to 9 or more: when all the figures are added, the result will therefore be less than 9: note this result. Proceed in like manner with the figures of the multiplier; noting the result. Multiply the two results together; retaining, as before, only what is left after the rejection of all the *nines* the new result contains. Do the same thing with the figures of the product; and compare this third result with that just found: if the two be the same, the work may be presumed to be correct; if they differ, it is certainly wrong.

The usual way of noting the four results is to make a cross, to put the first in the left hand opening; the second in the opposite opening; the third above, and the fourth below. If the upper and lower results are the same, the work is *most likely* correct, but otherwise it is wrong.



Let us proceed in this way to test the accuracy of the work at page 436. Commencing at the right of the multiplicand, we say 7 and 4 are 11, therefore rejecting 9, 2 and 6 are 8 and 2 are 10: the first result, therefore, rejecting 9 from this 10, is 1, which we place in the opening of the cross to the left. Taking now the multiplier, we say 6 and 5, 11; 2 and 3, 5, the second result, which we place opposite the former. The product of the two is 5, with no 9 to reject: this is the third result, to be placed above. Lastly, taking the product, we say 2 and 3 are 5, and 3 are 8, and 2 are 10: 1 and 4 are 5; which is the fourth result, and, as it agrees with the preceding, we conclude the work to be correct.

It is plain, however, that if any of the figures in the product were made to exchange places, the agreement of the third and fourth results would remain, though the product would be wrong; as would also be the case if one figure of it were increased and another diminished, by the same number: all, therefore, that we can safely infer, is, that the agreement spoken of *must* have place if the work be correct; so that if it fail the work is wrong. Suppose, for instance, that we had made 73084163×7584=554270392192: then, applying the test, we get, from the first factor, the result 5; from the second, the result 6; and from the product of these, the result 3: but, from the above-stated product of the two numbers, the result is 4: this product, therefore, is incorrect; and, upon revising the multiplication, we find that the 3, after the nought, should have been a 2.



Simple Division.—The operation by which we find how many times one number or quantity is contained in another number or quantity of the same kind, is called *division.* It is also the operation by which we find the 4th part, the 5th part, &c., of a number or quantity. The number or quantity divided is called the *dividend;* that by which we divide it, the *divisor;* and the result obtained, the *quotient.*

You must not fall into the common mistake of considering the quotient to express always *how many times* the dividend contains the divisor: the 4th part of a mere number tells us how many times that number contains 4; but the fourth part of a *quantity*—a sum of money, for instance—is just the fourth part, and nothing else:—it is itself also a sum of money. The division is called *simple* when the quantities concerned are of but one denomination. On coming to the division of *compound* quantities, you will find some further remarks on the true nature of division in general; at present both dividend and divisor, and therefore the quotient, are to be regarded as mere *numbers.* They are, in fact, only abstract expressions for the idea of quantity.

I. *When the Divisor is not greater than* 12.

Rule.—Place the divisor to the *left* of the dividend, with a mark of separation, thus), between the two.

Draw a line beneath the dividend, and, by the multiplication table, find how many times the divisor is contained in the first figure of the dividend, or in the number expressed by the first *two* figures, or even in the number expressed by the first *three* figures, should the number given by the first, and even by the first two, be *smaller* than the divisor; and write the quotient under the line, taking care to observe what is *over*, as the divisor may be contained a certain number of times in the number expressed by the leading figure or figures, and leave something *over.*

Proceed to the next figure of the dividend; regard what was over, if anything, to be *prefixed* to it; and find how many times the divisor is contained in the number you thus get; putting the quotient down, and, as before, carrying what is over to the next figure of the dividend, to which you must regard it as *prefixed.* And in this way figure after figure of the complete quotient is to be found, till all the figures of the dividend have been used. Should there be anything over at the end, this is called the *remainder:* it is to be written beside the quotient figures, with the divisor placed under it, and a line of separation between them.

$$\begin{array}{r} 3)25602 \\ \hline 8534 \\ \hline \end{array}$$

Suppose, for example, we have to divide 25602 by 3, then placing dividend and divisor (3) as in the margin, we proceed thus: 3 is contained in 2, *no* times; so that nothing is to be placed under the 2: 3 is contained in 25, 8 times and 1 over; 8 and carry 1: this 1, regarded as *prefixed* to the 6, gives the number 16: we therefore say: 3 in 16, 5 times and 1 over: 3 in 10, 3 times and 1 over: 3 in 12, 4 times. Therefore, the quotient is 8534; and this is the *complete* quotient, as there is no *remainder.*

$$\begin{array}{r} 5)7804623 \\ \hline 1560924\frac{3}{5} \end{array}$$

Again, suppose it were proposed to divide 7804623 by 5, we should say 5 in 7, 1; and 2 over: 5 in 28, 5; and 3 over: 5 in 30, 6: 5 in 4, 0: 5 in 46, 9; and 1 over: 5 in 12, 2; and 2 over: 5 in 23, 4; and 3 over. As there is here a remainder 3, we annex it, with the divisor 5 under it, to the figures of the quotient, and call $1560924\frac{3}{5}$, the complete *quotient.*

The principle upon which the foregoing operation depends is pretty evident: the leading figure in the dividend above is 7000000: the fifth part of this is 1000000 and 2000000 over; that is, with the local value of the next figure 8, 2800000; the fifth part of this is 500000, and 300000 besides; the fifth part of which is 60000: the fifth part of the 4000—the local value of the next figure—is 0 thousands, and 4000 over; this, with the local value of the 6, is 4600; of which the fifth part is 900, and 100 over; this, with the 20, is 120; the fifth part of which is 20, and 20 over; and lastly, the fifth part of the remaining 23 is 4, and 3 over; and, to imply that this 3 still remains to be divided, it is put down with the 5 underneath; because one number, placed in this way under another, is a form frequently used to denote that the *upper* number is to be divided by the *lower.* Hence the fifth part of the proposed number is 1560924, and the fifth part of 3 besides: this quotient being made up of the several parts which arise from taking a fifth of each of the above-mentioned component portions of the number.

The *sign* for division is ÷, which stands for the words *divided by:* thus, $6 \div 2 = 3$ is a short way of stating that 6 divided by 2 is equal to 3. As noticed above, there is another way of indicating division, namely, by putting the dividend above and the divisor below, a short line separating the two: thus, $\frac{6}{2} = 3$ expresses the same thing as the notation above. The learner may exercise himself in the rule just explained by proving by it the truth of the following statements expressed in one or other of the forms of notation here adverted to:

(1.) $2185095 \div 3 = 728365.$
(2.) $2208184 \div 8 = 276023.$
(3.) $47051412 \div 6 = 7841902.$
(4.) $\frac{462508}{4} = 115627.$
(5.) $\frac{835465}{6} = 139244\frac{1}{6}.$
(6.) $\frac{13900424}{7} = 1985774\frac{6}{7}.$
(7.) $\frac{2375920}{11} = 215992\frac{8}{11}.$
(8.) $\frac{46285439}{12} = 3857119\frac{11}{12}.$
(9.) $\frac{65283029}{10} = 6528302\frac{9}{10}.$

It is plain that division by 10 requires no work: the quotient is always the dividend itself, wanting the last figure, which is the *remainder*, and which, therefore, written as in this last example, with the divisor underneath, completes the quotient. In a similar way, to divide by 100 we have simply to cut off *two* figures from the dividend for remainder; to divide by 1000, to cut off *three* figures; and so on: thus—

$$\frac{78546}{100} = 785\tfrac{46}{100},\ \frac{78546}{1000} = 78\tfrac{546}{1000},\ \&c.$$

All this is obvious, because

$$78546 = 78500 + 46 = 78000 + 546,\ \&c.$$

II. *When the Divisor is greater than* 12.

RULE.—Place the divisor to the left of the dividend as in the former case, and to the right mark off a place for the figures of the quotient.

Find how many times the *leading figure* of the divisor is contained in that of the dividend, or in the number expressed by the first *two* figures, if the leading figure of the dividend be smaller than that of the divisor; and put the figure expressing the number of times in the quotient's place.

Multiply the divisor by this first quotient-figure, and subtract the product from the number formed by the leading figures of the dividend, and to the remainder annex the next figure of the dividend. The number thus formed will be a new dividend, and the number of times it contains the divisor—to be found as before—will be the second quotient-figure, the product of which and the divisor, being subtracted from the new dividend, will give a second remainder, to which the *next* figure of the original dividend is to be joined, and the operation continued till all the figures of the dividend have been used.

An example worked at length will explain the operation better than any verbal rule.

Let it be required to divide 256438 by 346.

```
346)256438(741
    2422
    ————
     1423
     1384
     ————
      398
      346
      ———
       52
```

Placing the divisor on the left of the dividend, and marking off a place for the quotient on the right, we look at the leading figure of the divisor and also at that of the dividend, with the view of seeing whether the latter contains the former, which it does not, 3 being greater than 2: we therefore commence with the number 25, formed by the first *two* figures of the dividend, and seeing that 3 is contained in 25, 8 times, we should put 8 for the first quotient-figure; but bearing in mind, that when the *whole* divisor is multiplied by this 8, we must attend to the *carryings*, we perceive that 8 is too great, we therefore try 7, and find 7 times 346 to be 2422, a number *less* than 2564 above it, so that we can obey the direction of the rule and *subtract:* the remainder is 142, which, when the next figure of the dividend is brought down, becomes 1423. We now take *this* as a dividend; and, looking only at *leading figures* in this new dividend and in the divisor, we see that the latter *will go*, as it is called, 4 times; we therefore put 4 for the second quotient-figure; and multiplying and subtracting, we get 39 for the second remainder; and, by bringing down another figure, 398 for a new dividend: the divisor goes into this *once;* so that the quotient is 741, and the final remainder 52: this remainder, as in the former case, must be annexed, with the divisor underneath, to the quotient-figures; so that the complete quotient is $741\frac{52}{346}$, which is the 346th part of 256438. Of the truth of this you may convince yourself by observing that 256438 has been cut up into portions, and the 346th part of each portion found; for the work above is nothing else but that here annexed, with useless repetitions suppressed. According to this arrangement it is at once seen that 700 is the 346th part of 242200, that 40 is the 346th part of 13840, and that 1 is the 346th part of 346, and that of 52, the 346th part, still remains to be taken. Now, $242200 + 13840 + 346 + 52 = 256438$; consequently 741, together with $\frac{52}{346}$, is the 346th part of the number proposed.

        52
```

It must be noticed that if any *dividend*, formed by a remainder and a figure brought down, should be *less* than the divisor, that the divisor will go *no times* in that dividend; so that a 0 will be the corresponding quotient-figure; and that then a *second* figure must be brought down, as in the operation here annexed; where the complete quotient is $102\frac{21}{472}$.

```

    472
    ———
      965
      944
      ———
       21
```

There is another thing also to be attended to. Sometimes the divisor ends with zeros or noughts: when such is the case, the best way is to cut the ciphers off, and entirely to disregard them in the division, cutting off, however, at the same time, as many figures from the end of the dividend, which latter figures help to form the final remainder: you will see by operating on the same example first with the ciphers retained, and then with the ciphers dismissed, that nothing is omitted but useless ciphers: the complete quotient being, by either way, $61\frac{126}{2700}$. In thus completing the quotient, by means of the final remainder, take care to restore the ciphers that were temporarily cut off from the divisor: in some books on arithmetic this has not been named. The following examples are subjoined for practice:—

```
2700)164826(61
     16200
     —————
      2826
      2700
      ————
  Rem. 126

27.00)1648.26(61
      162
      ———
       28
       27
      ———
  Rem. 126
```

(1.) $\frac{13301}{47} = 283$
(2.) $159894 \div 658 = 243.$
(3.) $\frac{278643}{35} = 7961\frac{8}{35}.$
(4.) $780967 \div 3700 = 211\frac{267}{3700}.$
(5.) $\frac{36326599}{1342} = 27069\frac{1}{1342}.$
(6.) $3939040647 \div 6889 = 571787\frac{4}{6889}.$

To *prove* whether the quotient, in any case, is correct, it is only necessary to multiply it and the divisor together: the product will be the dividend, if the operation be correct, as is obvious; for the object of division is to find a number which by its multiplication with the divisor shall equal the dividend. In thus proving division, if there be a *remainder*, this is to be added to the product of the divisor and quotient-figures. For example, to prove whether the work above is correct, we multiply and add as in the margin; and as the result is the same as the dividend, we may be sure that the quotient is right.

III. *When the Divisor is composed of Factors, none of which exceeds 12.*

The operation just explained is called *long* division, to distinguish it from the shorter process of the preceding case, where the divisor is not greater than 12. If any divisor be found to be the product of factors, each of which does not exceed this limit, the division may be performed by successive applications of the shorter rule: for we may divide first by one factor, then the quotient by another factor, the new quotient by a third factor; and so on, till all the factors have been used.

It is possible that the division by the first factor may leave a remainder; if so, it must, of course, be preserved: the division by the second factor may also leave a remainder; if so, multiply it by the *first* divisor, and add in the former remainder; the result will be the complete remainder as far as the operation has been carried: if there be a third division, and a third remainder, we must multiply it by both the *first and second* divisors, adding in the former complete remainder: and so on, till all the divisions are completed. For example, suppose we have to divide 38214 by 63: then since $63=7\times9$, we may operate as in the margin: the final quotient being $606\frac{36}{63}$. In like manner, if we have to divide 24611 by 126; then, since $126=3\times6\times7$, the operation by short division, is that here annexed: the remainder from the first division is 2; that from the second is 1; and this 1, multiplied by the first divisor 3, and the former remainder being taken in, gives 5 for the complete second remainder: the remainder from the third division is 2, which multiplied by 3, and by 6, *both* the former divisors, that is by 18, gives 36; which, with the preceding remainder 5, makes 41;—the final complete remainder: hence the complete quotient is $195\frac{41}{126}$.

The method here described of obtaining the final remainder, and thence completing the final quotient, cannot be clearly explained till some knowledge of *fractions* be acquired: parts of a whole, as one-half, one-third, two-fifths, &c., and which are denoted by $\frac{1}{2}$, $\frac{1}{3}$, $\frac{2}{5}$, &c., are called *fractions:* when you are a little acquainted with the management of these, the reason of the foregoing directions will be plainly seen.

Upon the principles now delivered depend all the operations of arithmetic. In what has preceded, they have been applied only to what are called *abstract* numbers, without any reference to particular objects or articles. It remains to show the application of the same principles to *concrete* quantities; that is, to real commodities, or things—as to money, weights, measures, &c. And, in order to this, a few *Tables* connected with these matters must first be given.

We may urge on the student the necessity of learning the whole of these tables by heart. He will find such to afford him great assistance; and it will prevent the necessity of frequent reference to them.—ED.

TABLES OF MONEY, TIME, WEIGHTS, AND MEASURES.

I.—MONEY.

Gold Coins.

Name.	Value. s.	d.	Weight troy. dwt.	gr.*
Sovereign (*one pound*)	20	0	5	$3\frac{171}{623}$
Half-sovereign	10	0	2	$13\frac{397}{623}$
Guinea†	21	0	5	$9\frac{39}{89}$
Half-guinea	10	6	2	$16\frac{64}{89}$

Silver Coins.

Name.	Value. s.	d.	Weight troy. dwt.	gr.
Crown	5	0	18	$4\frac{4}{11}$
Half-crown	2	6	9	$2\frac{2}{11}$
Shilling	0	12	3	$15\frac{3}{11}$
Sixpence	0	6	1	$19\frac{7}{11}$
Fourpenny-piece	0	4	1	$5\frac{1}{11}$
Threepenny-piece	0	3		$21\frac{9}{11}$

Pence Table.

	s.	d.		s.	d.
4 farthings make	0	1	80 pence make	6	8
12 pence ,,	1	0	84 ,, ,,	7	0
20 ,, ,,	1	8	90 ,, ,,	7	6
24 ,, ,,	2	0	96 ,, ,,	8	0
30 ,, ,,	2	6	100 ,, ,,	8	4
36 ,, ,,	3	0	108 ,, ,,	9	0
40 ,, ,,	3	4	110 ,, ,,	9	2
48 ,, ,,	4	0	120 ,, ,,	10	0
50 ,, ,,	4	2	130 ,, ,,	10	10
60 ,, ,,	5	0	132 ,, ,,	11	0
70 ,, ,,	5	10	140 ,, ,,	11	8
72 ,, ,,	6	0	144 ,, ,,	12	0

A farthing—that is, *one-fourth* of a penny—is represented thus, $\frac{1}{4}d.$; a halfpenny, thus, $\frac{1}{2}d.$; and three farthings, thus, $\frac{3}{4}d.$ To express a fraction of a farthing, the letter *f* is put against the fraction: thus, $\frac{1}{2}f.$ means half a farthing; $\frac{3}{5}f.$, *three-fifths* of a farthing, &c.

II.—TIME.

60 seconds	make 1 minute.
60 minutes	,, 1 hour.
24 hours	,, 1 day.
7 days	,, 1 week.
52 weeks 1 day, or 365 days	,, 1 year.
366 days	,, 1 *leap* year.

III.—AVOIRDUPOIS WEIGHT.

16 drams (*dr.*)	make 1 ounce.
16 ounces (*oz.*)	,, 1 pound.
28 pounds (*lb.*)	,, 1 quarter.
4 quarters (*qr.*), or 112 lb.	,, 1 hundredwt.
20 hundredweight (*cwt.*)	,, 1 ton.

IV.—TROY WEIGHT.

24 grains (*gr.*)	make 1 pennywt.
20 pennyweights (*dwt.*)	,, 1 ounce.
12 ounces (*oz.*)	,, 1 pound.

V.—APOTHECARIES' WEIGHT.

20 grains (*gr.*)	make 1 scruple.
3 scruples (℈)	,, 1 dram.
8 drams (ʒ)	,, 1 ounce.
12 ounces (*oz.*, or ℥)	,, 1 pound.

VI.—MEASURES OF LENGTH, OR LONG MEASURE.

12 inches	make 1 foot.
3 feet	,, 1 yard.
6 feet	,, 1 fathom.
5½ yards	,, 1 rod, pole, or perch.
4 perches, or 100 links	,, 1 chain (22 yards).
40 poles	,, 1 furlong.
8 furlongs	,, 1 mile.
3 miles	,, 1 league.

Cloth.

2¼ inches	make 1 nail.
4 nails	,, 1 qr. of a yard.
5 quarters	,, 1 English ell.
3 quarters	,, 1 Flemish ell.

VII.—MEASURES OF SURFACE, OR SQUARE MEASURE.

144 square inches	make 1 square foot.
9 square feet	,, 1 square yard.
30¼ square yards	,, 1 sq. rod, pole, or perch.
40 square perches	,, 1 rood.
4 roods, or 160 sq. perches	,, 1 acre.
10 sq. chains, or 100,000 sq. links	,, 1 acre.
640 acres	,, 1 square mile.
100 square feet	,, 1 square of flooring.
272¼ square feet	,, 1 sq. rod of brick-work.

---

* The mark *dwt.* stands for *pennyweights*, and *gr.* for *grains:* see the table of Troy weight. The reader can scarcely require to be informed that £ stands for *pounds*, *s.* for *shillings*, and *d.* for *pence*.

† The *coin* guinea has been long abolished, but the *name* is still retained for 21*s*. The name *pound* is given to 20*s*., because the quantity of silver in this sum originally weighed a pound troy.

VIII.—MEASURES OF SOLIDS, OR CUBIC MEASURE.*

1728 cubic inches	make	1 cubic foot.
27 cubic feet	,,	1 cubic yard.

IX.—MEASURES FOR LIQUID AND DRY GOODS.

4 gills	make	1 pint.
2 pints	,,	1 quart.
4 quarts	,,	1 gallon.
2 gallons	,,	1 peck.
4 pecks	,,	1 bushel.
8 bushels	,,	1 quarter.
2 cwt. of coals	,,	1 sack.
10 sacks	,,	1 ton.

It may be well to notice here, that the *avoirdupois* pound contains 7,000 grains, of which 5,760 make a pound *troy;* so that 144 pounds avoirdupois are equal to 175 pounds troy. The ounce troy *exceeds* the ounce avoirdupois by 42½ grains. The gallon contains 10 pounds avoirdupois of distilled water, and its solid measure is 277 cubic inches and 274 thousandths of an inch.

Reduction.—Arithmetic is now to be applied to *concrete* quantities, such as those named in the foregoing tables: hitherto its operations have been confined to *abstract* numbers. The name *reduction* is given to the methods by which quantities are changed to others of the same values, but of different denominations; as, for instance, the changing, or *reducing*, pounds to shillings, pence to farthings, yards to miles, minutes, hours, &c., to years—and so on. There are two rules for such reductions: the one applying when the quantity is to be converted from a higher to a lower denomination—as, for instance, from pounds to pence; and the other applying when the change is to be from a lower denomination to a higher, as from pence to pounds.

I. To reduce a Quantity to one of Lower Denomination.

RULE.—From the previous table see how many of the *next* lower denomination make 1 of the higher; multiply by this *number:* the product will be the number of quantities of the next lower denomination. If any of the lower denomination be connected with the proposed quantity, the number of these must be added in with the product.

Suppose, for example, we have to reduce £136 8*s.* 4¾*d.* to pence. Then, as 20*s.* make £1, we multiply the number 136 by the number 20, adding in the number 8: the product is 2728, the number of shillings. Again, since 12 pence make 1*s.*, we multiply the last number obtained by 12, taking in the 4: the product is 32740, the number of pence. And lastly, multiplying this by 4, because 4 farthings make 1*d.*, and taking in the 3, the number of farthings, we get 130963 for the number of farthings required.

£ s. d.
136 8 4¾
20
2728 numb. of shillings.
12
32740 numb. of pence.
4
130963 numb. of farthings.

Although we have been dealing here with *concrete* quantities, yet, after all, our operations are performed entirely with *abstract* numbers. We do not multiply £136 by 20, because we should then get £2728 for the product; much less do we multiply by 20 *shillings* (as some books direct us to do); for to attempt to *multiply* by *shillings* is to attempt an absurdity: "20 shillings times 136 pounds," is a mode of expression as ridiculous as it is meaningless.

As a second example, let it be required to reduce 217 days 14 hours and 36 minutes to minutes. Since 24 hours make 1 day, we multiply the number 217 by 24; and in adding in the 14, we include the *units* in the units' amount of the product—that is, in the first result of the first partial product—and the *tens* (1) in the first result of the second partial product. We thus get 5222, the number of hours; this number we multiply by 60, because 60 minutes make 1 hour, and we add in the 36—units with units, and tens with tens, as before: and we thus find the number of minutes to be 313356.

d. h. m.
217 14 36
24
872
435
5222
60
313356

Sometimes we have to multiply by a *fraction;* as, for instance, when perches of *length* are to be reduced to yards; for you see by the *table* that 5½ yards make 1 perch: also, in reducing *square perches* to *square yards*, we have to multiply by 30¼, the number of square yards in 1 square perch. Now, to *multiply* by ½ means simply to take *half* the multiplicand; that is, to *divide* it by 2; and to multiply by ¼, means to take a *fourth part*, or to divide the multiplicand by 4. This is certainly a departure from the primitive meaning of the word *multiply;* but it is sanctioned by common practice. It is customary to speak of two-and-a-half times this, or three-and-a-quarter times that, and so on: thus, two-and-a-half times 4 we know to mean 10; and two-and-a-quarter times, 9. The way to introduce such fractional parts in the arithmetical operation will be sufficiently seen from the two examples worked in the margin; the first being to reduce 248 *linear* perches to *linear* yards, and the second to reduce 248 *square* perches to *square* yards. If the number of perches had been 249, the multiplier ½ would have given 124½, and the multiplier ¼, 62¼. By aid of the tables, which ought, indeed, to be committed to memory, you will easily be able to show the truth of the following statements, namely:—

Linear perches.
2) 248
5½
1240
124 for ½
1364 yards.

Square perches.
4) 248
30¼
7440
62 for ¼.
7502 sq. yds.

(1.) 13*s.* 4*d.* = 160*d.*
(2.) £32 1*s.* 6*d.* = 7698*d.*
(3.) £5 12*s.* 4½*d.* = 5394 farthings.
(4.) 27 cwt. 2 qr. 22 lb. = 3102 lb.
(5.) 17 lb. 6 oz. 14 dwt. *troy* = 4214 dwt.
(6.) 131 miles 3 furlgs. 10 perches 3 yds. = 231278 yds.
(7.) 29 days 3 hours 21 minutes = 41961 minutes.
(8.) 37 acres 3 roods 12 perches = 183073 yards.
(9.) 239¼ gallons = 7664 gills.
(10.) 327 square perches = 9891¾ square yards.
(11.) 263 tons 18 cwt. 3 qr. 21 lb. = 591241 lb.

To reduce a Quantity to one of Higher Denomination.

RULE.—Find by the table how many of the given denomination make 1 of the next higher, and divide by this number; the quotient will express how many of the next higher denomination are in the proposed quantity. In like manner, divide by the number expressing how many of the new denomination make 1 of the next higher to it; and so on, till the required denomination is reached. Suppose, for instance, we had to find how many pounds there were in 2640397 farthings. Dividing the number of farthings by 4, we get the number of pence—namely, 660099, and one farthing over. Dividing the number of pence by 12, we get the number of shillings—namely, 55008, and three pence over; and lastly, dividing by 20, we get the number of pounds—namely, 2750, and 8*s.* over. Consequently, in the proposed number of farthings, there are £2750 8*s.* 3¼*d.*

4) 2640397
12) 660099...¼*d.*
2.0) 5500.8...3*d.*
£2750 8*s.* 3¼*d.*

Again: let it be required to convert 591241 lb. into tons, cwt., &c. As 28 lb. make 1 qr., the next higher denomination to pounds, we divide first by 28, or by 7 and by 4, the two *factors* of 28, as it is better to use *short* division: we thus get 21115, the number of quarters, with 21 lb. over. This number, divided by 4, gives the number of cwts.—namely, 5278 and 3 qrs. over: and lastly, dividing by 20, the number of cwt. in 1 ton, we get finally 263, the number of tons: so that there are 263 tons 18 cwt. 3 qr. 21 lb. in 591241 lb.

---

* A *cube* is a solid of six equal square faces, like a common die. If the edge of the figure be 1 inch, the solid is a *cubic* inch; while each face is a square inch. In a similar solid of which the edge is 1 foot, there are 1728 of the smaller cubes, or cubic inches.

7) 591241
4) 84463
4) 21115...21 lb.
2.0) 527.8...3 qrs.
263 t. 18 cwt. 3 qr. 21 lb.

All this is so easy and obvious that we need not occupy space with any more worked-out examples. We shall merely give one cautionary direction—it is this: that when you have to *divide* by 5½, bring both this divisor and the dividend into *halves*; that is, double both; making the divisor 11, instead of 5½; but remember that the *remainder* will be so many *halves*. In like manner, when you have to divide by 30¼, bring all into *quarters*; that is, divide 4 times the dividend by 121, which is 4 times 30¼; remembering, however, that the *remainder* will be *quarters*; so that a fourth part of the number, which is the remainder, will be the number of *wholes*. See the operation in the margin, where the *factors* of 121, viz., 11, 11, are used to get the quotient by short division. This quotient shows that there are 81 square perches, and 51 *quarter-yards* over; that is, 12¾ square yards: the result would therefore be written, 81 square perches, 12¾ square yards.

Square yards.
2463
4
11) 9852
11) 895...7
81...51

The examples given at page 440, may be employed for exercise in this rule, by taking in each the quantity on the right of the sign of equality, and converting it into that on the left; but others are added here:—

(1.) 28635 seconds = 7 h. 57m. 15 sec.
(2.) 10085760 gr. = 1751 lb. troy.
(3.) 633600 inches = 10 miles.
(4.) 397024 yds. = 225 mi. 4 fur. 26 per. 1 yd.
(5.) 91476 sq. ft. = 2 ac. 0 rds. 16 per.
(6.) 100000 cub. in. = 2 cub. yds. 3 ft. 1504 in.

The four fundamental operations of arithmetic may now be applied, in order, to *compound* quantities.

Addition of Compound Quantities.—To add together a set of concrete quantities of different denominations, the rule is as follows:—

RULE.—Arrange the quantities to be added one under another, so that all in the same vertical column may be of the same denomination.

Add up the quantities of *lowest* denomination: find how many of the next denomination are contained in the sum: put the *remainder* under the column, and carry the quotient to the next column.

Proceed in this way, from column to column, till all have been added up.

The principle of this rule is too obvious to require any explanation; the carryings merely transfer the quantities of advanced denominations to the columns in which those denominations are arranged, just as in the addition of abstract numbers.

£	s.	d.
17	9	3¼
42	13	4¾
16	10	2½
7	2	9½
1	18	10½
85	14	6½.

Thus the sums of money in the margin are arranged so that the denomination *farthings* forms one column, the denomination *pence* the next, *shillings* the next, and *pounds* the next. The sum of the farthings' column is 10 farthings, in which are contained 2 pence, and there are 2 farthings, or ½ over; this ½ is therefore put down, and the 2 pence carried to the pence column; the sum of this column is 30 pence, that is, 2*s.* 6*d.*: the 6*d.* is put down, and the 2*s.* carried to the shillings' column, the sum of which is 54*s.*, that is, £2 14*s.*; we therefore say 14, and carry 2; and this 2 added in with the pounds' column, makes the amount of that column £85; therefore the sum of the whole is £85 14*s.* 6½*d.*

It may be noticed, that in adding up the shillings' column of an account, the best way is to disregard the *tens* in that column till all the *units* have been added; then, having reached the top unit-figure, to proceed downwards, taking in every *ten* that appears. Thus, in the present example, the sum of units' column of shillings is 24; so that proceeding downwards, taking in each *ten* as we meet with it, we say 34, 44, 54; so that the sum is 54*s.*, or £2 14*s.*

lb.	oz.	dr.
8	13	11
9	10	13
4	6	9
11	11	15
7	3	8
41	14	8

Two other examples are here annexed; the one in *Avoirdupois weight*, and the other in *Time*. In the former the sum of the drams is found to be 56 dr.; by reduction, we find that in these drams there are 3 oz. 8 dr.; we therefore put down 8 dr. and carry the 3 oz. to the next column, which gives 46 oz., or 2 lb. 14 oz.; writing down the 14 oz., and carrying the 2 lb. to the column of lbs., we get 41 lb. for the sum of this column: therefore the whole sum is 41 lb. 14 oz. 8 dr.

d.	h.	m.	s.
34	13	9	15
18	9	0	37
27	21	11	19
14	18	23	4
10	7	14	16
13	14	21	19
119	11	19	50

In the next example the column of seconds amount to 110 seconds; that is, to 1 minute 50 seconds: the 50 seconds is put down, and the 1 minute carried to the next column, the amount of which is 79 minutes; that is, 1 hour 19 minutes, 19 and carry 1: the hour column amounts to 83 hours, or 3 days 11 hours; 11 and carry 3 to the day's column, the amount of which is 119: therefore the whole amount is 119 days, 11 hours, 19 minutes, 50 seconds.

Subtraction of Compound Quantities.—The subtraction of concrete quantities, of different denominations, is effected by the following rule:—

RULE.—Place the less of the two quantities under the greater, arranging the denominations as in addition.

Commence with the *lowest* denomination, and subtract, if the upper number be sufficiently great; if not, increase it by as many as will make 1 of the *next* denomination, and *then* subtract, taking care afterwards to carry 1, as in the subtraction of abstract numbers: and proceed in like manner with each denomination till the subtraction is finished.

£	s.	d.
124	16	9½
75	19	3¾
48	17	5¾

In this way the difference between £124 16*s.* 9½*d.* and £75 19*s.* 3¾*d.* is found, as in the margin. Since 3 farthings cannot be taken from 2 farthings, we increase the 2 farthings by 4 farthings, or 1*d.*, and say 3 from 6 and 3 remain; that is, ¾*d.*: carry 1: 4 from 9 and 5 remain: 19 from 36 (increasing the 16*s.* by 20*s.**) and 17 remain; carry 1: 6 from 14 and 8 remain; carry 1: 8 from 12 and 4 remain; therefore the difference is £48 17*s.* 5¾*d.*

m.	fur.	per.	yd.
43	0	1	1
24	6	21	2
18	1	19	4½

Again, suppose we have to subtract 24 miles, 6 furlongs, 21 perches, 2 yards from 43 miles, 1 perch, 1 yard. Then, having placed the quantities as in the margin, and seeing that the 1 yard is too small, we increase it by 1 perch, that is by 5½ yards, and subtract 2 yards from 6½ yards; we thus get the remainder 4½ yards; and carry 1: and as 40 perches make 1 furlong, we subtract 22 from 41, and get 19 for remainder: carrying 1 to the 6 we subtract 7 from 8—the furlongs in 1 mile—and get 1 for remainder: and carrying 1 to the 4, it merely remains to subtract 25 from 43: the complete remainder is therefore 18 miles, 1 furlong, 19 perches, 4½ yards.

If the complete remainder in an operation of this kind be added to the compound quantity immediately above it—that is, to the subtractive quantity—the sum will be equal to the upper row; that is, to the quantity which has been diminished: so that we may prove in this way the correctness of the subtraction. The following examples, if thus worked and proved, will afford exercise both in subtraction and addition :—

---

* Instead of thus increasing the upper term by the unit of next higher denomination, the learner will find it a little easier to subtract at once from this unit, expressed in the lower denomination, and to *add* the remainder to the term above: thus we may say, 19 from 20, 1; and 16 make 17.

(1.) Subtract £374 11s. 8¼d. from £920 17s. 7½d.
(2.) Subtract £173 9s. 4¾d. from £200.
(3.) Subtract 8 lb. 4oz. 23 gr. from 23 lb. 11 oz. 21 gr.
(4.) Subtract 342 mls. 6 fur. 4 per. 4 yds. from 687 mls. 3 fur. 1 per.
(5.) Subtract 324 gall. 2 quarts 1 pint from 570 gallons 1 quart.
(6.) Subtract 3 roods 7 perches 23 yards from 2½ acres.
(7.) Subtract 121 sq. yds. 7 ft. 132 in. from 237 sq. yds. 3 ft. 101 in.
(8.) Subtract 18 cubic yds. 37 ft. 211 in. from 47 cubic yds. 13 ft. 75 in.

Multiplication of Compound Quantities.—From the nature of multiplication, it is plain that a concrete quantity can be multiplied only by *an abstract number;* indeed —whatever be the multiplicand—the multiplier, which simply denotes how many times the former is to be taken, must necessarily be a mere number. Strange to say, however, books on arithmetic, of the most recent date, are to be found, in which the multiplication together of *concrete* quantities is insisted upon, and pretended to be taught. People have disputed over and over again about the product of £19 19s. 11¾d., multiplied by itself! They might as well have disputed about the multiplication of Cheapside by Lombard Street; or, as Mr. Walker pithily expresses it, about multiplying "5lbs. of beef by 3 bars of music."* This last operation, palpably absurd as the thing is, the arithmeticians referred to would not for a moment hesitate to undertake, provided the beef and music occurred in a rule-of-three question, as indeed they very well might; for they refer to the rule-of-three in justification of such a process.† Is it not ridiculous to appeal to a *rule* instead of to reason and common sense, in a subject which professes to be founded on rational principles, and supported by demonstration? We wish to warn you earnestly against this: receive no rule in any department of mathematics, the truth of which is not evident to your own understanding; and, therefore, in strict accordance with common sense. Multiplication is merely a short way of doing addition, and *addition* may always replace it: you have only to write the multiplicand down the proposed number of times, and to add all up. The *sum* is what in multiplication is called the *product;* but how could a sum of money be written down £19 19s. 11¾d. *times?* Even in common reduction, similar absurdities are to be met with in the books. If you wish to convert pounds into shillings, you are told to multiply the *pounds* by 20, and sometimes, which is worse, to multiply them by 20s. But if you multiply pounds by 20, you get—not shillings —but 20 times as many *pounds,* as is obvious: what you really do, is to multiply the *number* denoting *how many* pounds by 20; because there must be 20 times that *number* of shillings.

The following is the rule for multiplying a compound quantity by a number :—

RULE I.—*When the Multiplier is not greater than* 12.

Put the multiplier under the quantity of least denomination: multiply that quantity by it, and divide the product by the *number* that expresses how many of such quantities make 1 of the next denomination: put down the *remainder,* and carry the quotient to the product arising from the multiplication of the next term—and so on till all the terms have been multiplied.

When the multiplier is greater than 12, and is yet such as to admit of being formed from *factors,* multiply by each factor in succession, as in short multiplication.

The table of factors at the end will be found very useful in enabling us to tell at a glance whether any number not exceeding 100,000, can be decomposed into factors, within the limits of the multiplication table; and if so, what the factors are.

Multiply £23 14s. 7¾d. by 7. Putting the multiplier 7 under the farthings, and multiplying them by the 7, the product is 21 farthings; and dividing 21 by 4, the number of farthings in a penny, we get 5 and 1 over; so that in 21 farthings there are 5 pence and 1 farthing: we put down the 1 under *farthings,* and carry the 5 pence to the 49, the pence product; which gives 54 pence, or 4s. 6d.: we put down the 6d., and carry the 4 to the shillings product, and thus get 102 shillings, or £5 2s; and putting down the 2s., we carry the 5 to the pounds' product. The complete product is thus £166 2s. 6¼d.

£	s.	d.
23	14	7¾
		7
166	2	6¼

Suppose the multiplier, had been 105, then seeing by the table that 105 = 7 × 5 × 3; after the multiplication by 7, as above, we should have again multiplied by 5, and then by 3, as in the margin; from which we see that 105 times £23 14s. 7¾d. is £2491 17s. 9¾d.

£	s.	d.
23	14	7¾
		7
166	2	6¼
		5
830	12	7¼
		3
2491	17	9¾

RULE II.—*When the Multiplier exceeds* 12, *and is not divisible into factors, each less than* 13.

Take that number in the table which is *nearest* to the proposed multiplier, whether greater or less, and use the factors of this number. To the final product *add,* if the number be *less,* and *subtract* from it if the number be greater, the product arising from multiplying the given quantity by the *difference* between the multiplier and number taken from the table; the result will obviously be the complete product required.

For example, if the multiplier of the sum above had been 107 instead of 105, we should still have taken 105, and have used the factors of it, as just shown; but to the product by these factors, we should have *added* twice the multiplicand; we should thus have got 105 times the sum and twice the sum, that is 107 times the sum as proposed. If the multiplier had been 109, then from 112 times, that is, from 8 × 7 × 2 times, we should have *subtracted* 3 times the original multiplicand as in the margin, and should thus have found £23 14s 7¾d. × 109 = £2586 16s. 4¾d.

£	s.	d.
23	14	7¾ × 3
		8
189	17	2
		7
1329	0	2
		2
2658	0	4
71	3	11¼
2586	16	4¾

The following statements are left for the learner to verify after the manner now shown :—

(1.) £8 18s. 6d. × 6 = £53 11s. 0d.
(2.) £148 7s. 0¼d. × 9 = £1335 3s. 2¼d.
(3.) £148 7s. 0¼d. × 63 = £9346 2s. 3¾d.
(4.) 6s. 10¼d. × 97 = £33 6s. 10½d.
(5.) 15 mil. 3 fur. 2 per. 4 yds. × 75 = 1153 mil. 6 fur. 4 per. 3 yds.

Division of Compound Quantities.—Division of concrete quantities may be viewed under two aspects, accordingly as the divisor is itself a concrete quantity or merely abstract number.

If you have to divide by a concrete quantity, your object is to find *how many times* the smaller quantity—the divisor—is contained in the larger—the dividend. But if you have to divide by an abstract number, you then seek to divide the proposed quantity into *as many equal parts* as there are units in the divisor. These, you see, are two different objects; and precision and accuracy of thought require that you should bear in mind the distinction. When you divide one concrete quantity by another, your quotient is, of course, an *abstract number:* but when you divide a concrete quantity by an abstract number, your quotient is also a *concrete quantity* of the same kind. You will remember that we are not writing

---

* *Philosophy of Arithmetic,* p. 58.

† Paganini was a very wonderful performer on the violin. Many people would have given a good deal of beef for a few bars of his music. Suppose, in time of need, he had exchanged 11 bars for 5lb., how many lb. might have been exchanged, at the same rate, for 3 bars? This is a rule-of-three question, and there are plenty of books—Walkingame for instance —that would direct the following *stating* :—

Bars of music.		lb. of beef.		bars of music.		lb. of beef.
11	:	5	::	3	:	1 4/11

And to get this 1 4-11 lb. of beef, they would direct the beef and the music, in the second and third terms, to be multiplied together! The author of this would thus incorporate the beef and music.

a book on Arithmetic, exclusively with a view to mercantile practice. Our endeavour is to prepare you for a course of mathematical study; and we therefore wish you to cultivate habits of thought and reflection—to know what you are actually about, and not to feel contented by merely following a *rule*. We shall not insist upon any marked departure from the customary forms of expression, in the practical directions for working an example; but must insist upon accuracy of *thought*, whatever want of precision in *language* custom may authorise.

To divide a compound quantity by a *number*, the rule is this:—

RULE.—Commence with the *highest* denomination, and take the proposed part of *it*; reduce what is over to the next denomination, and carry the result to the next term of the dividend; take the proposed part of the sum, reducing what is over, and carrying as before; and so on, to the end.

Thus, if the 7th part of £22 15*s*. 9*d*. be required, we find it as in the margin: the 7th part of £22 is £3 and 20*s*. over: this, carried to the 15*s*., gives 35*s*.; the 7th part of which is 5*s*., and there is nothing to carry: the 7th part of 9*d*. is 1*d*.; and 2*d*., or 8 farthings, over; the 7th part of which is 1 farthing, and $\frac{1}{7}$ of a farthing; hence, the 7th part of the proposed sum is £3 5*s* $1\frac{1}{4}d. + \frac{1}{7}f.$

```

If the divisor exceed 12, we must proceed, upon the same principle, by long division, unless it can be decomposed into convenient factors; when the operation need to consist only of successive steps like that explained above.

When the divisor, instead of being an *abstract number*, is a *concrete quantity*, of the same kind as the dividend, the rule is as follows:—

RULE.—Reduce both dividend and divisor to the *lowest denomination* found in *either*, and then perform the division exactly as in the case of mere numbers: the quotient will denote the *number of times* the smaller quantity is contained in the greater.

For example, let it be required to divide £63 7*s*. by £13 2*s*. 3*d*. Then, as *pence* is the lowest denomination that occurs, we reduce *both* quantities to *pence*, and then divide as in the margin: the quotient shows that the smaller sum is contained in the larger between 4 and 5 times: it is contained in it 4 times and a *fractional part* of a time, represented by $\frac{2616}{3147}$, which is nearly another time, but not quite. You may shorten the work a little by reducing the two quantities—not to *pence*, but to *three-pences*—as shown below; observing, that as 4 three-pences make 1 shilling, we multiply the number of shillings by 4, and take in the odd threepence. From this mode of working, we should conclude that the dividend contains the divisor 4 times and a part of a time, denoted by the fraction $\frac{872}{1049}$, which differs from the former fraction only in appearance—not in value; for if we wish to express that one number is to be divided by another, we may, as you are aware, do so by writing the latter below the former, or by writing twice, three times, &c., the latter below twice, three times, &c. the former. This is pretty obvious, since the quotient of dividend and divisor is the same, whatever number *both* be multiplied by. It will be seen that the upper and lower numbers of the first fraction are only those of the second, each multiplied by 3.

There is no room in this treatise for many examples. We shall, however, give two. The first is to show that £33 19*s*. 6*d*. divided by 13 gives £2 11*s*. 6*d*. for quotient; the second is to show that the same sum divided by £13 gives $2\frac{319}{520}$ for quotient. In working the second example, you had better reduce to *sixpences*, not to *pence*.

Fractions.—What has preceded suffices to convey a general, and, we hope, a pretty accurate notion of the arithmetic of *integral* quantities. We are now to show how the fundamental operations are to be applied to *fractions*. It has been impossible to avoid all allusion to fractions in the foregoing part of the subject, because they force themselves upon our notice even when operating upon *integers*; but the arithmetic of fractions remains to be explained, and, indeed, the formal definition of a fraction to be given. In strictness, a fraction is a part of a *whole*—that is, it is *less* than the quantity of which it is said to be a fraction. Thus, $\frac{1}{3}$, $\frac{2}{5}$, $\frac{26}{43}$, are strictly fractions—*proper* fractions. The first denotes a third part of unit, or 1; the second a fifth part of 2; the third a forty-third part of 26; each part being *less* than one whole. But $\frac{4}{3}$, $\frac{7}{5}$, $\frac{64}{43}$, are also called fractions, though four-thirds, seven-fifths, sixty-four forty thirds, are all greater than one whole, as is plain. Fractions such as these, where the upper number, called the *numerator*, is not less than the lower, called the *denominator*, are said to be *improper fractions*. You will readily see why these terms, numerator and denominator, are so applied: the upper number *enumerates*, or states the number of parts of that particular *denomination* indicated by the lower number. Thus, $\frac{3}{4}$ means *three* of the parts called *fourths*: if it were $\frac{3}{4}$ of £1, then, since one-fourth is 5*s*., three-fourths, or $\frac{3}{4}$, would be 15*s*., and so on. Instead of reading this fraction *three-fourths*, we may, if we please, say *three divided by four*. Three pounds divided by the number 4, is evidently the same as three-fourths of one pound; and any fraction may be viewed in either of these two ways: thus it is matter of indifference whether we call $\frac{5}{7}$, *five-sevenths*, or 5 *divided by* 7. A moment's reflection will convince that five-sevenths of anything, is the same as a seventh part of *five* such things; for a seventh part of one of them added to a seventh part of another, then again this sum increased by a seventh part of another, and so on, till a seventh part of each of the five has been taken, and all these sevenths added, will be equal to all five divided by 7.

The fractional notation is perfectly general—*any number* may be expressed in it; a whole number, or an *integer*, as well as a fraction properly so called. Thus 6, 8, &c., may be written $\frac{6}{1}$, $\frac{8}{1}$, &c.; and it is sometimes convenient to write integers this way. *Here* the denominator is *unit*, or 1; but we may express an integer in the form of a fraction with *any* denominator. Thus, if 7 for denominator be chosen, the two numbers, 6, 8, may be written $\frac{42}{7}$, $\frac{56}{7}$, as is evident: you have only to multiply the number by the chosen denominator, and to place the factor, thus used as a multiplier, underneath—that is, as a divisor. The numerator and denominator are called the *terms* of the fraction; and when an integer is united to a fraction, the whole is called a *mixed* number. Thus, $2\frac{1}{3}$; $3\frac{5}{7}$, &c., are *mixed numbers*.

To reduce a Mixed Number to an Improper Fraction.

The rule is this: multiply the integer by the denominator of the fraction; add the product to the numerator, and put the denominator underneath. Thus, $2\frac{1}{3} = \frac{7}{3}$, $3\frac{5}{7} = \frac{26}{7}$; for 2 is evidently $\frac{6}{3}$, and $\frac{6}{3} + \frac{1}{3} = \frac{7}{3}$. In like manner 3 is $\frac{21}{7}$, and $\frac{21}{7} + \frac{5}{7} = \frac{26}{7}$; and so on. Here are other examples: $5\frac{3}{5} = \frac{28}{5}$; $4\frac{7}{8} = \frac{39}{8}$; $7\frac{13}{9} = \frac{76}{9}$; $12\frac{8}{11} = \frac{140}{11}$. To accomplish the contrary purpose—that is,

To reduce an Improper Fraction to a Mixed Number,

You have only to perform the division indicated by the denominator, and to annex to the quotient the fractional correction as in common division. Thus, $\frac{28}{5} = 5\frac{3}{5}$, $\frac{39}{8} = 4\frac{7}{8}$, $\frac{76}{9} = 8\frac{4}{9}$, and so on.

To reduce Fractions with Different Denominators, to others of the same Value, with Equal Denominators.

This is one of the most important operations in the arithmetic of fractions; for till fractions appear with a *common denominator*, they can neither be added to nor subtracted from one another: the reduction of fractions to a common denominator is thus a preliminary, indispensably necessary, for the application to them of the first rules of arithmetic. The operation is also useful in enabling us to discover at a glance which of two fractions, however nearly equal, is really the greater. Thus, of the two fractions, $\frac{33}{44}$, $\frac{32}{44}$, we see in a moment which is the greater, *because* their denominators are the same; but we could not so readily and confidently state which is the greater of $\frac{3}{4}$ and $\frac{8}{11}$: yet the former are only these reduced to a common denominator—the values are the same.

The rule for reducing fractions to a common denominator is as follows:—

RULE.—Multiply *each* numerator by the product of the denominators of all the *other fractions*; we shall thus get the *numerators* of the changed fractions.

Multiply *all* the denominators together; the product will be the *common denominator* belonging to each changed numerator.

For example: in order to reduce the fractions $\frac{2}{3}$, $\frac{1}{5}$, $\frac{3}{7}$, to others of the same value with the same denominator, we proceed as follows:—

$$\left.\begin{aligned} 2 \times 5 \times 7 &= 70 \\ 1 \times 3 \times 7 &= 21 \\ 3 \times 3 \times 5 &= 45 \end{aligned}\right\} \text{the new numerators;}$$
$$3 \times 5 \times 7 = 105 \quad \text{the common denominator;}$$

therefore the equivalent fractions, changed in form as required, are $\frac{70}{105}$, $\frac{21}{105}$, $\frac{45}{105}$.

If you compare these with the original fractions, you will see that they each arise from multiplying the numerator and denominator of the former by the same number. Thus, $\frac{70}{105}=\frac{2 \times 35}{3 \times 35}$; and it is obvious that one number divided by another (in this case 2 by 3), is the same as 35 times the former divided by 35 times the latter, or any number of times the former divided by the same number of times the latter. If you have any doubt of this, just consider, if you had to divide 2*s.* among 3 people, whether the *share* of each would not be the same as if you had to divide 35 times 2*s.*—that is, 70*s.*—among 35 times 3 people—that is, 105 people. It is plain that, in either case, each would get a third part of 2*s.*, or two-thirds of 1*s.*; or, to view the matter more generally, it is self-evident, that if you *multiply* any quantity by a number, and then *divide* by the same number, you virtually leave the quantity, as to *value*, untouched; for multiplication and division by the *same* number, are two operations which mutually neutralise one another. We may, therefore, always multiply numerator and denominator of a fraction by any number, without changing the value of the fraction.

The rule just given will *always* effect the object proposed by it; but not always in the shortest way. In particular cases it will be desirable to proceed differently. Thus, if the fractions $\frac{2}{3}$, $\frac{4}{6}$, $\frac{1}{2}$, are to be changed into equivalent ones with a common denominator, you see, by looking at the denominators, that the thing may be brought about without interfering with the middle fraction at all: you have only to multiply the terms of the first fraction by 2, and those of the third by 3, to get the desired result—the changed fractions being found in this way to be $\frac{4}{6}$, $\frac{4}{6}$, $\frac{3}{6}$. If you had applied the *rule*, the new fractions would have been $\frac{24}{36}$, $\frac{24}{36}$, $\frac{18}{36}$, forms far less simple than those above, although the same in *value*; they would be got by multiplying the terms of the simpler fractions, each by 6. In bringing fractions to a common denominator, you should always be on the look-out for the simplest multiplier of the terms of each that will accomplish the object, and use the *rule* only as matter of necessity—that is, only when simpler multipliers than the rule supplies, do not present themselves. Suppose you had $\frac{3}{8}$, $\frac{5}{6}$, $\frac{5}{3}$, do you not see, from a glance at the denominators, that if the first be multiplied by 3, the second by 4, and the third by 8, that the products will be all alike? Multiply, then, the terms of the first fraction by 3, those of the second by 4, and those of the third by 8, and you will get the following—viz., $\frac{9}{24}$, $\frac{20}{24}$, $\frac{40}{24}$, for equivalent fractions with a common denominator. The *rule* would have given you these—$\frac{54}{144}$, $\frac{120}{144}$, $\frac{240}{144}$, which, although equal to, are far less simple than the former.

The *smallest* number that can be a common denominator of a row of fractions is evidently the smallest number that is divisible by each of the given denominators: it is called the *least common multiple* of those denominators. There is a rule for finding the least common multiple of a set of numbers; but you see that it may often be discovered, without any rule, by a little reflection. We shall give you but one more instance here, since the reduction of fractions to a common denominator, as observed above, will form a necessary preparation for addition and subtraction. Let the fractions be $\frac{2}{3}$, $\frac{5}{9}$, $\frac{1}{6}$, $\frac{3}{2}$: here you see that the first two are brought to a common denominator by merely multiplying the terms of the first by 3; so that these two fractions are $\frac{6}{9}$, $\frac{5}{9}$. Again, the last two are brought to a common denominator by merely multiplying the terms of the fourth by 3; so that these two fractions are $\frac{1}{6}$, $\frac{9}{6}$. We have, therefore, now only to find the *least* number which will divide by 9 and 6; and it requires but little thought to discover that 18 is that number; so that we reach the desired result by the following steps:—

$$\begin{aligned} &\tfrac{2}{3},\ \tfrac{5}{9},\ \tfrac{1}{6},\ \tfrac{3}{2} \\ \text{or, }&\tfrac{6}{9},\ \tfrac{5}{9},\ \tfrac{1}{6},\ \tfrac{9}{6} \\ \text{or, }&\tfrac{12}{18},\ \tfrac{10}{18},\ \tfrac{3}{18},\ \tfrac{27}{18} \end{aligned}$$

where you see that a fraction in either of the lower rows is merely that above, with its *terms* multiplied by the same number. If you had applied the rule to the first row of fractions, you would have got $3 \times 9 \times 6 \times 2 = 324$ for a common denominator, instead of the more simple number 18.

Addition and Subtraction of Fractions.—RULE.—Reduce the fractions to equivalent ones, having a common denominator: then add or subtract the *numerators*, as proposed, and put the common denominator under the result.

For instance, let the fractions be $\frac{4}{9}$ and $\frac{2}{7}$: these, reduced to a common denominator, are $\frac{28}{63}$ and $\frac{18}{63}$, therefore $\frac{28}{63}+\frac{18}{63}=\frac{46}{63}$, their *sum*: $\frac{28}{63}-\frac{18}{63}=\frac{10}{63}$, their *difference*.

Again, let it be required to find the value of $\frac{3}{5}+\frac{2}{9}-\frac{1}{3}$. Here the second and third fractions will have a common denominator, if the terms of the third are multiplied by 3: the differing denominators will then be 5 and 9; that is, we shall have $\frac{3}{5}+\frac{2}{9}-\frac{3}{9}=\frac{3}{5}-\frac{1}{9}$; that is, by the rule for the common denominator, $\frac{27}{45}-\frac{5}{45}=\frac{22}{45}$.

Suppose the value of $1-\frac{8}{15}-\frac{9}{20}$ were required. It is easy to see that the denominators will be made alike if the first be multiplied by 4 and the second by 3; so that, multiplying numerators, as well as denominators, we have $1-\frac{32}{60}-\frac{27}{60}=1-\frac{59}{60}=\frac{60}{60}-\frac{59}{60}=\frac{1}{60}$.

And in like manner are the results following obtained: (1.) $\frac{1}{2}+\frac{2}{7}=\frac{11}{14}$. (2.) $\frac{1}{7}-\frac{1}{11}=\frac{4}{77}$. (3.) $\frac{2}{3}+\frac{3}{4}+\frac{5}{6}=2\frac{1}{4}$. (4.) $\frac{16}{21}-\frac{8}{15}=\frac{8}{35}$. (5.) $6\frac{3}{4}-5\frac{1}{3}=1\frac{5}{12}$. (6.) $11\frac{2}{3}+8\frac{7}{9}-9\frac{19}{22}=10\frac{115}{198}$.

In the subtraction of mixed quantities, it sometimes happens that the fractional part of the subtracted quantity is greater than the fractional part of that from which it is to be taken: when this is the case, it is better to convert a unit of the latter into a fraction, and to incorporate it with the fractional part: we shall thus have an improper fraction, from which the subtractive fraction may be taken; thus, if we had to take $3\frac{5}{6}$ from $5\frac{3}{8}$, we see, when the fractions are brought to a common denominator, by multiplying the terms of the first by 4, and those of the second by 3, that the subtractive fraction $\frac{20}{24}$ is greater than $\frac{9}{24}$, the other fraction; we therefore *fractionise* a unit of the 5, considering 5 to be $4\frac{24}{24}$, and therefore $5\frac{3}{8}$, or $5\frac{9}{24}$, to be $4\frac{33}{24}$; so that the work stands thus: $5\frac{3}{8}-3\frac{5}{6}=5\frac{9}{24}-3\frac{20}{24}=4\frac{33}{24}-3\frac{20}{24}=1\frac{13}{24}$.

Multiplication and Division of Fractions.—Multiplication.—If we have to multiply a fraction by a whole number, the product will, of course, be as many times that fraction as there are units in the whole number: thus, $\frac{2}{5} \times 3 = \frac{6}{5}$; that is, 3 times *two-fifths*: the *denominator* is not operated upon, because *this* merely states the *denominations*, not the *number* of them. If, instead of 3, the multiplier had been only a fourth part of 3, that is $\frac{3}{4}$, then only a fourth part of the above product,

$\frac{6}{5}$, could have resulted. A fourth part of $\frac{6}{5}$ is $\frac{6}{20}$, because a number (in this instance 6) divided first by 5, and then again by 4, gives the same result as a single division of it by 20. We know, therefore, that $\frac{2}{5}\times\frac{3}{4}=\frac{6}{20}$; that is, it is the product of the numerators, divided by the product of the denominators.

The same reasoning evidently applies, whatever be the fractions to be multiplied together: the product of the numerators, divided by the product of the denominators, is the product of the fractions.

Division.—Let us now try to discover how fractions are to be divided; and first let us consider the case in which the divisor, like the multiplier, in the foregoing instance, is a whole number.

If we have to perform the operation $\frac{2}{5}\div3$, we see that the quotient of 2 by 5 is to be divided by 3: but this we know, from simple division, is the same as the quotient of 2 by 15; for, if anything be divided by 5 and then the quotient by 3, the result is the same as we should get by dividing that thing at once by 5×3 or 15; therefore, $\frac{2}{5}\div3=\frac{2}{15}$.

But if, instead of 3, the divisor were $\frac{3}{4}$, that is, only a *fourth part* of 3, it is plain that the quotient ought to be 4 *times as great*; namely, $\frac{8}{15}$; so that $\frac{2}{5}\div\frac{3}{4}=\frac{8}{15}$; the same result as we should get by *inverting* the divisor $\frac{3}{4}$, and *multiplying*, instead of *dividing*; for $\frac{2}{5}\times\frac{4}{3}=\frac{8}{15}$. And as the reasoning evidently applies, whatever be the fractions chosen, we infer that division of fractions may always be converted into multiplication by inverting the terms of the divisor; that is, in fact, by turning the divisor upside down. Thus, $\frac{2}{5}\div\frac{6}{7}=\frac{2}{5}\times\frac{7}{6}=\frac{14}{30}$. We are thus led to the following rules, viz.:—

RULE.—*For multiplication.*—Multiply the numerators together for the numerator of the product.

Multiply the denominators together for the denominator of the product.

RULE.—*For division.*—Invert the terms of the divisor, and then proceed as in multiplication.

It is desirable that fractions which appear in the results of any operations, should be reduced to their lowest terms; that is, that both numerator and denominator should be divided by whatever number *will* divide them. Thus, in the instance above, where the product of $\frac{2}{5}$ and $\frac{3}{4}$ was found to be $\frac{6}{20}$, the result should be freed from the factor 2, common to both numerator and denominator; that is, we should divide both terms by 2, and write the result in the more simple form, $\frac{3}{10}$. The division of both terms by the same number cannot alter the *value* of the fraction, otherwise the *multiplication* of the terms of a fraction by the same number would alter its value, which we know to be not the case.

In multiplication and division, we may often prevent the entrance of these superfluous factors in the result; and it is of course better to do so than to allow them to enter, and then to remove them; thus, in multiplying $\frac{2}{5}$ by $\frac{3}{4}$ we foresee that, as 2 occurs in a numerator and 4 in a denominator, 2 will also occur in both numerator and denominator of the product, unless we previously prevent its entrance: this we should do by regarding the proposed fractions as $\frac{1}{5}$, $\frac{3}{2}$; the product of which is $\frac{3}{10}$. All the factors that enter alike into numerators and denominators, should thus be removed, for you then get your product in the simplest form at once, without being at the trouble to reduce it to lower terms. We shall here give examples of this:

(1.) $\frac{7}{8}\times\frac{6}{11}=\frac{7}{4}\times\frac{3}{11}=\frac{21}{44}$. (2.) $\frac{8}{9}\times\frac{3}{5}=\frac{8}{3}\times\frac{1}{5}=\frac{8}{15}$. (3.) $\frac{4}{5}\div\frac{16}{15}=\frac{4}{5}\times\frac{15}{16}=\frac{1}{1}\times\frac{3}{4}=\frac{3}{4}$. (4.) $\frac{11}{4}\div\frac{5}{6}=\frac{11}{4}\times\frac{6}{5}=\frac{11}{2}\times\frac{3}{5}=\frac{33}{10}=3\frac{3}{10}$. (5.) $\frac{19}{20}\div\frac{3}{5}=\frac{19}{20}\times\frac{5}{3}=\frac{19}{4}\times\frac{1}{3}=\frac{19}{12}$.

In this way the entrance of common factors into the numerator and denominator of each result in the following examples is to be provided against:—

(1.) $\frac{7}{8}\times\frac{12}{13}=\frac{21}{26}$. (2.) $\frac{13}{60}\div\frac{26}{50}=\frac{5}{12}$. (3.) $\frac{3}{10}\div\frac{1}{30}=9$. (4.) $\frac{2}{3}\div\frac{3}{11}=2\frac{4}{9}$. (5.) $\frac{13}{14}\div\frac{13}{15}=1\frac{1}{14}$. (6.) $\frac{7}{8}\times\frac{8}{7}=1$.

In these examples, the rules are applied to pure fractions. If we have to deal with mixed quantities, then we must reduce them to improper fractions before using either rule: thus $3\frac{2}{5}\div2\frac{1}{7}=\frac{17}{5}\div\frac{15}{7}=\frac{17}{5}\times\frac{7}{15}=\frac{119}{75}=1\frac{44}{75}$.

Proportion.—Four quantities are said to be in *proportion* when the first divided by the second is the same *abstract number* as the third divided by the fourth: thus, the four numbers, 6, 3, 8, 4 are in proportion, because $\frac{6}{3}=\frac{8}{4}$; and of any two equal fractions, the four terms are in proportion.

The quotient which arises from dividing one quantity by another *of the same kind*, is called the *ratio* of the former to the latter: thus, the ratio of 6 to 3 is 2, and the ratio of 8 to 4 is 2; *ratio* being only another name for the *quotient* of two quantities of the same kind. A proportion is thus said to be an equality of ratios: *ratio* implies two terms; *proportion*, four. The first term of a ratio (the dividend) is called the *antecedent*, the second (the divisor) its *consequent*. Instead of writing the antecedent as the numerator and denominator of a fraction to express the ratio, the same thing is indicated by simply putting two dots between them; thus, 6 : 3 is the same as $\frac{6}{3}$; and 8 : 4 the same as $\frac{8}{4}$; so that the proportion above may be expressed in this way, 6 : 3 = 8 : 4. Instead of the sign of equality, it is more common to use four dots, and to write the proportion thus: 6 : 3 :: 8 : 4, which is read, 6 is to 3 as 8 is to 4; a form of expression intended to imply that 6 is related to 3, in point of magnitude, just as 8 is related to 4. This idea of relative or comparative magnitude, which is essential to the correct notion of proportion, forbids our considering the term *ratio* in the same unrestricted sense as the term *quotient*: the two terms are to be regarded as meaning the same thing only when dividend and divisor are quantities of the same kind: *ratio is always an abstract number*. Now, the name quotient, as we have seen, is applied not only to abstract numbers, but to the concrete quantities that arise from taking the third, fourth, fifth, &c. part of concrete quantities. Be careful to observe this distinction; and to remember that the ratio of an antecedent to its consequent *always* has reference to the *number of times*, and parts of a time, by which the former contains the latter: so that it would be absurd to speak of the ratio of one thing to another of a different kind; as, for instance, of the ratio of £6 to the *number* 3; or of 8 cwt. to £4, and so on.

It thus appears, that if four quantities, ranged in order as above, form a proportion, the first and second must necessarily be of the same kind; and also that the third and fourth must be of the same kind: thus the following are proportions; they express equal ratios, the ratio in each case being the abstract number 2—

£6 : £3 :: 8 cwt. : 4 cwt.; again, 6 yds. : 3 yds. :: 8 oz : 4 oz.

From what has now been said, you see that the essential condition, and the only condition which four quantities must fulfil, in order that they may form a proportion, is this, namely—

$$\frac{\text{First term}}{\text{Second term}}=\frac{\text{Third term}}{\text{Fourth term}}$$

each of these fractions being an abstract number. If two fractions are equal, we know that two equal fractions will also result from inverting their terms; so that from the above we may infer that

$$\frac{\text{Second term}}{\text{First term}}=\frac{\text{Fourth term}}{\text{Third term}}$$

These being abstract numbers, we may multiply *any* quantity by either: the results will, of course, be equal, whichever we take for the multiplier, since they themselves are equal. Let us multiply "Third term" by each: the results will be

$$\frac{\text{Second term}}{\text{First term}}\times\text{Third term}=\text{Fourth term}.$$

You can have no doubt about the second result, as you know that divisor, multiplied by quotient, gives dividend; and the fraction above, on the right, denotes the *quotient* of the division of "Fourth term" by "Third term."

It appears, then, that in order to find the fourth term of a proportion, when the first three terms are given, we have only to divide the second by the first, and to multiply the third by the abstract number furnished by their quotient. Now, if the first and second terms are concrete quantities, you know that you *cannot* divide one by the other, and thus get the abstract number here spoken of, till the quantities are reduced to the same denomination.* When, however, this is done, you may entirely disregard *denomination*, and consider the resulting numbers to be *abstract* numbers; for the *quotient* is the same in both cases: thus $\frac{£6}{£3}$ is the abstract number 2; and so is $\frac{6}{3}$, or $\frac{6 \text{ cwt.}}{3 \text{ cwt.}}$, or $\frac{6 \text{ yds.}}{3 \text{ yds.}}$

This, though a very obvious, is yet an important fact; as we learn from it that, when the first and second terms of a proportion are reduced to the same denomination, we may consider both numerator and denominator of the fraction $\frac{\text{Second term}}{\text{First term}}$ as abstract numbers, as well as the fraction itself; and therefore that, without violating any principle of arithmetic, we may write the above equality, namely—

$$\frac{\text{Second term}}{\text{First term}} \times \text{Third term} = \text{Fourth term}$$

in the form

$$\frac{\text{Second term} \times \text{Third term}}{\text{First term}} = \text{Fourth term}$$

which is often the more convenient in practice; that is, after the reduction to the same denomination, as spoken of above, we may multiply the third term by the second (regarded as a *number*), and divide the product by the *number* denoting the first term.

We have thus established the general principle of what is called the *Rule of Three*, the object of which is, when three terms of a proportion are given, to find the fourth.

Rule of Three.—1. Write the three given terms in a row, taking care that the *third* term is a quantity of the same kind as the required *fourth* term; and also that, according as this fourth term is to be greater or less than the third, so may the *second* of the given terms be greater or less than the first. This is called *stating* the question.

2. Having thus properly stated the question, bring the first and second terms to the same denomination; and regard the results as *abstract numbers*, the *denomination* being suppressed.

3. Multiply the third term by the second, which is now a *number*; and divide the product by the first, which is also a number: the quotient will be the required fourth term, in the same denomination, of course, as that in which the third term was used.

You may sometimes simplify this operation: for the first and second terms may each be divisible by the same number; in which case you may employ only the quotients instead of the quantities themselves, on the principle that a fraction is not altered in value by discarding factors common to numerator and denominator. You may, also, in like manner, divide the first and third terms, when possible, on the same principle; and we would recommend you, in rule-of-three operations, to be always on the look-out for these means of simplification.

We shall now show the application of the rule by some examples.

1. If 16 cwt. cost £42 8*s.*, how much will 26 cwt. cost?

```
             £  s.   £  s.
16 : 26 :: 42  8 : 68 18
 8 : 13     20
           ----
           848
            13
           ----
          2544
           848
           ----
        8)11024s.
        ---------
       2,0)137,8s.
       -----------
        £68 18s.
```

As the answer or fourth term of the proportion is to be *money*, the £42 8*s.* given in the question must be the third term.

As the greater the number of cwt. the greater will be the cost, we must arrange the first two terms of the proportion, so that the second may be the greater; consequently, the stating will be 16 cwt. : 26 cwt. :: £42 8*s.* : the required fourth term. But as the first and second terms are already in the same denomination, namely, cwt., no reduction of them is necessary; we therefore, in the stating, entirely disregard this common denomination, and insert merely the abstract numbers, 16 and 26, as in the margin. But, a glance at these two numbers shows that each is divisible by 2; we, therefore, replace them by the quotients 8 and 13; and it now only remains to multiply £42 8*s.* by the number 13, and to divide the product by 8, to get the sum of money required. For convenience, we reduce the given sum to shillings; thus bring out the answer or required fourth term in shillings, and then convert these into pounds. When the work is finished, as here annexed, we complete the proportion, in the stating, by putting the result, viz., £68 18*s.* for the fourth term.

You see that, by dividing the first and second terms in the stating by 2, we have effected a little saving of figures in the work: but we might have simplified further, and have shortened the operation still more, by dividing the third term and the reduced first term both by 8; so that, having regard to the utmost attainable simplicity, we should have proceeded with the preliminary statings as here annexed, and thus have reduced the subsequent work to the small amount of figures here shown; 13 times 6*s.* is 78*s.*; that is, £3 18*s.*: putting down the 18*s.*, and carrying the £3, we have 13 times £5 = £65; and the £3 carried makes £68. Here is another example.

```
              £  s.
16 : 26 :: 42  8
 8 : 13
 1 : 13 ::  5  6
              13
          -------
          £68 18s.
```

2. If 28 persons reap a harvest in 36 days, how many will be required to reap it in 21 days?

As the answer is to be number of persons, the 28 persons given in the question must be the third term of the proportion; and as the fewer the days the greater must be the number of workmen, we arrange the first two terms of the proportion so that the second may be the greater; the stating is, therefore, 21 days : 36 days :: 28 persons : the number of persons required.

```
          Persons. Persons.
21 : 36 ::  28   :  48
 7 : 12
 1 : 12 ::   4
            12
            --
            48 persons.
```

But, as the first two terms are in the same denomination, we suppress *denomination*, and use only the abstract numbers 21 : 36. These we see have a common divisor, 3; we therefore replace them by the quotients 7 : 12; but the 7, and the 28 in the *third* term will divide by 7; we thus get the stating in the simple form 1 : 12 :: 4 persons; and then proceed as in the margin.

One example more must suffice.

A mass of 106 lb. of Australian gold, sold at the rate of £3 6*s.* 8*d.* per ounce: how much did it fetch?

```
                   £  s.  d.   £
1 oz. : 106 lb. :: 3  6   8 : 4240
          12       20
        ----      ----
        1272       66
         800       12
        ----      ----
    12)1017600    800
    ----------    ----
     2,0)8480,0
      --------
       £4240
```

Stating the question as in the margin, putting the greater weight in the second term, because the greater sum must be in the fourth, we see that the first and second terms differ in denomination; we must, therefore, reduce the second to ounces, before we can regard the stating in the proper form for working with: it then becomes 1 oz. : 1272 oz. :: £3 6*s.* 8*d.*

The common denomination *ounces* is now suppressed, and, for convenience, the money is reduced to *pence*, the denomination in which the required fourth term must therefore appear: we have then merely to multiply 800 *pence* by the abstract number 1272; and the required value comes out 1017600 pence; for, as the first term is 1, there is no division.

Instead of making 1272 the multiplier of 800, we make 800 the multiplier of 1272, for convenience; as we know that the *number*, furnished for the product, is the same in one case as the other; this *number*, therefore, represents so many *pence*; which, when reduced to *pounds*, is £4240.

---

* See *ante*, p. 443.

The following are a few examples for exercise:—

(1.) If 57 cwt. cost £216, what will 95 cwt. cost?—Ans. £360.

(2.) If 148 gallons cost £119 10*s*., how many gallons will £89 12*s* 6*d*. buy?—Ans. 111.

(3.) What is the value of 2 qr. 24 lb. at £5 7*s*. 4*d*. per cwt.?—Ans. £3 16*s*. 8*d*.

(4.) What is the income of a person who pays £22 7*s*. 5*d*. for income tax, at the rate of 7*d*. in the pound?—Ans. £767.

(5.) $44\frac{1}{2}$ guineas used to be coined out of 1 lb. of standard gold: how many sovereigns are now coined out of this weight?—Ans. $46\frac{29}{40}$.

(6.) 66*s*. are coined out of 1 lb. of standard silver: what is gained in coining £100 of silver, if the price of the silver be 5*s* 2*d*. per oz.?—Ans. £6 $9\frac{1}{31}$*s*.

The Double Rule of Three.—The double rule of three is so called because there are at least *two* single rule-of-three statings implied in it. The following is an example, namely:—

If 12 horses plough 11 acres in 5 days, how many horses will plough 33 acres in 18 days?

This may be divided into two single rule-of-three questions; thus—1st. If 12 horses plough 11 acres, how many will plough 33 acres *in the same time?*

$$11 : 33 :: 12 \text{ horses} : \frac{12 \times 33}{11} \text{ horses} = 36 \text{ horses.}$$

2nd. If 36 horses can perform a work in 5 days, how many can perform *the same* in 18 days? By the former rule,

$$18 : 5 :: 36 \text{ horses} : \frac{36 \times 5}{18} \text{ horses} = 10 \text{ horses.}$$

It is plain that by these two single rule-of-three operations, the correct answer to the question is obtained; but it is more readily obtained by the following arrangement:—

$$\left.\begin{matrix} 11 : 33 \\ 18 : 5 \end{matrix}\right\} :: 12 \text{ horses} : \frac{12 \times 33 \times 5}{11 \times 18} \text{ horses} = 10 \text{ horses.}$$

The fourth term of this *compound proportion*, as it is called, being got by multiplying the third term by the product of the *consequents*, and then dividing by the product of the *antecedents*; and it is by the same multiplications and divisions that the final result is arrived at in the two distinct statings above. This more compact form of working is described in the following rule:—

RULE.—Put for the third term that one of the given quantities which is of the same kind as the quantity sought, just as in the single rule of three.

Then taking any pair of the remaining quantities like in kind, complete the stating, as if for the single rule of three, paying no regard to the other quantities, or rather considering them to remain *the same*.

Then take another pair, like in kind, as a new antecedent and consequent to be placed under the former pair; these, with the third term above, completing a second single rule-of-three stating. And proceed in this way till all the pairs are used.

Multiply the third term by the product of all the consequents, and divide the result by the product of all the antecedents, and the answer will be obtained.

Each given antecedent and consequent is of course to be regarded as an abstract number. It is convenient to *indicate* merely the several multiplications, at first, to place the divisor under the dividend, in the form of a fraction, as in the above example, and then, before performing the operations, to expunge factors common to numerator and denominator.

EXAMPLE.—If £15 12*s*. pay 16 labourers for 18 days, how many labourers will £35 2*s*. pay, at the same rate, for 24 days?

As the answer is to be a certain number of *labourers*, the given 16 labourers is to be the third term; then taking *days* for the first antecedent and consequent, and money for the second antecedent and consequent, attending to whether either consequent should be greater or less than its antecedent, as in the former rule, the operation is as follows:—

$$\left.\begin{matrix} 24 & : & 18 \\ \pounds 15\ 12s. & : & \pounds 35\ 2s. \end{matrix}\right\} :: 16 \text{ labourers} : 27 \text{ labourers.}$$

$$\begin{matrix} 20 & & 20 \\ \hline 312 & & 702 \end{matrix} \text{ therefore}$$

$$\frac{16 \times 18 \times 702}{24 \times 312} \text{ lab.} = \frac{4 \times 3 \times 351}{156} \text{ lab.} = \frac{351}{13} \text{ lab.} = 27 \text{ lab.}$$

The 18 is placed in the second term, because *fewer* labourers are required for 24 days, the *work* being the same, than for 18; and the £35 2*s*. is placed in the second term, because *more* labourers can be paid for that sum than for £15 12*s*., the *time* being the same. If the question had been worked by two single rule-of-three statings, we should have had

$$\text{1st. } 24 : 18 :: 16 \text{ lab.} : \frac{16 \times 18}{24} \text{ lab.} = 12.$$

$$\text{2nd. } 312 : 702 :: \frac{16 \times 18}{24} \text{ lab.} : \frac{16 \times 18 \times 702}{24 \times 312} \text{ lab.} = 27 \text{ lab.}$$

You see, therefore, that the double rule of three merely compounds the several single proportions into one; it is thus called *compound proportion*.

We add two examples for exercise in this rule:—

1. If 8 persons can be boarded for 16 weeks for £42, how long will £100 support 6 persons at the same rate?—Ans. $50\frac{50}{63}$ weeks.

2. If a family of 13 persons spend £64 in butcher's meat in 8 months, when meat is 6*d*. per lb., how much money, at the same rate of consumption, should a family of 12 persons spend in 9 months, when meat is $6\frac{1}{2}$*d*. per lb.?—Ans. £72.

In this example, there would be *three* separate statings, if the question were worked by the single rule of three; these are here to be compounded into *one*.

Decimals.—It was observed at the commencement of this chapter, that in our system of arithmetic, numbers are expressed in the *decimal* notation, and the reason for this designation was stated:—it is simply this—namely, that the unit of any figure in a number has a value of *ten times* the unit of the figure in the next place to the right. Thus, in a number consisting of unit-figures—as for instance, in the number 1111—the second unit, beginning with the right-hand one, is 10 times the first, the third 10 times the second, the fourth 10 times the third, and so on; or beginning with the first on the left, the second is the tenth part of the first, the third the tenth part of the second, and so on till we come down to the last unit, which is merely *one*. Now, we may evidently extend this principle still further; and, on the same plan, may represent one-tenth of *one*, one-tenth of *this*, or one-hundredth of *one*, one-thousandth of *one*, and so on, by simply putting some mark of separation between the *integers* and these *fractions*. The mark actually used is a *dot*, thus: 1111·1111. The unit next the dot, on the left, is 1; the unit one place from this on the left is 10; the next is 100; the next, 1000; and so on. In like manner, the unit one place from the 1 on the right, is $\frac{1}{10}$, the next $\frac{1}{100}$, the next $\frac{1}{1000}$, and so on. This being agreed upon, it is easy to interpret such a number as 36·427: it is $36 + \frac{4}{10} + \frac{2}{100} + \frac{7}{1000}$; each figure, to the right of the point, being a *fraction* of a known denominator; the denominator being 10 for the first figure, 100 for the second, 1000 for the third, and so on. The *sum* of the fractions represented by the *decimal* ·427, above, is obviously $\frac{427}{1000}$; in like manner, the fraction expressed by ·2643 is $\frac{2643}{10000}$; and in general the denominator of the equivalent fraction is always 1 followed by as many zeros as there are decimal places, the numerator being the number itself, when the prefixed dot, or *decimal point*, as it is called, is suppressed. You will thus easily see that the following are so many *identities*—namely:—

$24{\cdot}6 = 24\frac{6}{10}$; $136{\cdot}54 = 136\frac{54}{100}$; $73{\cdot}641 = 73\frac{641}{1000}$; $2{\cdot}07 = 2\frac{7}{100}$.

Any decimal may therefore be converted into its equivalent fraction at sight: it will be shown presently how any fraction may be converted into its equivalent decimal, though not with the same rapidity.

It is pretty evident that whatever whole number be prefixed to a decimal, the same may be prefixed to the numerator of the fraction which replaces that decimal: thus, taking the previous values, we have

$24·6=\frac{246}{10}$; $136·64=\frac{13664}{100}$; $73·641=\frac{73641}{1000}$; $2·07=\frac{207}{100}$.

for this is only reducing the foregoing *mixed quantities* to improper fractions.

To reduce a Proper Fraction to a Decimal.

RULE.—Annex a zero to the numerator, and then actually divide by the denominator: if there be a remainder, annex another zero, and continue the division, still annexing a zero, either till the division terminates without remainder, or till as many decimals as are considered necessary are obtained; the quotient, with the decimal point before it, will be the value of the fraction in decimals.

```
8)3·000
 ——————
  ·375 = 3/8
```

For example: let it be required to express $\frac{3}{8}$ in decimals; the operation is that in the margin. That $\frac{3}{8}$ = ·375 is easily proved; for $\frac{3}{8}=\frac{3000}{8000}$; consequently, dividing numerator and denominator by 8, we have $\frac{3}{8}=\frac{375}{1000}$ = ·375, from the very nature of decimals. If an *improper* fraction had been chosen, the operation would clearly have been just the same, only there would have been an integer prefixed to the decimal: thus, the operation for $\frac{19}{8}$ would have been as here annexed, showing that $\frac{19}{8}$ = 2·375. We need not take the trouble of actually annexing the zeros, as here: it is enough that we proceed as if they were inserted, as in the marginal example, for reducing $\frac{6}{11}$ to a decimal; where it is plain, from the remainders, that 54 would recur continually; so that $\frac{6}{11}$ is equal to a *recurring* decimal; the recurring *period* being 54. As a final example, let it be required to convert $\frac{8}{113}$ into a decimal. When one 0 is annexed to the 8, the divisor 113 will go *no times;* therefore, the first decimal place is to be occupied with a 0. Annexing now a second 0, the next decimal figure is 7, and the work proceeds as in the margin: the *noughts* being suppressed, though conceived to be annexed to the 8, and brought down one at a time, as in ordinary division. The quotient shows that $\frac{8}{113}$ = ·07079, &c.: the decimals may be carried out to any extent; but if we stop the work here, the error cannot be so great as ·00001; that is, it is less than $\frac{1}{100000}$: but it is obvious that, by continuing the work, we can make the error as small as we please.

The following are a few examples for exercise:—

(1.) $\frac{15}{8}$ = 1·875. (2.) $\frac{7}{16}$ = ·4375.
(3.) $\frac{11}{40}$ = ·275. (4.) $\frac{1}{32}$ = ·03125.
(5.) $\frac{1}{13}$ = ·076923, &c. (6.) $\frac{5}{1024}$ = ·00488, &c.

Addition and Subtraction of Decimals.—The rules for these fundamental operations are in reality the same as those for integers. We must here be careful not only to place units under units, tens under tens, and so on, but also place *tenths* under *tenths*, *hundredths* under *hundredths*, &c.: that is, the *decimal points* must all range under one another in the same vertical line. This attended to, the operations are just the same as those with integers. (See the operations in the margin.)

Multiplication of Decimals.—Multiplication requires no special rule. The multiplier is to be placed under the multiplicand, just as if both were integers, no regard being paid to the decimal points. The only thing to be attended to is the marking off the proper number of decimal places in the product; and that is a very easy matter. We have seen that a number involving decimals is, in fact, a fraction with that number, the decimal point being suppressed, for numerator, and 1, followed by as many ciphers as there are decimal places, for denominator. Two such fractions multiplied together, being the product of the numerators divided by the product of the denominators, will therefore be a fraction of which the denominator is 1, followed by as many ciphers as there are in both factors. Consequently, in the multiplication of decimals, as many decimal places are to be marked off in the product as there are decimal places in *both* factors.

The example in the margin will suffice for illustration. As there are three decimals in the multiplicand, and two in the multiplier, *five* are marked off in the product.

Division of Decimals.—This operation, like that of multiplication, is the same for decimals as for integers; and the way to estimate the number of decimal places in the quotient is suggested by the plan adopted in multiplication.

All the decimals employed in the dividend, including, of course, whatever ciphers may have been added to it to carry on the division, are to be counted. We have then only to provide so many in the quotient, that when added to the number of them in the divisor, we may have just as many as in the dividend.

If the quotient figures, though all be considered as decimals, be too few in number to make up, with those in the divisor, the number in the dividend, then ciphers sufficient for this purpose are to be *prefixed* to the quotient figures, and the decimal point to be placed before them. (See the second example in the margin.) In the first of these examples, *six* have been used in the dividend, and as there are *two* in the divisor, there must be *four* in the quotient, which is therefore 10·0515. The last decimal, 5, is a little too great; but it is easy to see that if we had made it 4, the error in *defect* would have exceeded the present error in *excess;* and in limiting the number of decimals, we always make the *last* figure as near the truth as possible. In the second example, *five* decimals have been used in the dividend; and as there is but *one* in the divisor, *four* are required in the quotient; and to make up this number, a cipher is prefixed. The quotient is, therefore, ·0265, as far as the decimals have been carried: that is, to four places.

The following examples will serve for exercise in these two rules:—

(1.) ·321096 × ·2465 = ·079150164.
(2.) 464·3 × ·00521 = 2·419003.
(3.) 56·10833 ÷ 17·371 = 3·23.
(4.) 2·419003 ÷ 464·3 = ·00521.

Extraction of the Square Root.—If a number be multiplied by itself, the product is called *the second power*, or the *square*, of that number. If this also be multiplied by the same number, the product is called *the third* power, or the *cube* of that number: and so on for the *fourth power, fifth power, &c.* This raising of powers, which is called *involution*, is therefore nothing more than the multiplication together of *equal factors*, and is easy enough. But the reverse operation—that is, to find the factor which, involved in this manner, shall produce a *given number*—is a problem not so readily disposed of. The factor referred to is called the *root* of the power; so that the reverse problem spoken of is the problem of the *extraction of roots.* To extract the *square* root of a given number, is to find a number which, when squared, or raised to the second power, or, which is the same thing, when multiplied by itself, shall reproduce the given number. The rule for this operation is as follows:—

RULE.—Commencing at the units' figure, cut off *two* figures, then two more, and so on, thus dividing the number into *periods*, as they are called.

If the number of figures be *even*, we shall therefore have two figures in every period; but if *odd*, the first period, on the left, will have but a single figure.

Take the square root of this first period, or find the root of the nearest square to it, which nearest square is not, however, to be *greater* than the number forming the first period. The root thus found will be the leading figure of the root of the proposed number, and the square of this leading figure is to be subtracted from the first period.

To the remainder annex the second period: the resulting number will be the *first dividend*, and the divisor for it is to be found as follows:—

Put *twice* the root-figure, just found, in the divisor's place; the leading portion of the complete divisor will thus be obtained. This leading portion, as in common division, is enough to suggest the corresponding quotient-figure, which is now to be found, and annexed to the former root-figure, and *also* to the leading portion of the divisor employed in finding it: the divisor will then be *completed;* so that proceeding as in common division, a second remainder will be obtained, to which the *next* period being united, a *second dividend* will result.

To find the corresponding divisor, put *twice* the number, of *two figures*, now in the root's place, in the divisor's place: we shall thus have the leading portion of the complete divisor, by aid of which a *third* root-figure may be found; which, as before, is to be annexed to the former root-figures, and *also* to the incomplete divisor, in order to complete it; and the work is to be then carried another step, as in common division; and so on, till all the periods have been brought down, and annexed, step after step, to the successive remainders, thus supplying the successive *dividends*. If there be a remainder after all the periods have been brought down, the operation may be continued by annexing successive periods of *ciphers* to the successive remainders, or successive periods of the decimals in the given number, should any be there: in either case, the root-figures become *decimals* from the time that ciphers or decimals are annexed.

As the root multiplied by itself produces the original number, the decimal places in the root must, of course, always be just half as many as have been employed in determining it. And the root is only to be regarded as an *approximation* to the truth, whenever a remainder is left at the step where the work terminates.

Here follow three examples, worked by these precepts.

The symbol for the operation of the square root is $\sqrt{\ }$; which is no doubt a degenerated form of *r*, the initial letter of the word *radix*, or *root;* it appears from the foregoing operations that

$\sqrt{459684}=678$; $\sqrt{31640625}=5625$; $\sqrt{3{\cdot}65}=1{\cdot}910497$, &c., the last root being true as far as the sixth decimal place.

By the same process it is found that
(1.) $\sqrt{473256}=687{\cdot}936$. (2.) $\sqrt{784{\cdot}375}=28{\cdot}0067$.
(3.) $\sqrt{11}=3{\cdot}316625$. (4.) $\sqrt{{\cdot}3236068}={\cdot}5688645$.
(5.) $\sqrt{794\frac{1}{5}}=\sqrt{794{\cdot}2}=28{\cdot}18155425$.

ADDENDA.

The preceding able article, by Professor Young, may, perhaps, be rendered more practically useful, if we extend the principles therein laid down to some of the requirements of mercantile life. For this purpose we shall explain a very simple plan of calculating the cost of any number of articles, at any price, reckoned in pence. The ordinary "Rule of Three" may be employed for that purpose, or the old plan of "Practice" is equally eligible where accuracy of result alone is desired. In the hurry of business, however, a more rapid mode of calculation is desirable; and we have no hesitation in recommending that which we are about to describe.

It is first necessary that the table subjoined be learned carefully by heart, because the success of the system depends essentially thereon. In using the table so committed to memory, it is only required to multiply the value of the number of articles reckoned at a *penny* each, and reduced to pounds, shillings, and pence, by the price of each article. Suppose, for example, that 240 articles are sold at sixpence each, what would be their total value?

By referring to the table, we find that 240 articles, at one penny each, would amount to one pound. Now, multiplying this by the price in pence, we have the total of six pounds. If this sum were reckoned by the old method, it would stand as follows:—

240 articles
6 price each
12)1440 total value in pence
20)120
6 0 0 value in pounds.

Now it will be at once seen how much time and figuring is saved by the plan we propose. The only difficulty is that of learning off the table: this, however, is soon done by any person possessed of an average memory. It may be as well that we should give the rule in an explicit form; which is as follows:—

Rule.—Suppose the number of articles to be of the value of one penny each, and by memory reduce the amount to its value in pounds, shillings, and pence. Multiply the value so obtained by the price in pence, and the total will be the sum sought. If farthings constitute part of the price, then the fourth for a farthing, the half for a halfpenny, and the three-fourths for three farthings, of the value of the article at a penny, must be added to the sum obtained.

Pence Table reduced to Shillings and Pounds.

	£	s.	d.		£	s.	d.
60 pence =	0	5	0	1260 pence =	5	5	0
120 ,,	0	10	0	1320 ,,	5	10	0
180 ,,	0	15	0	1380 ,,	5	15	0
240 ,,	1	0	0	1440 ,,	6	0	0
300 ,,	1	5	0	1500 ,,	6	5	0
360 ,,	1	10	0	1560 ,,	6	10	0
420 ,,	1	15	0	1620 ,,	6	15	0
480 ,,	2	0	0	1680 ,,	7	0	0
540 ,,	2	5	0	1740 ,,	7	5	0
600 ,,	2	10	0	1800 ,,	7	10	0
660 ,,	2	15	0	1860 ,,	7	15	0
720 ,,	3	0	0	1920 ,,	8	0	0
780 ,,	3	5	0	1980 ,,	8	5	0
840 ,,	3	10	0	2040 ,,	8	10	0
900 ,,	3	15	0	2100 ,,	8	15	0
960 ,,	4	0	0	2160 ,,	9	0	0
1020 ,,	4	5	0	2220 ,,	9	5	0
1080 ,,	4	10	0	2280 ,,	9	10	0
1140 ,,	4	15	0	2340 ,,	9	15	0
1200 ,,	5	0	0	2400 ,,	10	0	0

It will be seen that the above table contains the value of so many articles at one penny each. We have restricted it to every five shillings of value; and if any intermediate quantities have to be calculated, their value at a penny each can easily be reckoned and added to that sum next lowest in amount, as found in the table. The following examples will assist our readers in acquiring the use of this method:—

How much will 550 articles at 7*d.* each come to?
550 at a penny = £2 5 10
Multiply by 7
£16 0 10 Answer.

How much will 768 articles at 8¾*d.* each amount to?
768 at a penny = £3 4 0
Multiply by 8
25 12 0
Halfpenny ½ . . 1 12 0
Farthing ¼ . . 0 16 0
¾*d.* £28 0 0 Answer.

From the above instances our readers will at once see how simple and easily managed this plan is; and we feel convinced, from our own experience, that its use will prove of great advantage to all engaged in commercial pursuits. If the price of the articles involves shillings, the values may be obtained by multiplying by the number of shillings, and reducing the product to pounds, &c., adding this to the amount of the cost of the article in the pence, as obtained above. Of course, if pounds are also involved, then the number of articles must be multiplied by the number representing pounds. The following is an instance of the kind:—

Required the value of 250 articles at £1 2*s.* 8*d.* each?

		£	s.	d.
250 at £1	=	250	0	0
250 ,, 2*s.* = $\frac{1}{10}$ of £1	=	25	0	0
250 ,, 8*d.* {= £1 0 10 8				
		8	6	8
		£283	6	8 Answer.

CHAPTER II.

ALGEBRA.

WE need scarcely remark, that the study of Algebra requires a previous acquaintance with the principles of common Arithmetic; it is upon these that its operations are based, and the processes of Algebra are, for the most part, only the processes of Arithmetic, extended and rendered more comprehensive by the aid of a new set of symbols, taken in combination with the well-known symbols of Arithmetic. The symbols of Arithmetic are the *figures* of Arithmetic 1, 2, 3, &c.; and the new symbols introduced by Algebra are the letters of the alphabet, *a*, *b*, *c*, &c. As noticed at page 433, the peculiar marks or symbols employed in any science constitute the *notation* of that science; the notation of Algebra is therefore of a mixed character, consisting of the figures of Arithmetic and of the letters of the alphabet. The *letters* may be regarded as standing for *figures*; and the reason why figures alone will not enable us to do all that Algebra will, is that a *figure* always has a fixed and invariable signification: thus a 3 or a 5, or a 7, conveys the same meaning to everybody—no one uses the mark or symbol 3 to denote anything but *three*. But a *letter*, as *a*, or *b*, may be used to denote *any figure whatever:* a 3, or a 4, or a 7, &c.; and it may therefore be made to stand even for a figure whose value may be unknown to us, and which value it may be the object of the inquiry to discover. This is one of the principal advantages of algebraical notation; that part of this notation, which is borrowed from Arithmetic, enables us to express the *known* figures in any mathematical investigation by marks intelligible to all; while the other part, the letters, enables us to represent the figures or quantities, at the outset *unknown*, but which it is the object of the problem to determine.

But besides the marks or symbols of *quantity*—the figures and letters—other marks are introduced into the notation, as *signs of operation*. Some of these are used alike, both in Arithmetic and Algebra—as the sign (+) for addition, the sign (—) for subtraction, and one or two others with which the reader of the Arithmetic must be already familiar. The signs of operation in most frequent request in Algebra we shall now explain, and shall give a few easy examples of their application before entering on the formal rules of the science. We wish the reader to understand, at the outset, that we are about to exhibit the first principles of Algebra to *mere beginners*—to persons who, as yet, know nothing at all of the subject. Some experience in elementary teaching has convinced us, that to succeed in an undertaking of this kind, the instructor must forego all self-importance, descend to the level of his pupil, and, as it were, sit familiarly down by his side, and address him in that simple and unadorned style that no intelligent individual can fail to understand. We shall endeavour, therefore, to be very plain and simple in the language employed.

Definitions and Explanations of First Principles.—You already know, from arithmetic, that *numbers* are of two kinds:—*abstract* numbers, and *concrete* numbers. An abstract number is simply a *figure*, or number formed by two or more figures: thus, 3, 23, 147, &c., are abstract numbers; but 3 *oz.*, 23 *ft.*, £147, are *concrete* numbers. Abstract numbers merely denote how many *times* or *repetitions*; and, accordingly, whenever you use a *multiplier*, you use an abstract number. Concrete numbers denote how many *things*; and some mark or symbol, to tell us *what* the things are, must always be joined to the figure or figures which tell us the *number* of them. The mark or symbol *oz.*, as you know, means *ounces*; the symbol *ft.*, *feet*; and £ stands for *pounds*, in money. In algebra, *letters* are used to stand for numbers, whether they be abstract or concrete. Instead of writing down the abstract number, 23, a letter, *a*, for instance, may be put to represent 23; in like manner, instead of writing down the concrete number 23 *ft.*, a single letter may be made to stand for it. You see, therefore, that a *letter* serves for a number of *either* kind, while a *figure* must have a particular symbol joined to it when a *concrete* quantity is to be represented.

It is the business of a teacher of algebra to show how the operations carried on in arithmetic, by the help of figures *alone*, may be conducted with figures and letters *both*. The letters, as just noticed, representing numbers, whether abstract or concrete, are called *symbols of quantity;* and the marks or signs which *indicate* operations performed with the letters, are called *signs of operation*. We are now to explain to you some of these signs of operation: most of them, however, have been used in the Arithmetic.

The mark + is the *sign of addition:* whenever you see it put before a number or letter, you are to understand that the *addition* of whatever that number or letter signifies is meant: thus, $7 + 3$, which is read 7 *plus* 3, denotes that the 3 is to be *added* to the 7; in like manner, $a + b$, that is, *a plus b*, signifies that the *b* is to be added to the *a:* but you will ask—how can a *b* be added to an *a*? Our reply to this is, that *a* and *b* both stand for *numbers*, abstract or concrete; and although we say, according to custom, that "*b* is to be added to *a*," what we really mean is, that the *number* represented by *b* is to be added to the *number* represented by *a*. In the case of 7 *plus* 3, that is, of $7 + 3$, we can obey the direction of the sign of operation, and we know that 10 is the result; but in the case of $a + b$, we *cannot* obey the direction of the sign till we know the interpretation of *a* and *b:* we can only *indicate* the addition—but cannot *perform* it.

The sign — is the sign of subtraction: whenever it is placed before a quantity, it indicates that the quantity is to be *subtracted:* thus, $7 - 3$, which is read 7 *minus* 3, means that 3 is to be subtracted from 7; and, in like manner, $a - b$ means that *b* is to be subtracted from *a*. In the case of $7 - 3$, the result of the subtraction is 4; the result of $a - b$ cannot be given so long as the numbers represented by *a* and *b* remain unknown.

The sign × placed between two quantities denotes the *multiplication* of those quantities together: it is called *the sign of multiplication;* thus, 7×3 means that 7 and 3 are to be multiplied together; and, in like manner, $a \times b$ means the product of *a* and *b*. In the case of 7×3, the result or product is 21; in the case of $a \times b$, the result remains unknown till the number represented by the multiplier is stated. Every multiplier, as you are aware, must be an abstract number; if *a* stand for the abstract number 5, then $a \times b$ is $5 \times b$; that is, 5 *times b*, whatever *b* may stand for. The sign just explained is not *always* used to indicate multiplication; instead of it a *dot* placed between the two quantities, is often employed to mean the same operation: thus, 7.3 and *a.b* mean the same as 7×3 and $a \times b$; and, *in the case of letters*, even this sign is usually omitted, and the letters simply written side by side, without any intervening mark for multiplication at all; thus *ab*, *a.b*, and $a \times b$, all equally mean *the product of a and b*. When *figures* are to be multiplied, *some* sign for multiplication *must* be put between them, to prevent misunderstanding; if, when we meant 7×3, or 7.3, we put merely 73, we should be thought to mean *seventy-three*, instead of *seven times three*.

The sign ÷, placed before a quantity, denotes *division by that quantity:* it is called the *sign of division;* thus, $12 \div 4$ means 12 divided by four, and $a \div b$ means *a* divided by *b*. Division is otherwise indicated by writing the dividend above, and the divisor below a short line, as in the notation for a fraction: thus, $12 \div 4$ and $\frac{12}{4}$ mean the same thing; as also do $a \div b$ and $\frac{a}{b}$. As in the former instances, so here, the operation can be only *indicated*, not actually *performed*, except in the case of *numbers*.

The sign = stands for the words *equal to;* it is called *the sign of equality:* thus, $5 + 2 = 7$ is a brief way of saying that 5 plus 2 are *equal to* 7; and $5 - 2 = 3$ states, in like manner, that 5 minus 2 is *equal to* 3. Also $4x + 2x = 6x$, states that four times x plus twice x are equal to six times x; and $4x - 2x = 2x$, expresses, in symbols, that four times x minus twice x is equal to twice x.

A *figure*, or number, prefixed to a letter, as a *multiplier*, is called the *coefficient* of that letter; thus, 4 is the coefficient of x in the quantity $4x$; and 6 is the coefficient of x in $6x$. In like manner, 8 is the coefficient of xy in the quantity $8xy$, and 23 is the coefficient of xyz in the quantity $23xyz$.

Every quantity which, like each of those just noticed, is *not separated into parts* by any plus or minus sign, is called *a simple quantity*, or *a simple expression*—or it is said to consist of but a single *term*. But when a quantity is made up of parts, linked together by plus or minus signs, the quantity is called *a compound quantity*, or *a compound expression*. The following are simple expressions: they each consist of but one *term*.

$$4ax,\ 7aby,\ 14xyz,\ \frac{2ab}{7},\ \frac{3abx}{4y},\ 37amnxz,\ \&c.$$

The following are compound expressions: the first consists of two terms, the second of three terms, and the third of four terms.

$$5a - 2b,\ 3ax + 5by - 4z,\ 16axy - \frac{4bcz}{3x} - 2dmx + 5en.$$

You see what in Algebra is meant by a *term* and an *expression;* the first row of quantities above, is formed by *six* distinct *expressions*, each expression consisting of only one *term:* the second row is formed by *three expressions*, of which the first consists of two terms, the second of three terms, and the third of four terms. The first row is a row of *simple* expressions, the second a row of *compound* expressions.

We shall now give you a few easy exercises by which you may prove to yourself whether you fully understand the meaning of the signs already explained. You must not forget that whenever two or more quantities are placed side by side, without any sign of operation between them, the *multiplication* of those quantities, or rather of the *numbers* they represent, is always meant.

EXERCISES.

NOTE.—In these exercises $a=4$, $b=2$, $c=3$, $d=5$, $m=8$, $n=1$.

All that you have to do is to give these interpretations to the letters, thus translating the algebra into arithmetic, and then to put down the numerical value of each expression. To prevent mistakes we will here show you how to deal with example 4; that is, with $21m - 9d$. As m is presumed to stand for 8, and d for 5, the translation of the expression is $21 \times 8 - 9 \times 5$; that is, $168 - 45 = 123$, which is the numerical value of the proposed expression, on the supposition that m and d stand for 8 and 5 respectively. And in a similar manner are all the other examples to be treated. Do not forget that when the multiplication of *numbers* is indicated, the *multiplication sign* must be interposed between them.

Find the values in numbers of the following expressions:—

1. $3a + 4c$[*]
2. $5c - 2a$
3. $13n + b$
4. $21m - 9d$
5. $7d + 4n - 2a$
6. $3a + 4b - 5c$
7. $6m - 5n - 3b$
8. $14 - 3c + m$
9. $11b + n - 13$
10. $-4d + 5m - 2n$
11. $\frac{3m}{4} + 6 - \frac{m}{2}$
12. $\frac{5a}{2} + \frac{4d}{5} - 2c$
13. $\frac{2a + 3b}{7} + m - n$
14. $\frac{3a - 4b + 6c - 2}{10}$
15. $3ab + dm - 5b + 6cn - 9 \times 2$
16. $2abm - 3cdm + \frac{3dm}{8} + ad$
17. $\frac{5am - 2bc + n - 49}{140} - n$
18. $\frac{24}{m} + \frac{5abc}{24} - \frac{60}{bcd} - \frac{m + n}{2b + d}$

The first ten of these exercises are free from fractions: the next four all contain *algebraic fractions:* the fourteenth is a *single* fraction; it is an algebraic expression consisting of but *one term*. The numerator of this expression is, however, a *compound* quantity, as it is made up of *simple* quantities, united together by the signs + and —. The leading term in each of the above expressions, with the exception of Exercise 10, has no *sign* prefixed to it. You must take notice that a term, without any prefixed sign, is always to be regarded as *plus:* the actual insertion of the +, before a leading term, is unnecessary; since, when it is *minus*, the sign — is always put before it. The *plus* quantities are all called *positive* quantities, and the *minus* quantities, *negative* quantities. There is another thing which you must also take note of. You know that the *numerical multiplier* prefixed to a letter, or to a group of letters, is called the *coefficient* of the letter or letters connected with it. Now, although no coefficient should appear before a letter, you are not to say that the coefficient is *nothing*, any more than you are to say, when the plus sign is absent, that the *sign* is nothing: the second term in Exercise 3, is $+ b$, that is, plus *once* b, and the coefficient 1, although not actually written, is to be understood. If the question were asked, therefore, you should say that the coefficient of the b is 1: this 1 is omitted from before the b on the same principle that the + is omitted from before the $13n$; the insertion of either would add to the number of symbols, without adding any clearness to the meaning of the expression; for $13n + b$ can never be mistaken for anything but $+ 13n + 1b$, that is, *thirteen times n plus b;* or, as an algebraist would read it, *thirteen n plus b;* the word *times* being suppressed. Exercise 15 would be read thus: *three a, b; plus d, m; minus five b; plus six c, n; minus twice nine, or 9 times 2.*

From your recollection of the terms employed in common arithmetic, you will know the meaning of the word *factor:* the numbers which, multiplied together, give a *product*, are called *factors* of that product: so here, in algebra, every *multiplier* is a *factor:* thus the factors of $5axy$ are 5, a, x, and y: the factors of $bcyz$ are b, c, y, and z. A product is not altered by changing the order of its factors: the following different arrangements of the factors all imply the same product: $bcyz$, $bycz$, $cyzb$, &c., &c.; but it is usual, when *letters* are the factors, to write them one after another in the order in which they follow in the alphabet; so that the first of the above arrangements would be that generally adopted. In a similar way, since quantities connected together, some by the *additive* or *positive* sign, and others by the *subtractive* or *negative* sign, furnish the same *result*, in whatever order they succeed one another, the order fixed upon is mere matter of accident or choice: Exercise 10 is the same expression whether written

$-4d + 5m - 2n$, or $5m - 4d - 2n$, or $-2n - 4d + 5m$; but the *second* of these ways would be preferred simply because a *sign* is thus saved. The leading term there being *positive*, the leading sign + is dispensed with.

From the explanations that have now been given, and from the practice afforded by the exercises already worked, you must perceive this fact—that although the sign + before an algebraic quantity is a direction to *add*, and the sign — a direction to *subtract*, yet you cannot, in general, obey these directions till the algebra is converted into arithmetic, by a translation of the

---

[*] The Answers to all the Exercises and Questions in this Chapter will be found at the end.

letters into *numbers*. But in many cases you can actually add and subtract, though you may remain in utter ignorance as to the *meaning of the letters:* there is such a thing as addition of *algebra* as well as addition of common numbers; and subtraction of *algebra* as well as arithmetical subtraction. We shall now introduce you to these operations; you will at once see how it happens that you can actually *perform* the operations indicated by + and —, even upon quantities whose values are unknown, by examining a simple instance or two, before proceeding to RULES. Suppose we have such an expression as $5ax + 3ax - 7ax + 2ax - ax$; you would surely not require to know what ax stands for, before you could *perform* the operations indicated by the signs; you would say to yourself—whatever thing ax may represent, 5 *plus* 3 of them must make 8 of those things: 8 of them *minus* 7 of them leaves *one;* this, with the two following, make 3 of them, which diminished by *one*, gives 2 of the things, whatever they be, as the amount of the whole row; you would thus be sure that the result is $2ax$; you would thus state with confidence that

$$5ax + 3ax - 7ax + 2ax - ax = 2ax.$$

The *compound* expression on the left of the sign of equality, is thus reduced to the *simple* expression on the right, solely because the several quantities in the compound expression are *like quantities;* that is, they differ in nothing except in *coefficient* and in *sign;* the *letters* are the same in all. It is only when the terms of a compound expression are *unlike quantities* that the operations indicated by + and — cannot be performed till the values of the letters are stated. You will no doubt be able of yourself to put the proper simple value, on the right of the sign of equality in each of the following cases:

1. $2xy - 4xy + 13xy + 3xy =$
2. $-axz - 7axz + 11axz + axz =$
3. $9mnx + 5mnx - 13mnx =$
4. $6\frac{a}{b} + 2\frac{a}{b} - 5\frac{a}{b} - 2\frac{a}{b} + \frac{a}{b} =$

ADDITION.

Addition of algebra is the finding the amount of a set of quantities, of which some are *additive*, and the others *subtractive*. It differs, therefore, from addition in common arithmetic in this; that, in the latter operation all the numbers are *additive*. Addition of algebra therefore combines the two operations which, in arithmetic, are called addition and subtraction.

CASE I.—*When the quantities to be added are all* like quantities.

RULE 1. Find the sum of the *positive coefficients*.
2. Find the sum of the *negative coefficients*.
3. Take the *difference* of these two sums, and prefix to that difference the sign belonging to the *greater* sum.
4. Annex to the difference the *letters* common to all the quantities, and the correct sum will be obtained.

1.
$$\begin{array}{r} 3a \\ 5a \\ -2a \\ 7a \\ -4a \\ \hline 9a \\ \hline \end{array}$$

2.
$$\begin{array}{r} 7x \\ -3x \\ -2x \\ 13x \\ -x \\ \hline 14x \\ \hline \end{array}$$

3.
$$\begin{array}{r} 6ay \\ 2ay \\ -5ay \\ ay \\ -9ay \\ \hline -5ay \\ \hline \end{array}$$

4.
$$\begin{array}{r} 2ax + 3by \\ 3ax - 2by \\ -5ax + 4by \\ 4ax - by \\ 6ax + 7by \\ \hline 10ax + 11by \\ \hline \end{array}$$

5.
$$\begin{array}{r} 5axz - 3bcy \\ -6axz - 2bcy \\ 2axz + 5bcy \\ -3axz - bcy \\ -4axz + 4bcy \\ \hline -6axz + 3bcy \\ \hline \end{array}$$

The fourth and fifth of these examples each consists of two vertical rows of *like quantities;* the *first row is always that which is first computed;* so that in algebra we begin with the column at which, in arithmetic, we end. The reason why the columns are added up in this order is, that it is more convenient to write the results of the several columns, with the proper signs, from left to right, than from right to left.

From carefully looking over these examples, you will see that the only *work* performed is the adding up of all the *positive coefficients* in each column, and all the *negative coefficients* in separate totals, and then writing the *difference* of these sums for the coefficient of the result, prefixing to it the sign belonging to the greater of the two sums, and then writing against it the *letters* common to all the terms in the column. The work, therefore, is purely arithmetical; the *letters* in the finished result are simply *copied* from the terms above.

EXAMPLES FOR EXERCISE.

1.
$$\begin{array}{r} 2b \\ 7b \\ 9b \\ 11b \\ -3b \\ \hline \\ \hline \end{array}$$

2.
$$\begin{array}{r} 4ax \\ -2ax \\ 3ax \\ 7ax \\ 12ax \\ \hline \\ \hline \end{array}$$

3.
$$\begin{array}{r} 6by \\ 3by \\ -4by \\ -5by \\ 7by \\ \hline \\ \hline \end{array}$$

4.
$$\begin{array}{r} 3axy \\ -axy \\ -2axy \\ 7axy \\ -12axy \\ \hline \\ \hline \end{array}$$

5.
$$\begin{array}{r} 4a + 3x \\ 2a - 7x \\ 6a - 2x \\ 5a + x \\ -a - x \\ \hline \\ \hline \end{array}$$

6.
$$\begin{array}{r} 3ax - 2bz \\ 5ax + 3bz \\ -4ax - 8bz \\ -2ax + 6bz \\ 7ax - 4bz \\ \hline \\ \hline \end{array}$$

7.
$$\begin{array}{r} 8pqy + 3mx - n \\ 2pqy - 4mx + 2n \\ -3pqy - 2mx - 5n \\ -6pqy - 5mx - 3n \\ 4pqy + 6mx + 4n \\ \hline \\ \hline \end{array}$$

8.
$$\begin{array}{r} 4xyz - 2ab \phantom{{}-13} \\ 3xyz + 7ab - 6 \\ -2xyz - 3ab + 7 \\ 5xyz - ab - 13 \\ -8xyz + 4ab + 9 \\ \hline \\ \hline \end{array}$$

9.
$$\begin{array}{rrrr} -abz & -3x & +a & -3 \\ -2abz & +x & -2a & \\ -4abz & -7x & & +2 \\ 5abz & -13x & +4a & \\ 11abz & & +5a & \\ \hline \\ \hline \end{array}$$

10.
$$\begin{array}{rrr} 9acx & +2bey & -kg \\ 2acx & -7bey & +3kg \\ -4acx & -3bey & -2kg \\ acx & & +8kg \\ 7acx & -5bey & \\ & -4bey & -kg \\ \hline \\ \hline \end{array}$$

11.
$$\begin{array}{rrr} 3z & +abc & -17mp \\ & 5abc & +4mp \\ 7z & -2abc & -3mp \\ 5z & & +9mp \\ & 13abc & -2mp \\ & -4abc & +mp \\ \hline \\ \hline \end{array}$$

12.
$$\begin{array}{rrr} 34ky & -3mz & +2abc \\ -16ky & +9mz & -8abc \\ & -5mz & \\ 4ky & +6mz & -3abc \\ -5ky & & +7abc \\ 2ky & -11mz & -abc \\ \hline \\ \hline \end{array}$$

Add together the following quantities:—

13. $7abz-3cey+2mx$, $+3abz-7mx$, $4cey+mx$, $+9mx$.
14. $2gx+6pqy-13$, $+8pqy+11$, $+7gx-2$, $-3gx-pqy$, $+17$.
15. $3axy$, $7ab-c$, $3axy+2ab+5c$, $-axy-5ab-2c$.
16. $5xyz-2am+3bn$, $7am-7bn$, $6xyz-bn$, $4am-5bn$.
17. $6bcx+3ny$, $7mz$, $-8ny$, $2bcx-ny$, $5ny-3mz$, $-2mz$.
18. $9exz-13$, $7bcy+4$, $6exz-4bcy+1$, $13bcy-3$, $4exz-bcy$.
19. $-4mpy-2ax+3$, $-5ax-7$, $3mpy-2$, $mpy+8ax+6$.
20. $-cgx-4$, $-6ab+2$, $3cgx-ab-5$, 17, $4cgx+7ab$, -13.

CASE II.—*When the quantities to be added are* not all *like* quantities.

When rows of quantities are arranged one under another, so as to present a set of vertical columns, as in Examples 1 to 12 above, if the vertical rows are not rows of *like* quantities, then you will have carefully to examine *all* the rows, and to pick out from among them the different sets of *like* quantities, and add them together as before; those quantities that have none *like* them must be merely connected with their signs to the sums thus found; for we cannot *actually* add or subtract when the quantities are unlike. The following is the rule.

RULE.—Add together the different sets of *like* quantities; and put down each separate result, exactly as in the last case; then, to the sum thus found, connect, by the signs belonging to them, the remaining *unlike* quantities.

Although it matters not in what order a row of algebraical terms is written, yet *in addition*, it is usual to commence with the quantity at the *top* of the left-hand column, and to select from among all the columns the several quantities like *it*; then passing to the quantity at the top of the next column, to add together the quantities like *it*, and so on.

1.

$$\begin{array}{r} 3x - 7y + 2z \\ 4y + 6z - x \\ -3z - 2y + a \\ 4x + 3z - y \\ \hline 6x - 6y + 8z + a \\ \hline \end{array}$$

2.

$$\begin{array}{r} -5ax + 2by - 7 \\ 3by + 18 - 4z \\ 4ax - 9 - by \\ 26 + 3ax - 2by \\ \hline 2ax + 2by + 28 - 4z \\ \hline \end{array}$$

3.

$$\begin{array}{r} 7xy - 4az + 2bc \\ 6az + 5mn - 3p \\ 2bc - 3xy + 8az \\ -xy - bc - az \\ -4az + 3xy - 4bc \\ \hline 6xy + 5az - bc + 5mn - 3p \\ \hline \end{array}$$

4.

$$\begin{array}{r} -2yz - 3ab \\ -5cx + 2yz + 5ab \\ 7ab - 3cx + yz \\ 4ek - 6yz - cx \\ 2cx + yz - 8 \\ \hline -4yz + 9ab - 7cx + 4ek - 8 \\ \hline \end{array}$$

EXAMPLES FOR EXERCISE.

1.

$$\begin{array}{r} 2ax + 3by + 4c \\ 5by + 3c - ax \\ 7c + 4ax - 2by \\ 3cx - 5ax + 12 \\ \hline \\ \hline \end{array}$$

2.

$$\begin{array}{r} 5xy - 3az + 7 \\ 6xy + 4bx - 3 \\ 4az - 2xy + c \\ -19 + ax - xy \\ \hline \\ \hline \end{array}$$

3.

$$\begin{array}{r} 9yz + 8ax - 3bc \\ -2en - 4bc + 2yz \\ xyz + 3ax - 4yz \\ -2ax - yz + 3en \\ \hline \\ \hline \end{array}$$

4.

$$\begin{array}{r} 4ab - 3cd + 5ef \\ -7e - 4ab \\ 6cd + ef - 6e \\ 2ef - 3cd + 14 \\ 3e + ab - cd \\ \hline \\ \hline \end{array}$$

5.

$$\begin{array}{r} -7xy - 3bz + 4w \\ -5bz + 4xy - 3cd \\ 2w - 6bz + 9xy \\ -4xy + 3w - bz \\ -16 + 5xy + w \\ \hline \\ \hline \end{array}$$

6.

$$\begin{array}{r} 2amz + 2nx - 3bv \\ 6cw - 8bv - amz \\ 5bv + 4amz + 6 \\ -amz - 2bv - 7nx \\ -8nx - 14 \\ \hline \\ \hline \end{array}$$

From comparing the examples in this second case of addition with those given in the first, you will see that, although the placing of the several expressions to be added one under another was of considerable assistance *there*, because the *like* quantities all appeared in vertical rows, yet the arrangement is of no advantage *here*, since we have to pick out the *like* quantities after a careful search for them among the entire set of expressions. We could do this just as well if the expressions were all written side by side, as in the next examples, without taking the trouble of first arranging them one under another. If you think it easier, however, you may select first one set of like quantities out of the expressions in each of the following examples, and arrange them as in Case I.; then a second set, and so on. You may thus change this Case II. into Case I., taking care, however, that the *unlike* quantities be connected to the sum of the *like* quantities in the final result.

7. $2axy-3bz+4,\ 7bz-6,\ 5+2bz-3axy,\ 4bz-3c+2.$
8. $-6abc-3de-4f,\ 6f-2abc+de,\ 4de-3abc+8,\ abc-f.$
9. $4\frac{1}{2}z+2y-7x+9,\ 3x-\frac{1}{2}y+z,\ 8y-5z+2x,\ 2y-3x.$
10. $8\frac{x}{y}+ax-5b,\ 6b-4\frac{x}{y}-3ax,\ 2\frac{x}{z}-3\frac{x}{y},\ 4-7b.$
11. $-7xyz-3\frac{z}{a}-2bc,\ 5\frac{z}{a}-4mn+p,\ 12bc+3xyz,\ -xyz-7\frac{z}{a}.$
12. $\frac{2}{3}ax-5y+7z-8,\ -\frac{1}{2}y-2z,\ 4z-6ax+2y,\ 3y-9z+ax.$

SUBTRACTION.

Before giving you the rule for subtraction of algebra, we must explain the principle upon which the rule is founded; for whatever part of mathematics be studied, you must never confide in a "Rule" till convinced of its correctness.

Now, let us take any two numbers at random, say 9 and 4; and let us endeavour to *subtract* the latter from the former, when the algebraic signs +, —are, the one or the other, prefixed to the 9 and the 4, and try to put down what we are certain must be the correct *remainder*. You know that to *subtract* means to *take away;* if, therefore, we can *actually* take away the 4 with its sign, from the 9 with *its* sign, we shall be sure of the remainder sought. In order to this, let us write 9 in this form, namely, 9 + 4 — 4, which you see, although it takes up more room is only 9, for 4 — 4 is *nothing*. From the 9 thus expressed, *take away* the + 4, that is, fancy it actually taken up in your fingers and removed, or which will answer as well, take it away by rubbing it out; what remains is evidently 9 — 4 or 5.

Again, from the same expression for the 9, now take the — 4 away; that is, rub it out: what remains is evidently 9 + 4 or 13.

You thus see that if from a positive number, as 9, you have to subtract a positive number, as 4, the true remainder will be got by *changing the sign* of the number to be subtracted, and *then adding*, as in the margin. And that if, from a positive number, you have to subtract a *negative* number, the true remainder will be got, in like manner, by *changing the sign* of the number to be subtracted, and *then adding;* as in the margin.

$$\begin{array}{r} 9 \\ -4 \\ \hline 5 \\ \hline \end{array} \qquad \begin{array}{r} 9 \\ 4 \\ \hline 13 \\ \hline \end{array}$$

Hitherto, the 9 has been supposed *positive:* let it be negative, and, in imitation of the plan above, let us write this — 9 in the form — 9 + 4 — 4.

From the — 9, thus written, take away, or remove, the + 4; the remainder is — 9 — 4, or — 13.

From the same expression for the — 9, take away the — 4; the remainder is — 9 + 4, or — 5.

You see, therefore, that if from a negative number, as — 9, you have to subtract a positive number, as 4, the true remainder will be got by *changing the sign* of the number to be subtracted, and *then adding*, as in the margin. And that if from a negative number you have to subtract a negative number, the true remainder will, in like manner, be got by *changing the sign* of the number to be subtracted, and *then adding*, as in the margin.

$$\begin{array}{r} -9 \\ -4 \\ \hline -13 \\ \hline \end{array} \qquad \begin{array}{r} -9 \\ 4 \\ \hline -5 \\ \hline \end{array}$$

This reasoning, which of course applies to any pair of numbers, as well as to 9 and 4, at once suggests the following rule for subtraction of algebra.

RULE.—Change the signs of all the terms in the quantity to be *subtracted*, or *conceive them to be changed;* then proceed as if it were *addition* instead of subtraction: the result will be the *remainder*.

$$\begin{array}{lr} \text{1. From} & 9a + 6b - 5c \\ \text{Take} & 4a - 2b + 3c \\ \hline \text{Rem.} & 5a + 8b - 8c \\ \hline \end{array} \quad \left\{ \begin{array}{l} \text{or, which is the} \\ \text{same thing,} \end{array} \right\} \quad \begin{array}{lr} \text{To} & 9a + 6b - 5c \\ \text{Add} & -4a + 2b - 3c \\ \hline & 5a + 8b - 8c \\ \hline \end{array}$$

In the operation on the left, the signs of the subtractive terms are only *conceived* to be changed, and then *addition* performed. On the right the change is actually made, and the terms then added. We need scarcely say that the results of subtraction, like those of addition, are written from left to right.

$$\begin{array}{ll} \text{2. From} & 4ax - 3by - 7cz \\ \text{Take} & 5ax + 4by - 9cz - 2 \\ \hline \text{Rem.} & -ax - 7by + 2cz + 2 \\ \hline \end{array}$$

$$\begin{array}{ll} \text{3. From} & 8mz + bx - 6ay - 2 \\ \text{Take} & -2mz - 3bx + 4ay - 3 \\ \hline \text{Rem.} & 10mz + 4bx - 10ay + 1 \\ \hline \end{array}$$

As subtraction is thus converted into addition, all that has been said about addition applies of course here. Terms that have no *like* are to be brought down in the *remainder* with their *proper* signs; those that are in the subtractive row *with changed signs.*

EXAMPLES FOR EXERCISE.

1.
$$\begin{array}{l} 5x - 6y + 3z \\ 2x + 4y - 5z \\ \hline \\ \hline \end{array}$$

2.
$$\begin{array}{l} 2ax + 4by - 7cz \\ 3ax - 2by + 4cz \\ \hline \\ \hline \end{array}$$

3.
$$\begin{array}{l} -4xy - 6ax + 7 \\ -5xy + 9ax - 4 \\ \hline \\ \hline \end{array}$$

4.
$$\begin{array}{l} -23ay - 14bx + 6 \\ -18ay - 9bx \\ \hline \\ \hline \end{array}$$

5.
$$\begin{array}{l} 11abc + 3de - 6fg \\ -9abc - 7de + 5 \\ \hline \\ \hline \end{array}$$

6.
$$\begin{array}{l} 2bz - 3ax - m \\ -4bz + 2ax + en \\ \hline \\ \hline \end{array}$$

7.
$$\begin{array}{l} 8 - 6 + 2 - 4 - 7 \\ 3 + 5 - 9 + 2 - 4 \\ \hline \\ \hline \end{array}$$

8.
$$\begin{array}{l} 10dy - 11ex - 12fz - 3m \\ 9dy - 11ex + 12fz + 8n - 4 \\ \hline \\ \hline \end{array}$$

9.
$$\begin{array}{l} -7ayz - 9bx + 6c - 2e \\ 4ayz + 8bx + 2c - 4d \\ \hline \\ \hline \end{array}$$

10.
$$\begin{array}{l} 9cex - 7aby + 2dx + 11 \\ -3cex + aby - 2dx - 3z \\ \hline \\ \hline \end{array}$$

In the following examples the suitable *arrangement* of the terms, so as to bring like quantities under one another, is left for you to manage yourself.

11. From $5ax - 3by + 7cz$ take $2by - 3ax + 2cz$.
12. From $-4bz - 2cy - ax$ take $3ax + 4cy - 8bz$.
13. From $7ay + 5bx - 16$ take $-3bx + 4ay + 3cz$.
14. From $4\frac{1}{2}x - 2y + 13z - 4$ take $5z + 6y - \frac{1}{2}x$.
15. From $-8\frac{1}{2}axy - 3\frac{1}{2}bz + 4m$ take $-6\frac{1}{2}bz - 4axy + 2n$.
16. From $6\frac{1}{2}yz - 5\frac{1}{2}ax - 2\frac{1}{4}$ take $4ay - 3\frac{1}{2}ax + 4yz + \frac{3}{4}$.

If you have correctly worked the examples now given, you will have acquired a pretty good knowledge of Algebraical Addition and Subtraction, and have become familiar with the meaning and use of the plus and minus signs. We shall now explain a few further particulars, and shall then give a short specimen of the application of Algebra to what are called Simple Equations. These will throw some light upon the practical utility of the science; they will afford an insight into the value of algebraic symbols in matters of calculation, and enable you to see the great advantage in such matters of combining *letters* with *figures.*

You already know that the sign *minus* prefixed to a quantity indicates the *subtraction* of that quantity. Hitherto the sign has been prefixed to *simple* quantities only; but it may be prefixed to a *compound* quantity, so as to indicate that all the simple terms of which it is composed are to be subtracted. In order to this it is only necessary to unite all the terms by some link, so as to imply that when a sign is put before the compound quantity, that sign is to affect *the whole quantity,* or every individual term of which it is composed: whatever be the link employed, it is called a *vinculum.* Suppose we have the compound quantity $4a - 2b + 3c$ to subtract from $9a + 6b - 5c$, as in Exercise 1, page 454. We might *indicate* the subtraction thus:—

$$9a + 6b - 5c - (4a - 2b + 3c);\ \text{or}$$

$$9a + 6b - 5c - \left\{ 4a - 2b + 3c \right\};\ \text{or}$$

$$9a + 6b - 5c - [4a - 2b + 3c].$$

Such *vincula* as these are also called *brackets.* It is plain, from the rule of subtraction, that a *bracketed quantity* may be freed from the brackets, when a *minus sign* is prefixed to it, by simply *changing* the *signs* of all the terms which compose it. Thus the preceding expression, without brackets, is,

$$9a + 6b - 5c - 4a + 2b - 3c = 5a + 8b - 8c.$$

And the subtraction of a compound quantity may in general be performed in this way without taking the trouble of writing it under the quantity it is to be taken from. When the terms to be subtracted are all connected, with changed signs, as above, to the other quantity, we shall merely have a row of terms to be united, like with like, as in addition; just the same as in the example now given.

If the sign *plus* appear before a bracketed quantity, then, since *addition* implies no change of sign, the signs must remain undisturbed, though the brackets be removed: thus—

$$9a + 6b - 5c + (4a - 2b + 3c) = 9a + 6b - 5c + 4a - 2b + 3c$$
$$= 13a + 4b - 2c.$$

Now, that you may never find yourself puzzled, as to signs, when you have to free an expression from brackets, always be careful to notice the *sign,* whether + or —, which precedes the bracket; fancy this sign rubbed out along with the brackets; if it be +, the terms thus set free present their proper signs, without any change being necessary. Of course the *leading* term within the brackets, if itself a *plus* term, as the $4a$, above, will not have its *sign* actually inserted; so that when the + *before* the bracket is rubbed out with the brackets themselves, there will be a gap as between the $5c$ and the $4a$ here; you need scarcely be told that in this gap the + belonging to the $4a$ must be inserted, because $4a$ is *now* not a leading quantity.

But if the sign before the bracket be —, then having rubbed out this sign, with the brackets, or having fancied it rubbed out, write all the terms, thus set free, with *changed signs.* For example—

$$8ax + by + (-5ax - 3by) = 8ax + by - 5ax - 3by$$
$$= 3ax - 2by.$$

$$8ax + by - (-5ax - 3by) = 8ax + by + 5ax + 3by$$
$$= 13ax + 4by.$$

You see that in the first of these expressions you have only to fancy that, with the tip of your finger, you rub out the marks + (, between the by and the $-5ax$; and in the second expression, that you in like manner rub out — (, between the by and the $-5ax$, and *then* that the signs of the terms thus set free are *changed.* By attending to these hints, you will not be likely "*to stick*" at bracketed expressions.

Coefficients are frequently found before bracketed quantities: you are aware that coefficients are *multipliers* or *factors.* When the brackets are removed, the factor is to be introduced into each simple term, as in the instances following:—

$$3(4a - 2b + 3c) = 12a - 6b + 9c;\ 6(-5ax - 3by)$$
$$= -30ax - 18by$$

$$-4(-3x - 5ay + 2) = 12x + 20ay - 8;$$
$$2a(3xy - 2bz) = 6axy - 4abz.$$

As already stated, brackets are not the only kind of *vincula* used to bind a set of simple quantities into one compound whole; a *bar* or *line,* put over the row of quantities, is sometimes, though less frequently, employed; thus, $a + b + \overline{a - b}$, and $a + b - \overline{a - b}$, are the same as $a + b + (a - b)$, and $a + b - (a - b)$; but this kind of vinculum is getting out of use, though the bar or line, which separates the numerator from the denominator of a fraction, still performs the office of a vinculum when there are several terms in the *numerator;* thus, in the fraction$-\dfrac{ax - by + c}{m}$, the minus sign, *before the bar of separation,* operates as it would do if the compound numerator were enclosed in brackets; thus, $\dfrac{-(ax - by + c)}{m}$, that is, the fraction is the same as $\dfrac{-ax + by - c}{m}$

We shall not detain you further with these explanations, except to remark, that the two instances given before, to show the meaning of the *bar-vinculum*, suggest two arithmetical theorems, which, although very simple, you will do well to remember, as they are useful. The expressions referred to are—

$a + b + (a - b) = 2a$, and $a + b - (a - b) = 2b$.

Now, as a and b may stand for any two numbers whatever, we learn from these results that—

1. *The sum* $(a + b)$ *of any two numbers, increased by their difference* $(a - b)$, *is twice the greater number*, that is, $2a$.

2. *The sum of any two numbers, diminished by their difference, is twice the less*; viz., $2b$.

Take, for instance, the two numbers 7 and 3; their sum 10, increased by their difference 4, is 14—double of the *greater*, 7. And the same sum, 10, diminished by their difference, 4, is 6—double of the *less;* and the same of any pair of numbers whatever.

SIMPLE EQUATIONS.

We shall now show a few applications of the principles laid down in the foregoing articles to the *solution of simple equations*. What we here propose to give, must be regarded, however, as only an introduction to the complete consideration of the subject, which will be resumed hereafter.

An *equation* is merely a statement, in the characters of algebra or arithmetic, that two quantities are *equal:* thus, that *two and five are equal to seven*, is a statement of equality, which, when expressed in figures and signs, thus, $2 + 5 = 7$, is an equation. In like manner, all these are equations—namely: $6 + 2 - 3 = 5$, $7 - 4 = 6 - 3$, $2 + 8 - 1 = 9$, $3x - 2 = 10$, &c., &c. All but the last are purely arithmetical equations; the last is an *algebraical* equation, as it contains the algebraical character or symbol x. You see that an equation consists of two *members* or *sides:* one on the left of the sign of equality, and the other on the right. These members or sides, if equally increased, or equally diminished, equally multiplied, or equally divided, give results that must evidently be *new equations*, because *equal* quantities thus operated upon must give *equal* quantities for the results of the operations. This is a general axiom which you must pay attention to, as your success in solving the equations about to be given will depend chiefly upon your skill in applying it. But we must tell you what is meant by *solving* an equation.

You are said to have *solved* a question in arithmetic when you have worked it out and arrived at the *answer;* till you have completed the calculation, the answer remains *unknown*. It is the same in algebra; *the solution of an equation* is the finding the value or interpretation of some letter or letters, which at the outset is unknown. Unknown values are usually represented by letters towards the *end* of the alphabet, as z, y, x, &c.; while letters whose numerical value are already known, are chosen from the beginning, as a, b, c, &c. In the equation given above, namely, $3x - 2 = 10$, x represents a number, at present unknown, such that three times that number, diminished by 2, is equal to 10; the operation by which the number, or value of x, is discovered, is the solution of the equation. This is effected as follows :—

Add 2 to each *side;* the result is the new equation $3x = 12$; that is, 3 times x is equal to 12.

Divide each side of this by 3: the result is $x = 4$: so that x, at first an unknown value, turns out to be equal to 4; and you see that three times 4 diminished by 2 *is* equal to 10.

As here, so in the examples which follow, x will always be used to stand for the value at the outset unknown; so that the solution of the equation will be the *finding the value of* x; the operations for this purpose will be very easy: they are called *Transposition* and *Clearing Fractions*.

Transposition.—The operation called transposition consists simply in taking quantities from one side of an equation, and putting them on the other side, still, however, taking care to preserve the *equality* of the two sides; for whatever operations we perform, we must never disturb the equality of the two sides: the *result* of each operation must still be an *equation*. Now, if you remove a quantity from one side of an equation, and place it on the other side; that is, if you rub it out, sign and all, from one side, and then write it down on the other, the change you thus make will not disturb the equality of the two sides, provided only the quantity rubbed out be written on the other side with a *changed sign*. You will be convinced of this by an example or two. Let there be the equation $4x - 5 = 3x - 2$: then if we wish the 5 on the left to be removed to the right, all we have to do is to *add* 5 to *both sides* of the equation; the result is the equation $4x = 3x - 2 + 5$. Here you see that the 5 is *transposed;* it is taken from the left side and put on the right *with changed sign*. The new equation is therefore $4x = 3x + 3$. Again: if we now wish to remove the $3x$ from the right to the left, all we have to do is to *subtract* $3x$ from *both sides;* the result is the equation $4x - 3x = 3$. Here you see that the $3x$ is *transposed:* it is taken from the right and put on the left *with changed sign*. The new equation is therefore $x = 3$. We have thus actually *solved* the equation $4x - 5 = 3x - 2$; the x in this equation, at the outset unknown in value, is now found out to stand for 3. If you put this 3 for the x in the proposed equation, it becomes the numerical equation $12 - 5 = 9 - 2$; which you see is true, each side being 7.

Clearing Fractions.—When a fraction occurs in an equation, we may *clear* the equation of the fraction by multiplying both sides of it by the denominator of the fraction. You know from common arithmetic, that if you multiply a fraction by its denominator, the result is simply the numerator: thus, $\frac{2}{3} \times 3 = 2$; $\frac{4}{5} \times 5 = 4$; $\frac{2}{7} \times 7 = 2$, and so on. In like manner, $\frac{x}{3} \times 3 = x$; $\frac{4x}{5} \times 5 = 4x$; $\frac{2a}{7} \times 7 = 2a$, &c. If, therefore, we have such an equation as $2x + \frac{x}{3} + 2 = 22 - x$ it will become cleared of fractions by multiplying both sides by 3: the result of this multiplication is the new equation $6x + x + 6 = 66 - 3x$, which is free from fractions. To complete the solution of the equation, that is, to find the value of x, we must, by transposition, bring *all* the unknown quantities to one side of the equation, and *all* the known quantities to the other: we shall thus have $6x + x + 3x = 66 - 6$; that is, $10x = 60$: consequently, dividing each side by 10, there results finally $x = 6$: and if this be put for x in the original equation, you will find the two sides of it to be numerically equal, for each side will be 16.

To solve a simple equation containing only one unknown quantity.

RULE I.—If there be a fraction in the equation, clear it away by multiplying both sides by the *denominator* of the fraction.

2. If known and unknown quantities are linked together, separate them by *transposition;* so that *all* the unknown quantities may appear on one side of the equation, and all the known quantities on the other.

3. Collect the terms on each side into one sum, so that there may be only a single unknown term on one side of the equation, and a single known term on the other.

4. Lastly, divide each side by the coefficient or multiplier of x, the unknown quantity, the result will be x *alone* on one side, and its value or interpretation on the other side of the sign of equality.

EXAMPLE 1.—Given the equation $5x - 8 = 3x + 2$ to find the value of x. As it is usual to choose the *left* hand side of the equation for the unknown quantities, and the other side for the known numbers, we shall *transpose* the known number 8, and thus get the equation $5x = 3x + 2 + 8$; then transposing the unknown quantity $3x$, we shall obtain the equation $5x - 3x = 2 + 8$, the *left* side of which is occupied wholly with unknown, and the *right* side wholly with known quantities. Reducing now each side to a single term, the equation is $2x=10$; and dividing by 2, there results $x=5$. The steps of the solution, as you would be expected to solve the equation, would stand as follows:—

Given equation, $5x-8=3x+2$
By transposition, $5x-3x=2+8$
Collecting the terms, $2x=10$
Dividing by 2, $x=5$

2 Given the equation $2x-9=31-3x$ to find the value of x.

By transposing, $2x+3x=31+9$
Collecting, $5x=40$
Dividing by 5, $x=8$

3. Given the equation $\frac{2x}{3}+\frac{x}{4}-22=0$ to find the value of x.

Multiplying by 3, to clear the first fraction,

$$2x+\frac{3x}{4}-66=0$$

Multiplying by 4, to clear the remaining fraction,

$$8x+3x-264=0$$

Transposing, $8x+3x=264$
Collecting, $11x=264$
Dividing by 11, $x=24$

4. Given $\frac{x}{3}+\frac{x}{4}+\frac{x}{5}=1$, to find the value of x.

Multiplying by 3, $x+\frac{3x}{4}+\frac{3x}{5}=3$
" by 4, $4x+3x+\frac{12x}{5}=12$
" by 5, $20x+15x+12x=60$
* $\therefore$ $47x=60$, $\therefore x=\frac{60}{47}=1\frac{13}{47}$

EXAMPLES FOR EXERCISE.

Find the value of x in each of the following equations:—

NOTE.—Since any quantity may be removed from one side of an equation to the other, provided its *sign be changed*, it follows that if *all* the signs on one side, and *all* the signs on the other be changed, the *equality* of the two sides will not be disturbed; for this changing of *all* the signs is merely the same as *transposing* the two sides.

1. $2x-7=x+4$
2. $5x-3=3x+5$
3. $6x+2=4x+8$
4. $3x-1=x+7$.
5. $8x-13=4x-1$
6. $2(x+3)=20$
7. $3(x-4)=6$
8. $4(x-1)=x+5$
9. $5(x+2)=2(x+8)$
10. $3(2x-3)=4(x-2)$
11. $\frac{x}{3}+\frac{x}{4}=7$
12. $\frac{x}{3}-\frac{x}{4}=1$
13. $\frac{2x}{3}-\frac{x}{4}=5$
14. $\frac{x}{2}+\frac{x}{3}=31-\frac{x}{5}$
15. $\frac{x}{3}+\frac{x}{4}+\frac{x}{6}=1$
16. $2x-(48-x)=x+12$
17. $\frac{5(3x+2)}{2}=35$
18. $\frac{x+3}{5}-1=2-\frac{x}{7}$
19. $\frac{x}{2}+\frac{x}{3}-\frac{x}{5}-1=0$
20. $\frac{x}{2}+\frac{x}{3}-\frac{x}{4}-\frac{1}{2}=0$
21. $11-\frac{5x}{8}=\frac{x}{2}-\frac{2x}{3}$
22. $4x-2(3-x)=\frac{x+3}{2}$
23. $6x-\frac{4-3x}{5}=\frac{29}{5}$
24. $\frac{x-6}{2}+\frac{x}{3}=20-\frac{x-2}{2}$
25. $\frac{3x-13}{7}+\frac{11-4x}{3}=0$
26. $6-\frac{x-1}{2}-\frac{x-2}{3}=\frac{3-x}{4}$

QUESTIONS TO BE SOLVED BY SIMPLE EQUATIONS.

Every *question*, whether in arithmetic or algebra, has for its object the discovery of some unknown value by means of the conditions, stated in the question, which connect it with *known* values. In algebra, the first thing to be done is to express these conditions in the form of an *equation*, some letter, as x, being made to stand for the unknown quantity; the solution of the *equation* is the solution of the *question*. If there are several unknown quantities to be determined, as many distinct equations will in general be necessary; at present those questions only will be considered that furnish a single equation with one unknown quantity. The method of translating such questions into equations will be better learnt by the study of a few examples than by verbal directions. We shall therefore here give some instances of the modes of proceeding.

1. There are two numbers of which the difference is 8 and the sum 38: what are the numbers?

Let x stand for the smaller of the two numbers: then $x+8$ must represent the greater: and since by the question the sum of the two is 38, we have the equation,

$$x+x+8=38.$$

Or transposing the 8, $2x=30$, $\therefore x=15$, the smaller number; and as $x+8$ is the greater, $\therefore 15+8=23$, is the greater.

You see that these numbers satisfy the conditions of the question; for $23-15=8$, and $23+15=38$.

2. From two places, 160 miles apart, two persons, A and B, set out at the same time to meet each other. A travels 18 miles a-day, and B 22 miles: in how many days will they meet?

Suppose they meet in x days: then A will have travelled $18x$ miles, and B, $22x$ miles: the *sum* of these distances is, by the question, 160 miles: hence we have the equation,

$$18x+22x=160;$$

that is, $40x=160$, $\therefore x=4$, the number of days.

3. A father is three times as old as his son; but five years ago he was four times as old: what are their ages now?

Let the present age of the son be x years: then, by the question, that of the father is $3x$ years. Also five years ago the age of the son must have been $x-5$, and that of the father $3x-5$. The question tells us that this latter number is four times the former: that is,

$$3x-5=4(x-5);$$

or, removing the vinculum, $3x-5=4x-20$; $\therefore$ transposing the 20 to the left, and the $3x$ to the right,

$$20-5=4x-3x, \therefore 15=x;$$

that is, the son's age is 15 years; and $3x$, the age of the father, is 45.

4. A vessel holding 120 gallons is partly filled by a spout which delivers 14 gallons in a minute: this is then turned off, and a second spout, delivering 9 gallons in a minute, completes the filling of the vessel. How long did *each* spout run, the time occupied by *both* in filling the vessel being 10 minutes?

Suppose the first ran x minutes: then the second ran $10-x$ minutes. As the first delivers 14 gallons a minute, the quantity delivered by this spout must be $14x$ gallons; and the quantity delivered by the other, at 9 gallons a minute, must be $9(10-x)$ gallons; $\therefore$ the *whole* number of gallons delivered is,

$14x+9(10-x)=120$, by the question;
that is, removing vinculum, $14x+90-9x=120$;
$\therefore$ transposing, $14x-9x=120-90$;
collecting, $5x=30$, $\therefore x=6$.

$\therefore$ the first spout ran 6 minutes, and the second $10-6=4$ minutes.

5. What number is that of which the third part exceeds the fifth part by 48?

Let x be the number: then by the question

$$\frac{x}{3}-\frac{x}{5}=48$$

Multiplying by 3, $x-\frac{3x}{5}=144$
" by 5, $5x-3x=720$;
that is, $2x=720$, $\therefore x=360$, the number required.

The third part of this is 120; the fifth part is 72; and the difference between these parts is 48.

6. A vessel can be filled from a tap in 3 hours, and from a second tap in 5 hours: in what time will it be filled if both taps run together?

Let the number of hours be x: then the part of the vessel filled in *one* hour will be the $\frac{1}{x}$ part.

---

* The sign $\therefore$, stands for the word *therefore*; on account of its convenience it will be frequently used hereafter.

But the part filled by the first tap in 1 hour is the $\frac{1}{3}$ part, and by the second tap the $\frac{1}{5}$ part;

$$\therefore \frac{1}{3}+\frac{1}{5}=\frac{1}{x}; \text{ that is, } \frac{8}{15}=\frac{1}{x}$$

Multiplying by 15, $8=\frac{15}{x}$

" by x, $8x=15$, $\therefore x=\frac{15}{8}=1\frac{7}{8}$

∴ the time is one hour and seven-eighths.

These specimens of the solution of questions by simple equations must suffice for the present. It will be seen, from an examination of them, that the only thing of any difficulty, in thus applying the first principles of Algebra, is the translation of the conditions of the question into algebraical language, under the form of *an equation;* the process by which this equation is to be solved, and the unknown quantity in it discovered, is in general sufficiently suggested by the appearance of the equation itself. As the aim is to isolate the x, so that it alone may occupy one side of the equation, while known numbers occupy the other, every step in the solution is made to contribute to this end. By transposition, clearing fractions, collecting like terms, &c., the equation is made to pass through one change after another, till at length a single unknown term appears on one side, and a known number, which is its interpretation, on the other. It then only remains to divide each side by the coefficient of x, if it have a coefficient other than unity, and x itself becomes known.

QUESTIONS FOR EXERCISE.

1. There are two numbers, of which the difference is 9, and the sum 43: what are the numbers?

2. From two places, 108 miles apart, two persons, A and B, set out at the same time to meet each other. A travels 17 miles a-day, and B travels 18: in how many days will they meet?

3. Find two numbers of which the difference is 13, and which are such that if 17 be added to their sum, the whole will amount to 62.

4. There are two numbers, of which the difference is 15, and which are such that if 7 times the less be subtracted from 5 times the greater, the difference is 19: what are the numbers?

5. A person starts from a certain place, and travels at the rate of 4 miles an hour. After he has been gone 10 hours, a horseman, riding 9 miles an hour, is dispatched after him: how many hours must the horseman ride to overtake him?

6. A person has 264 coins—sovereigns and florins; he has $4\frac{1}{2}$ times as many florins as sovereigns: how many of each coin has he?

7. A person spends $\frac{1}{4}$th of his yearly income in board and lodging, $\frac{1}{3}$th in clothes and other expenses, and he lays by £85 a-year: what is his income?

8. What number is that whose *third* part exceeds its *fifth* part by 72?

9. I have a certain number in my thoughts. I multiply it by 7, add 3 to the product, and divide the sum by 2. I then find that if I subtract 4 from the quotient, I get 15: what number am I thinking of?

10. A man 40 years old has a son 9 years old; the father is therefore more than 4 times as old as his son: in how many years will the father be only twice as old as his son?

11. Two persons, A and B, 120 miles apart, set out at the same time to meet each other. A goes 3 miles an hour, and B 5 miles: what distance will each have travelled when they meet?

12. Divide £250 among A, B, and C, so that B may have £23 more than A, and C £105 more than B.

13. A can execute a piece of work in 3 days which takes B 7 days to perform: in how many days can it be done if A and B work together?

14. A cistern can be filled by three pipes; by the first in 2 hours, by the second in 3, and by the third in 4: in what time can it be filled by all the pipes running together?

15. Solve the preceding question when the first pipe fills the cistern in 1 hour 20 minutes; the second in 3 hours 20 minutes; and the third in 5 hours.

16. After A has been working 4 days at a job which he can finish in 10 days, B is sent to help him; they finish it together in 2 days: in what time could B alone have done the whole?

17. Divide £143 among A, B, and C, so that A may receive twice as much as B, and B three times as much as C.

18. A person has 40 quarts of superior wine, worth 7*s.* a quart; he wishes, however, so to reduce its quality as that he may sell it at 4*s.* 6*d.* a quart: how much water must he add?

19. Divide 90 into four parts, such that if the first be increased by 2, the second diminished by 2, the third multiplied by 2, and the fourth divided by 2, the results may all be equal.

20. Divide 39 into four parts, such that if the first be increased by 1, the second diminished by 2, the third multiplied by 3, and the fourth divided by 4, the results may all be equal.

The preceding examples may serve to show how the first principles of Algebra may be applied to inquiries of a practical nature. It is time that we now proceed to the other two rules, multiplication and division; for, as in Arithmetic, the four rules comprehend all the operations of the science. But two or three particulars must be previously defined.

We know that when factors are multiplied together, the result is called *a product;* if the factors are all *equal*, the product is called *a power* of the factor whose repetition in the multiplication has produced it: thus, in the following instances, namely—
$5+5=25$; $3+3+3=27$; $2+2+2+2=16$, &c., 25 is *the second power*, or *the square* of 5; 27 is *the third power*, or *the cube* of 3; 16 is *the fourth power* of 2; 32 is *the fifth power* of 2; 64 *the sixth power*, and so on. The fourth power of a is $aaaa$; the fifth power of x is $xxxxx$, and so on. But as this repetition of the factors is tedious and cumbersome, it is agreed to represent a power by writing down the factor only *once*, and placing over the right hand upper corner the *number* which denotes the *repetitions;* thus, the fourth power of a is written a^4, the fifth power of x is written x^5, and so on. Suppose, for example, that x stands for 3; then $x=3$, $x^2=9$, $x^3=27$, $x^4=81$, $x^5=243$, $x^6=729$, $x^7=2187$, &c. The small figures, thus used in the notation for powers, are called *exponents* or *indices;* the exponent or index for the *cube*, or *third power*, is 3, that for the fourth power 4, and so on.

The number or quantity, which thus produces a *power*, is called a *root* of that power; thus, 3 is the *square root* of 9, the *cube root* of 27, the *fourth root* of 81, and so on. There is a convenient notation for *roots* as well as for *powers*.

The sign $\sqrt{\ }$, for a root, is called the radical sign; it is prefixed to the quantity whose root is meant, and a small figure, denoting *what* root is to be understood, is connected with it; thus, $\sqrt[2]{4}$ means the *second*, or *square* root of 4, that is, 2; because the *second power*, or *square* of 2, is 4; in like manner, $\sqrt[3]{8}$ means the *third*, or *cube* root of 8, namely, 2; because the *third power*, or *cube* of 2, is 8; $\sqrt[4]{x}$ means the *fourth root* of x; that is, it is a number such that the *fourth power* of that number is the number that x stands for. It must be observed, however, that in the case of the *second* or *square* root, the little 2 is always omitted; so that when there is no *index-figure* connected with the *radical sign* $\sqrt{\ }$, the *square root* is always to be understood. You will now easily make out the following statements or equations:—

$$\sqrt{9}=3,\ \sqrt[3]{125}=5,\ \sqrt[4]{a^4}=a,\ \sqrt[5]{x^5}=x,\ \sqrt{z^2}=z.$$

But besides the radical sign, there is another contrivance for indicating roots—a contrivance like that for denoting powers, namely, the attaching an *exponent* to the quantity whose root is meant; thus, the equations above, expressed in this other form of notation, are as follows:—

$$9^{\frac{1}{2}}=3,\ 125^{\frac{1}{3}}=5,\ (a^4)^{\frac{1}{4}}=a,\ (x^5)^{\frac{1}{5}}=x,\ (z^2)^{\frac{1}{2}}=z.$$

In the case of a *power* of a quantity, the exponent is a whole number, which indicates *what power* is meant; in the case of a root, the exponent is a fraction, the denominator of which indicates *what root* is meant. The *power* of a proposed quantity may be easily determined, as the *multiplication* may be actually executed with but little trouble; but to find a specified *root* of a proposed quantity—even of a common number—is often a difficult matter; some numbers, indeed, have no *exact* roots. But we shall have to speak about roots again.

MULTIPLICATION.

CASE I.—*When the factors are simple quantities.*

RULE 1. Observe whether the *signs* of the two factors are *like* or *unlike*; if they are *like*, that is both + or both —, write + for the sign of the product; but if they are *unlike*, that is, one + and the other —, write — for the sign of the product.

2. After the sign, write the product of the *coefficients*.

3. After the product of the coefficients, write that of the *letters*: that is, put down the letters in both factors, one after the other, without any sign between them, and the complete product will be exhibited.

Thus, if we have to multiply together the two factors, $-4ax$ and $3by$, we first observe the signs; these being *unlike*, we know that the sign of the product is *minus*; after this *minus* we write 12, the product of the coefficients, and finally we place against the 12 the quantity $abxy$, this being the product of the letters when arranged in alphabetical order, ∴ the product is $-12abxy$. Again, if we have to multiply $-7bxz$ by $-5acy$, then the signs being *like*, we write + for the sign of the product, 35 for the product of the coefficients, and $abcxyz$ for the product of the letters; ∴ $-7bxz \times -5acy = 35abcxyz$, the *plus* sign being omitted, as unnecessary. In a similar way we have—

$$3mx \times 6ay = 18amxy,\ 2bcy \times -4ax = -8abcxy.$$
$$-4a^2x \times 5a^3bx = -20a^5bx^2,\ -3bz^2 \times -8a^3bxz = 24a^3b^2xz^3.$$

You will observe that the *third* of these examples is the same as $-4aax \times 5aaabx = -20aaaaabxx$; and that this result, in the more brief notation for *powers*, is $-20a^5bx^2$. And you must perceive that, by always adopting this notation, the multiplication of *powers of the same quantity* is reduced simply to the *addition of the exponents* of the factors; thus, the factors in $x^2x^3x^5$, factors which are all powers of the same quantity x, are x^2, x^3, x^5; the *sum* of the exponents is $2+3+5=10$; so that $x^2x^3x^5=x^{10}$; nothing, therefore, can be more easy than the multiplication of powers of *the same* quantity. We need scarcely tell you that x is the same as x^1, so that $xx=x^2$, $x^2x=x^3$, &c.

The preceding direction, as to the *sign* of the product of two factors, is called the *Rule for the signs*. It is briefly expressed thus:—*Like signs give* PLUS; *unlike signs*, MINUS.

You may satisfy yourself that *the rule for the signs* is true as follows:—

Take any two factors whatever, say 7 and 3; then all the possible varieties, as to signs, will be these—namely,

$$7\times3,\ -7\times3,\ 7\times-3,\ -7\times-3.$$

The first is the case of common arithmetic, the product being 21; the second case requires no consideration; for -7, repeated three times, is necessarily -21. The third case is peculiar; but we may arrive at the true product thus: increase the multiplier -3 by 4; the product, whatever it be, will obviously be 4 times 7—that is, 28 *too great*; but the multiplier increased by 4 becomes 1; and *once* 7 is 7, and as this is 28 too great, the correct product must be $7-28$, that is -21, ∴ $7\times-3=-21$.

In like manner, in the fourth case, increase the multiplier -3 by 4; then, as before, the product will be four times -7, that is, -28 too great; in other words, -28 must be *subtracted* from the erroneous product to make it correct; but the multiplier increased by 4, is 1, and once -7 is -7; ∴ the correct product is $-7+28$, that is 21; because the sign of the -28 must be *changed* when subtracted; ∴ $-7\times-3=21$. You thus see that when the factors have *like* signs, the product is *plus*; and that when they have *unlike* signs, the product is *minus*; and, from the foregoing reasoning, it is plain that the same conclusion would have followed if any other two factors had been chosen; ∴ the *rule for the signs* in multiplication is general.

Ex. 1. $\begin{array}{l} 7ax \\ 3b \\ \hline 21abx \\ \hline \end{array}$ 2. $\begin{array}{l} -7ax^2 \\ 3bx \\ \hline -21abx^3 \\ \hline \end{array}$

3. $\begin{array}{l} -7x^2y^3 \\ -3ax^3 \\ \hline 21ax^5y^3 \\ \hline \end{array}$ 4. $\begin{array}{l} -8ayz^2 \\ -7bxy \\ \hline 56abxy^2z^2 \\ \hline \end{array}$

6. $\begin{array}{l} 13a^2b^3x \\ -9ab^2x^4 \\ \hline -117a^3b^5x^5 \\ \hline \end{array}$ 7. $\begin{array}{l} 16cy^3z^4 \\ -ab^2z^2 \\ \hline -16ab^2cy^3z^6 \\ \hline \end{array}$

8. $\begin{array}{l} -\frac{1}{2}a^3x^4y^5 \\ -6ax^2y^3 \\ \hline 3a^4x^6y^8 \\ \hline \end{array}$ 9. $\begin{array}{l} -\frac{1}{2}x^4y^6z^2 \\ \frac{1}{2}ax^3y^6z^2 \\ \hline -\frac{1}{4}ax^7y^6z^3 \\ \hline \end{array}$

10. $3a^4x^2z^3\times7a^2xy^3=21a^6x^3y^3z^3$
11. $-4x^5yz^3\times5x^2y^4z=-20x^7y^5z^4$
12. $-6b^2cx^6\times-3b^4c^2x=18b^6c^3x^7$
13. $-\frac{2}{3}a^2z^3\times\frac{3}{5}ax^2z^4=-\frac{2}{5}a^3x^2z^7$

EXAMPLES FOR EXERCISE.

[NOTE.—You will observe that the rule for the signs enables us to fix the sign of the product of *two* factors only; but it is unnecessary that it should do more than this; if there are *three* factors, the product of *two* becomes *a factor* to be combined with the *third*. It is plain that, however numerous the factors when the number of them preceded by the *minus* sign is *odd*, the sign of the product is *minus*; and that when the number of minus factors is *even*, the sign of the product is *plus*.]

1. $9a^3y^2\times4a^2y^3$ 2. $-7bx^2y^3\times8b^4y^5$
3. $-4a^2x^3z^4\times-6$ 4. $-5b^3c^2y\times-3c^4y^3z$
5. $11a^4xy^2z^3\times-9a^5x^7y^5z^2$ 6. $-13a^2x^3y^4\times14a^4x^3y^2$
7. $\frac{1}{2}b^4x^3y^2\times-4b^2xy^5$ 8. $\frac{1}{2}ax^4z^2\times\frac{1}{2}x^3yz^4$
9. $2ax^2y\times-3a^2y^3\times-4a^3x^4$
10. $-3b^2yz\times-2y^2z^2\times-4ab^3y$
11. $\frac{1}{2}axy^3\times\frac{2}{3}x^2y\times-3a^2y^2$
12. $\frac{2}{3}a^2z^3\times-\frac{1}{4}x^2y^3\times-\frac{3}{5}a^3y^2z$
13. $-\frac{5}{6}a^2y^3\times-3b^2z^3\times-\frac{2}{7}abx^2yz$
14. $\frac{7}{8}a^3x\times-\frac{4}{5}x^2y\times-2y^2z\times-10a^2xz^3$

CASE II.—*When the multiplicand is a compound quantity, and the multiplier a simple quantity.*

RULE.—Multiply each simple term in the multiplicand by the multiplier, beginning always at the *left* hand; connect the several products together by their proper signs, and the complete product will be exhibited.

1. $\begin{array}{l} 4a^2x^3-2by^2 \\ 3axy \\ \hline 12a^3x^4y-6abxy^3 \\ \hline \end{array}$ 2. — $\begin{array}{l} 3axy^2-4bz+2a^2 \\ 5axz^2 \\ \hline -15a^2x^2y^3z^2-20abxz^3+10a^3xz^2 \\ \hline \end{array}$

3. $\begin{array}{l} 6x^2yz-2ay^2-3b^2y \\ -2xz^2 \\ \hline -12x^3yz^3+4axy^2z^2+6b^2xyz^2 \\ \hline \end{array}$

4. $\begin{array}{l} -5ax^3y-by^2z+\frac{1}{2}ab^3 \\ -6a^2by^3 \\ \hline 30a^3bx^3y^4+6a^2b^2y^5z-3a^3b^4y^3 \\ \hline \end{array}$

5. $\begin{array}{l} 4a^2x+\frac{1}{2}by^2+az^3 \\ -abx \\ \hline -4a^3bx^2-\frac{1}{2}ab^2xy^2-a^2bxz^3 \\ \hline \end{array}$

EXAMPLES FOR EXERCISE.

1. $$\begin{array}{l} 3ax^2-2bxy\\ 4a^2x\\ \hline \\ \hline \end{array}$$

2. $$\begin{array}{l} 5a^2y^2-4x^2y^3\\ -3axy\\ \hline \\ \hline \end{array}$$

3. $$\begin{array}{l} -6b^2yz^2+4ab^2y^2\\ -2ayz\\ \hline \\ \hline \end{array}$$

4. $$\begin{array}{l} 7a^2b^4x^6-3x^2y^4+5\\ 4ax^3y\\ \hline \\ \hline \end{array}$$

5. $$\begin{array}{l} 9m^2nz^2-7a^2y^2-2b^2x^3y\\ -7an^2x^3\\ \hline \\ \hline \end{array}$$

In the following examples, the *vinculum* or *brackets* may be removed, and the simple factor (the multiplier) placed under the leading term of the compound one, as in the preceding instances; but in most cases you will be able to write down the result of the multiplication at once, without resorting to this arrangement.

6. $(2a^2bx^3-5xy^3)\ 3ax^2y$
7. $(2axy^3-3x^2z+2x)\times-4axy$
8. $(mxy^3+3ny^3-2y^2z)\times-6m^2x^2y$
9. $(4y^2z^3-3ax^5-5by^3)\times-5ab^2y$
10. $(5cx^2z^3-y^4z^2-3z^4)\ 12c^2x^3yz^3$
11. $(\frac{2}{3}ax^2-\frac{1}{2}by^3-2cz^2)\times-12a^2bc^3$
12. $\{4ay^2-(2b^2z^3-yz-2)3a^2yz^3$
13. $\{2bx^2y^3-(5cy^2z+4yz^3-3z^5)\}\times-3x^2y$
14. $\{5a^2x^3-(3b^2y^2+2a^2x^3-4ay^3)\}\times-2a^2b^2xy$

CASE III.—*When multiplicand and multiplier are both compound quantities.*

RULE 1.—Multiply *all* the terms of the multiplicand by *each* term of the multiplier, proceeding with each as in the last case.

2. Collect together the several products that are *like*, as in addition, and to the sums of these unite, by their proper signs, the other products; and the complete product will be obtained.

1. Multiply $x+y$ by $x-y$.

$$\begin{array}{r} x+y\\ x-y\\ \hline x^2+xy\\ -xy-y^2\\ \hline \end{array}$$

$$\therefore (x+y)(x-y)=x^2\quad-y^2$$

2. Multiply $x+y$ by $x+y$.

$$\begin{array}{r} x+y\\ x+y\\ \hline x^2+xy\\ xy+y^2\\ \hline \end{array}$$

$$\therefore (x+y)^2=x^2+2xy+y^2$$

3. Multiply $x-y$ by $x-y$.

$$\begin{array}{r} x-y\\ x-y\\ \hline x^2-xy\\ -xy+y^2\\ \hline \end{array}$$

$$\therefore (x-y)^2=x^2-2xy+y^2$$

We have a remark to make in reference to these three examples; you will do well to keep it in remembrance. It is this: since x and y stand for any two numbers whatever, we learn that—

1. The sum of two numbers $(x+y)$ multiplied by their difference $(x-y)$ is the difference of the squares of those numbers (x^2-y^2).

2. The square of the sum $(x+y)$ of two numbers (x and y) is equal to the sum of their squares (x^2+y^2), together with twice their product $(2xy)$.

3. The square of the difference $(x-y)$ of two numbers is equal to the sum of their squares (x^2+y^2), diminished by twice their product $(2xy)$.

EXAMPLE.—Let 7 be one number and 3 the other: then, 1st, their sum, 10, multiplied by their difference, 4, is 40; the *squares* of the numbers are 49 and 9; so that $7^2-3^2=(7+3)(7-3)=40$. 2nd. $(7+3)^2=10^2=100$, and $7^2+3^2=49+9=58$; also *twice* 7×3, that is, $2\times7\times3=42$; and $58+42=100$. 3rd. $(7-3)^2=4^2=16$; and $58-42=16$.

4. Multiply $(x+y)^2$ by $x+y$, that is, multiply out or *develope* $(x+y)^3$.

$$\begin{array}{r} (x+y)^2=x^2+2xy+y^2\\ x+y\\ \hline x^3+2x^2y+\ xy^2\\ x^2y+2xy^2+y^3\\ \hline \end{array}$$

$$\therefore (x+y)^3=x^3+3x^2y+3xy^2+y^3$$

5. *Develope*, or multiply out $(x-4)\ (x+3)$; $(x+5)\ (x-7)$; $(2x+3)\ (3x+2)$ and $(x+a)\ (x+b)$.

$$\begin{array}{rcr} x-4 & \qquad & x+5\\ x+3 & & x-7\\ \hline x^2-4x & & x^2+5x\\ 3x-12 & & -7x-35\\ \hline x^2-x-12 & & x^2-2x-35\\ \hline \end{array}$$

$$\begin{array}{rcr} 2x+3 & \qquad & x+a\\ 3x+2 & & x+b\\ \hline 6x^2+9x & & x^2+ax\\ 4x+6 & & bx+ab\\ \hline 6x^2+13x+6 & & x^2+(a+b)x+ab\\ \hline \end{array}$$

In the third of these results, the $13x$ is got by actually *adding* the coefficients 9 and 4: in the fourth example, the corresponding coefficients of x, not being *numbers*, cannot be actually *added;* but the addition may nevertheless be *indicated*, as above: and where, in the *third* example, the middle term of the product was written $13x$, that is, $(9+4)x$, the corresponding term *here* is written $(a+b)x$; this is better than making *two* terms of the same quantity, and writing it thus, $ax+bx$. *Here* the coefficients of x are a and b; and, being *letters*, they are called *literal coefficients:* the coefficient of x, in the result above, is $(a+b)$. Whenever a common factor enters several of the terms of a compound expression, this common factor may always be written outside a vinculum, and whatever multiplies it, *within;* repetitions of the same factor are thus avoided; and in the answers to questions, or the final results of operations, this more compact form of expression should be adopted. Thus, such a result as $abx+4cx-3mx$, would have an unfinished appearance; it should be changed into $(ab+4c-3m)x$. *This*, you will see, is more easily computed than the former, when the letters are replaced by the numbers they represent. Suppose, for instance, $a=12$, $b=6$, $c=5$, and $m=9$; and that $x=23$; you will find that the numerical value of the expression is more readily obtained from the second form than from the first. And we may as well tell you here, once for all, that algebraists always take care that their *results* are presented in a form that will give the *least* trouble to the arithmetical computer. This principle will in general be observed in what follows.

We shall now work an example which suggests a principle of some interest in arithmetic.

(6.) Multiply $n+r$ by $n'+r'$.

$$\begin{array}{r} n+r\\ n'+r'\\ \hline nn'+n'r\\ nr'+rr'\\ \hline nn'+n'r+nr'+rr'\\ \hline \end{array}$$

Now suppose a number to be divided by any other number, say 9, and to leave a remainder, which we may denote by r: then, if we express this number, *wanting the remainder*, by n, the entire number will be denoted by $n+r$. In like manner, a second number may be denoted by $n'+r'$, where n and n' represent numbers exactly divisible by 9; and r and r' numbers less than 9. You see by the above expression for the product of the two proposed numbers $n+r$ and $n'+r'$, that the whole of it is necessarily divisible by 9, except the part $r\,r'$, because n or n' is a factor of every other term: you may, therefore, at once conclude that if you divide a *multiplicand* and its *multiplier* each by 9 (or indeed by any other number), and note the remainders (r, r'), and then divide the product of these remainders by 9 (or the other number), the remainder arising from this last division must be the very same as the remainder arising from dividing the *product* of multiplier and multiplicand by 9 (or the other number). And thus you have the principle of *the method of proving multiplication by casting out nines.* (Arith., p. 437). The reason that 9 is chosen for divisor is, because that for the divisor 9, the remainder is the same whether the number itself, or only the sum of the figures composing it, be divided; and it is easier to sum up the figures, and reject the *nines*, than to perform the division on the number.

EXAMPLES FOR EXERCISE.

1. Multiply $2ax^2 - 3bx - 2$ by $3x^2 - 2x$
2. Multiply $4ay + 3bx - 4c$ by $3by + 2c$
3. Multiply out $(5x^3 - 4x^2 + 3x - 2)\,(2x^2 - x + 1)$
4. Multiply out $(x+2)\,(x-2)\,(x+3)\,(x-3)$
5. Multiply out $(x+a)\,(x-a)\,(x^2-a^2)$
6. Multiply out $(2x+3a)\,(4x-5a)\,(x+a)$
7. $(3ax-b)\,(4ax+c)\,(5ax-3)$
8. $(4ax+3by-1)\,(2ax-by+2)$
9. $(x-y)^2(x+y)$ 10. $\{x^2-(a+b)\,x+c\}\,(x-c)$
11. $3^2(x^2-a^2)^2$ 12. $(2x+3)\,(2x-3)\,(4x^2+9)$
13. $\{(x+2)\,(x-2)\}^2$
14. $(x^2-\frac{1}{2}x+1)\,(x^2+2x-1)$

INVOLUTION.

Involution is nothing more than *multiplication:* it is a term employed to signify that the factors multiplied together are all *equal*, the product or result being a *power*. Example 4, for instance, page 460, is a case of involution; for $x+y$ is *raised*, as it is called, or *involved*, to the third power. Involution is thus the operation of raising a proposed quantity to a proposed power, and this operation is *multiplication*. The following are examples of the involution of *simple quantities*.

$(2ax)^3 = 8a^3x^3$, $(2a^2x)^4 = 16a^8x^4$, $(-ax^2y^3)^5 = -a^5x^{10}y^{15}$, &c.

The RULE for obtaining the powers in such cases as these is pretty obvious.

To the power of the *coefficient* annex the letters, with their several exponents *multiplied by the exponent of the power.*

The *rule of signs* must of course be attended to. If the quantity to be raised or involved be *negative*, the sign of every *even* power must be *positive*—that of every *odd* power *negative*. See following examples:—

1. $(3a^2x^2)^2$ 2. $(7by^3)^4$
3. $(-4a^2b^3x^4)^3$ 4. $(2x^4y^2z)^5$
5. $(-3a^3y^2z^2)^6$ 6. $(-8b^2x^5y^3)^3$
7. $(5a^2b^3c^4)^4$ 8. $(-2^2a^3x^2y)^3$

When the quantity to be involved is a compound quantity, the proposed power of it is to be found by multiplying the quantity the requisite number of times by itself, as in the examples below:—

1. To find the cube of $a-2x$.

$$\begin{array}{rl}
 & a-2x \\
 & a-2x \\
\hline
 & a^2-2ax \\
 & \quad\;\; -2ax+4x^2 \\
\hline
(a-2x)^2 = & a^2-4ax+4x^2 \\
 & a-2x \\
\hline
 & a^3-4a^2x+4ax^2 \\
 & \quad -2a^2x+8ax^2-8x^3 \\
\hline
\therefore (a-2x^3) = & a^3-6a^2x+12ax^2-8x^3
\end{array}$$
[*]

2. To find the cube of $3ax-4y$.

$$\begin{array}{rl}
 & 3ax-4y \\
 & 3ax-4y \\
\hline
 & 9a^2x^2-12axy \\
 & \qquad\quad -12axy+16y^2 \\
\hline
(3ax-4y)^2 = & 9a^2x^2-24axy+16y^2 \\
 & 3ax-4y \\
\hline
 & 27a^3x^3-72a^2x^2y+48axy^2 \\
 & \qquad\quad -36a^2x^2y+96axy^2-64y^3 \\
\hline
\end{array}$$

$$\therefore (3ax-4y)^3 = 27a^3x^3-108a^2x^2y+144axy^2-64y^3$$

EXAMPLES FOR EXERCISE.

1. $(a+2x)^2$ 2. $(3ax-4y)^3$ 3. $(a+b+c)^2$
4. $(3x^2+2x+5)^2$ 5. $(a-2b+3c)^2$
6. $\{(a+x)\,(a-x)\}^2$ 7. $\{(x+2)\,(x-2)\}^3$
8. $\{(2x-3)\,(2x+3)\}^4$ 9. $\{(x-a)^2+2ax\}^4$
10. $\{(x+1)\,(x-1)\,(x^2+1)\}^2$ 11. $\{(x-1^2\}^3$

The following is a table of the powers of $(a+x)$ *developed* in order, from $(a+x)^1$ up to $(a+x)^8$: the result of the actual multiplication is called the *development*, and sometimes the *expansion* of a power. The table exhibits the developments of the powers of an expression, consisting of *two* simple terms, a and x. Every expression of two terms is called a *binomial.*

Table of the developments of the powers of a binomial.

$(a+x)^1 = a+x$
$(a+x)^2 = a^2+2ax+x^2$
$(a+x)^3 = a^3+3a^2x+3ax^2+x^3$
$(a+x)^4 = a^4+4a^3x+6a^2x^2+4ax^3+x^4$
$(a+x)^5 = a^5+5a^4x+10a^3x^2+10a^2x^3+5ax^4+x^5$
$(a+x)^6 = a^6+6a^5x+15a^4x^2+20a^3x^3+15a^2x^4+6ax^5+x^6$
$(a+x)^7 = a^7+7a^6x+21a^5x^2+35a^4x^3+35a^3x^4+x21a^2x^5+7ax^6+x^7$
$(a+x)^8 = a^8+8a^7x+28a^6x^2+56a^5x^3+70a^4x^4+56a^3x^5+28a^2x^6+8ax^7+x^8$

This table, which may be carried to any extent, shows that the coefficients of the terms in the development of a binomial follow one another according to a remarkable *law*, by observing which, they may be derived, each from that which precedes it, with very little trouble, so that the actual involution of the binomial may always be dispensed with. By examining the several rows of coefficients, you will discover the law to be this; namely—

If the coefficient of any term be multiplied by the exponent of a in that term, and the product be divided by the number which marks the *place* of the term in the row (as the 2nd place, 3rd place, &c.), the quotient will be the coefficient of the *next* term. Thus, look at the development of $(a+x)^7$. The *first* term in that development we might know to be a^7, without actual multiplication. The coefficient of this first term is 1; and $\frac{7\times1}{1}=7$ is the next coefficient, the complete term being $7a^6x$. This is the second term; and $\frac{6\times7}{2}=21$, is the next coefficient, the third term being $21a^5x^2$; and from this we get $\frac{5\times21}{3}=35$, the next coefficient, the fourth term being $35a^4x^3$. In like manner, from this we find $\frac{4\times35}{4}=35$, the next coefficient; and in this way all the coefficients may be found, one after another, without involution. As to the *letters* connected with these coefficients, the writing of *them* involves no trouble at all. The *first* term is the first term of the binomial, with the exponent of the power over it; the *last* term is the other term of the binomial, with the same exponent over *it;* this is the highest exponent in the row of terms; in each intermediate term, *both* the letters occur in conjunction; and, in proceeding from term to term, the exponents of a regularly *descend* in value, and the exponents of x as regularly *ascend;* that is, the powers of a are—

$$a^7 \quad a^6 \quad a^5 \quad a^4 \quad a^3 \quad a^2 \quad a^1$$

and those of x, $\quad x^1 \quad x^2 \quad x^3 \quad x^4 \quad x^5 \quad x^6 \quad x^7$

the *sum* of the exponents of *both* letters always making

---

[*] See Example 1, p. 460.

7, in every term. And, generally, the sum of the exponents, in each term, is always equal to the exponent of the power.

There are one or two other things which it is important to take note of in looking at the foregoing developments.

1. The number of terms is always *one more* than the number which marks the power of the binomial. Thus, when the exponent is 1, the number of terms is *two*; when the exponent is 2, the number of terms is *three*, and so on; ∴ when the exponent is *odd*, the number of terms is *even*; and when the exponent is *even*, the number of terms is *odd*.

You cannot, therefore, with propriety, speak of *a middle term*, except when the exponent of the power is *even*; when it is *odd*, there are *two middle terms*; and you see that the *coefficients* of these middle terms are always *the same*—another remarkable circumstance.

2. But perhaps the most remarkable thing of all is, that when, in the case of an *even* power, you have reached the middle coefficient, as above directed, the remaining coefficients are got by simply writing those which precede the middle one *in reverse order*; so that these remaining coefficients require no *computing*. When, in the case of an *odd* power, you have reached the first of the two middle coefficients, you have only to *repeat* this coefficient, and then to write all the coefficients, before the middle ones, in reverse order, as in the other case; so that no coefficient beyond the middle *one*, or the middle *pair*, need ever be *computed*; they have only to be *copied*.

The present examination affords a good opportunity to bring another particular for our attention. The foregoing *table* presents us with a set of *equations*, but they differ from the equations solved at pages 456, &c., in a very marked manner; you must take notice of this. The equations at the pages referred to fix certain *conditions*, which the value of x must be such as to satisfy—no *other* values of x would do; but in the equations in the preceding *table*, no *conditions* are implied—both a and x in each may stand for anything whatever; for the second side, or member, is only the first side *developed*, unfolded, or spread out; in other words, one side is nothing but the other side put in a different form; so that, write what we will for a and x, the two sides must of necessity remain equal. Equations such as these, in which one side is only the other in a changed form, are called *identical equations*, or simply *identities*. Now, as in identities anything may be substituted for the *letters*, you may in the table put $-y$ for x; you will thus get the developments of the different powers of $a-y$, or, to be uniform, of $a-x$; all you have to do is to change x into $-x$ on both sides; you will see that the only change in the development is that the *second*, and every *alternate* term, becomes *minus*; thus—

$$(a-x)^3 = a^3 - 3a^2x + 3ax^2 - x^3$$
$$(a-x)^4 = a^4 - 4a^3x + 6a^2x^2 - 4ax^3 + x^4,$$

and so on. With these changes, therefore, in the alternate signs, the table exhibits the developments of the power both of $a+x$ and $a-x$.

What has now been said in reference to the powers of $a+x$, that is, in reference to the powers of a *plus or minus* x, must be very carefully read over, and fully understood. We have been giving to you the leading particulars of the celebrated BINOMIAL THEOREM, and you must try to impress them on your mind. In order to this, you should write out the developments of $(a-x)^6$, $(a-x)^7$, &c., and to try $(a+x)^9$, $(a-x)^9$, &c., finding the coefficients according to the short and easy method explained above; that is, deriving them, one after another, from the *law* shown to prevail, as far at least as to the eighth power. It prevails universally, but the *general* demonstration of the *Binomial Theorem* requires more advanced principles of Algebra; you will do right to refuse assent to the law *at present*, for an exponent higher than 8, unless you like to put it to the test for 9, 10, &c. You will find the theorem in a more general form hereafter. As an application of the Binomial Theorem, let it be required to develope $(a-3y)^5$, which is the same as $(a+x)^5$, when $-3y$ is put for x.

From what is shown above, it appears that the terms, without the coefficient, are—

$$a^5,\ a^4\,(3y),\ a^3\,(3y)^2,\ a^2\,(3y)^3,\ a\,(3y)^4,\ (3y)^5.$$

And from the law of the coefficients, these are—

$$1,\ 5,\ \frac{4\times 5}{2}\ \text{(or 10)},\ 10,\ 5,\ 1;$$

the last three being those of the first three written in reverse order; therefore, remembering to write the terms alternately plus and minus,

$$\begin{aligned}(a-3y)^5 &= a^5 - 5a^4\,(3y) + 10a^3\,(3y)^2 - 10a^2\,(3y)^3 + 5a\,(3y)^4 - (3y)^5,\\ &= a^5 - 15a^4y + 90a^3y^2 - 270a^2y^3 + 405ay^4 - 243y^5\end{aligned}$$

Again, let Example 2, page 461, be taken; namely, $(3ax-4y)^3$. The terms, without the coefficients, are—

$$(3ax)^3,\ (3ax)^2 4y,\ 3ax(4y)^2,\ (4y)^3;$$

therefore, introducing the coefficients, 1, 3, 3, 1, we have—

$$\begin{aligned}(3ax-4y)^3 &= (3ax)^3 - 3\,(3ax)^2 4y + 3.3ax\,(4y)^2 - (4y)^3\\ &= 27a^3x^3 - 108a^2x^2\,y + 144axy^2 - 64y^3.\end{aligned}$$

EXAMPLES FOR EXERCISE.

1. $(a+y)^4$. 2. $(a-x)^5$. 3. $(a+2x)^3$.
4. $(1-x)^6$. 5. $(1+3x)^4$. 6. $(x+2y^2)^5$.
7. $(x^2+3y^2)^6$. 8. $(2a-x)^6$. 9. $(x-2y^2)^7$.

NOTE.—The preceding process may be extended to expressions of *three* terms, *four* terms, &c., in the manner following:—

$$\begin{aligned}[a+b+c]^2 = [\,(a+b)+c]^2 &= (a+b)^2 + 2\,(a+b)\,c + c^2\\ &= a^2 + 2ab + b^2 + 2\,(a+b)\,c + c^2\\ &= a^2 + b^2 + c^2 + 2\,(ab + ac + bc)\end{aligned}$$

$$\begin{aligned}[a+b+c+d]^2 = [\,(a+b)+(c+d)\,]^2 &= (a+b)^2 + 2\,(a+b)\,(c+d) + (c+d)^2\\ &= a^2 + 2\,ab + b^2 + 2\,(ac + ad + bc + bd) + c^2 + 2cd + d^2\\ &= a^2 + b^2 + c^2 + d^2 + 2\,(ab + ac + ad + bc + bd + cd).\end{aligned}$$

So that the square of the sum of *three* quantities, or of the sum of *four* quantities, is equal to the squares of the quantities themselves, together with twice the sum of the products of every possible pair of them; and the same is true for *five*, and for any number of quantities. An extended use of involution will be found in the calculation of logarithms, in a subsequent chapter.

DIVISION.

When one quantity (called the *dividend*) is to be divided by another (called the *divisor*), the object is to find a third quantity (called the *quotient*), such, that if the quotient and divisor be multiplied together, the product will be the dividend; and this is to be brought about whether the quantities concerned are the figures of arithmetic, or the symbols of algebra. The rule for division is thus suggested by that for multiplication; it is as follows:—

CASE I.—*When dividend and divisor are both simple quantities.*

RULE 1.—Determine the *sign* of the quotient, on the principle that if the signs of dividend and divisor be like, the quotient is *plus*: if unlike, *minus*.

2. Having found the sign, next find the coefficient by dividing the coefficient of the dividend by that of the divisor, as in common arithmetic.

3. To the coefficient, annex the *letters*, which must be such, that when they are united to the letters already in the divisor, they may exactly make up those in the dividend.

It is plain, that by following these precepts, you will get a quantity for quotient such, that when it and the divisor are multiplied together, the resulting sign will be that of the dividend, the resulting coefficient also that of the dividend, and finally the resulting letters, arising from combining those of divisor and quotient together, will be the same as the letters in the dividend.

If it should happen that there are letters in the divisor, that is to say *factors* in the divisor, which are not also in the dividend; then, like as in arithmetic, since actual division by these cannot be performed, they must be written as divisors in the quotient; the quotient will then appear as a *fraction* incapable of reduction to a simpler form—just as in division of numbers.

1. Divide $-12a^3x^2y$ by $3ax$. Here $\frac{-12a^3x^2y}{3ax} = -4a^2xy$; for the signs being unlike the sign of the quotient is *minus*; also 12 divided by 3 gives 4, so that -4 is the coefficient in the quotient; and since, from looking at the letters in dividend and divisor, we see that two *a*'s, one *x*, and a *y*, must be united to the divisor to make up the letters in the dividend, these wanting letters are those which the quotient must supply; the complete quotient is therefore $-4a^2xy$. If the divisor had been $3axz$, then the foregoing quotient must have been further divided by *z*; that is, $\frac{-12a^3x^2y}{3axz} = \frac{-4a^2xy}{z}$; for it is plain that to divide by $3axz$ is the same as first to divide by $3ax$ and *afterwards* by the other factor *z*. In like manner, to divide by $3axy^2$ is the same as first to divide by $3axy$, and then again to divide by the other factor *y*, $\therefore \frac{-12a^3x^2y}{3axy^2} = -\frac{4a^2x}{y}$. All this is the same as in arithmetic; thus, if we have to divide 48 by 36, we may proceed as follows: $\frac{48}{36} = \frac{12.4}{12.3} = \frac{4}{3}$; for $\frac{12.4}{12} = 4$, and this divided by the other factor 3, gives $\frac{4}{3}$*

2. $\frac{14a^4x^6y^2}{2ax^3y^2} = 7a^3x^3$ 3. $\frac{-8a^5x^2z}{4a^3x^3z^2} = \frac{-2a^2}{xz}$

4. $\frac{-12b^3y^7x^2}{-4b^4y^3x} = \frac{3y^4x}{b}$ 5. $\frac{7ax^3y^5}{2ax^2y^4} = \frac{7xy}{2}$

6. $\frac{-3x^4y^5z^6}{-4ax^2y^3} = \frac{3x^2y^2z^6}{4a}$ 7. $\frac{-9ay^3z^4}{-6a^2y^2z} = \frac{3yz^3}{2a}$

8. $\frac{-16a^2x^3\sqrt{y}}{-4ax^2} = 4ax\sqrt{y}$

9. $\frac{-4xy\sqrt{z}}{6x^3y^2} = \frac{-2\sqrt{z}}{3x^2y}$ or $-\frac{2\sqrt{z}}{3x^2y}$

NOTE.—When the numerator of a fraction is *minus*, and its denominator *plus*, it is matter of indifference whether we put the minus before the *numerator*, or before the entire fraction; because, from the rule of signs, a *minus* quantity is the result of the division indicated. Thus, in the last example it is indifferent whether we write $-\frac{2\sqrt{z}}{3x^2y}$ or $\frac{-2\sqrt{z}}{3x^2y}$. The same is true when the denominator is *minus*, and the numerator *plus*; for in division of one quantity by another, as in multiplication, whichever of the quantities be minus, provided only the other be plus, the result is minus. Thus, the following all express the same thing: $\frac{-a}{b} = \frac{a}{-b} = -\frac{a}{b}$. For you see, that in either case, when *a* and *b* are interpreted, and the division performed, the quotient is *minus*. For instance—

$$\frac{-6}{2} = -3,\ \frac{6}{-2} = -3,\ -\frac{6}{2} = -3, \text{ \&c.}$$

Before proceeding to the following exercises, it will be well for you to look again at precept 3 of the Rule, from which you may yourself draw an inference of some importance in the general theory of exponents. The inference is, that when *the same letter* occurs in both dividend and divisor, and that the exponent of it in the former is greater than that in the latter; the *quotient*, as far as this letter is concerned, is got by simply subtracting the smaller exponent from the greater, and placing the difference over the letter; thus, in example 2, a^4 in the dividend, and a^1 in the divisor, give a^3 in the quotient, and x^6 in the dividend, and x^3 in the divisor, give x^3 in the quotient; the y^2 in *both* is *cancelled*. You thus see, that when the same letter or quantity is concerned, division becomes the *subtraction of exponents*: multiplication, as you are aware, being the *addition* of *exponents*. You will no doubt think, when the exponent in the divisor is *greater* than that in the dividend, that this view of division must be abandoned; but it is not so, as you will shortly see.

EXAMPLES FOR EXERCISE.

1. Divide $8ax^2y^2$ by $4axy$
2. $-6bx^3y^2z$ by $2bx^3y$
3. $-12x^3y^4z^5$ by $-3x^2y^3z^2$
4. $16ax^2y^3$ by $-4a^3xy^2$
5. $7ax^4yz^2$ by $5a^2x^2yz^3$
6. $-8b^6y^3z$ by $6b^3y^6z^2$
7. $24cy^3$ by $-21c^3y^2z$
8. $-36a^2x^2y^3$ by $2\times7a^2x^4y$
9. $5abx^2\sqrt{y}$ by $10ab^3x\sqrt{y}$
10. $-3a^2c^5x^4$ by $-12ac^2x^4\sqrt{z}$
11. $-2mx^4y^3$ by $8m^2x^4y^6$
12. $-13x^2y^6z^{\frac{1}{2}}$ by $-26y^4\sqrt{z}$†

CASE II.—*When the dividend is a compound quantity, and the divisor a simple quantity.*

RULE 1. Find the quotient of the divisor, and *each term* of the dividend by the former rule.

2. Connect the separate quotients together, by the signs which belong to them, and the complete quotient will be obtained.

1. $\frac{4x^3y^4 - 6x^2y^3 + 8xy^2}{2xy^2} = 2x^2y^2 - 3xy + 4$
2. $\frac{12ax^2z^3 - 8a^2xz^2 - 4xz}{4xz^2} = 3axz - 2a^2 - z^{\frac{1}{3}}$
3. $\frac{21a^3x^2 + 7a^2x^3 - (42a^4x - 28)}{7a^2x}$. Here the *compound* term in the numerator is to be *subtracted* from what precedes, *therefore* the signs of the subtractive quantities are to be changed, and they are then to be added.‡ Hence the fraction is—

$$\frac{21a^3x^2 + 7a^2x^3 - 42a^4x + 28}{7a^2x} = 3ax + x^2 - 6a^2 + \frac{4}{a^2x}$$

EXAMPLES FOR EXERCISE.

1. $\frac{9a^2x^3 - 3a^3x^3 + 6a^4x}{3a^2x}$
2. $\frac{12x^3yz^4 + 6x^3y^3z^3 - 3x^2y^2}{3x^2yz^2}$
3. $\frac{3ax\,(4xy - 8ay^2) + 12axy}{6axy}$
4. $\frac{8x^3y^4 - 4(4ax - 2y)x}{4x^2y}$
5. $\frac{8a^2x^2y^2 - 2(3ax^2y^2z^2 - 1)}{4axy}$
6. $\frac{16a^4b^2x^3 - (8 - 3a^2bx^4)}{4a^2bx^2}$

CASE III.—*When both dividend and divisor are compound quantities.*

RULE 1. Arrange the terms of dividend and divisor so that the exponents of the powers of some one letter in both of them may appear in decreasing or increasing order; that is, if *x*, for instance, be the letter chosen to govern the arrangement, place the terms in either of these two ways:—Let the term containing the highest power of *x* be put first; that containing the next power immediately after, and so on; or else let the term containing the lowest power of *x* be put first, that containing the next lower immediately after, and so on; but do not write the terms at random.

2. The dividend and divisor, thus arranged, being placed as dividend and divisor are placed in arithmetic, divide the *first* term of the dividend by the *first* term of the divisor; the result is the first term of the quotient.

3. Then, as in arithmetic, multiply the *whole divisor* by the part of the quotient thus found, and subtract the product from the dividend.

4. To the remainder annex another term, brought down from the dividend, or annex more of the terms if more are seen, from the extent of the divisor, to be required; the row of terms thus got is a new dividend, with which, and the divisor, proceed as at first, and a second quotient term will be obtained. And in this way

---

* The learner will perceive, that having indicated the division by a fraction, whether the fraction be algebraical or purely numerical, all we have to do is to *cancel* all the *factors* common to numerator and denominator: the result is the value of the fraction, reduced to its simplest form.

† See *ante*, p. 458.

‡ See p. 455.

the operation is to proceed, like the corresponding operation in arithmetic, till all the terms of the dividend have been brought down. When the last term has been brought down, and annexed to the remainder—no term in the dividend having been overlooked or neglected—then the row of terms thus got is the *complete remainder.* Should it happen that the divisor will not *go* into this complete remainder, the operation is at an end, and you do just as you would in the similar case of arithmetic; you place this complete remainder, with the divisor underneath, in the quotient, as a fractional correction.

Divide $6x^2 - ax - a^2$ by $2x - a$. Here dividend and divisor are arranged according to the *descending* powers of x, the highest power of that letter occurring in the first term. If the arrangement be the reverse of this, the operation will be that of the second form below; *minus* the dividend is divided by *minus* the divisor for convenience.*

$$\begin{array}{l}
1.\quad 2x - a)6x^2 - ax - a^2(3x + a \\
\qquad\qquad \underline{6x^2 - 3ax} \\
\qquad\qquad\qquad 2ax - a^2 \\
\qquad\qquad\qquad \underline{2ax - a^2}
\end{array}
\qquad\qquad
\begin{array}{l}
2.\quad a - 2x)a^2 + ax - 6x^2(a + 3x \\
\qquad\qquad \underline{a^2 - 2ax} \\
\qquad\qquad\qquad 3ax - 6x^2 \\
\qquad\qquad\qquad \underline{3ax - 6x^2}
\end{array}$$

$$\begin{array}{l}
3.\quad x^2 + 2ax + a^2)x^5 + 5ax^4 + 10a^2x^3 + 10a^3x^2 + 5a^4x + a^5(x^3 + 3ax^2 + 3a^2x + a^3 \\
\qquad\qquad\qquad\qquad \underline{x^5 + 2ax^4 + a^2x^3} \\
\qquad\qquad\qquad\qquad\qquad 3ax^4 + 9a^2x^3 + 10a^3x^2 \\
\qquad\qquad\qquad\qquad\qquad \underline{3ax^4 + 6a^2x^3 + 3a^3x^2} \\
\qquad\qquad\qquad\qquad\qquad\qquad 3a^2x^3 + 7a^3x^2 + 5a^4x \\
\qquad\qquad\qquad\qquad\qquad\qquad \underline{3a^2x^3 + 6a^3x^2 + 3a^4x} \\
\qquad\qquad\qquad\qquad\qquad\qquad\qquad a^3x^2 + 2a^4x + a^5 \\
\qquad\qquad\qquad\qquad\qquad\qquad\qquad \underline{a^3x^2 + 2a^4x + a^5}
\end{array}$$

$$\begin{array}{l}
4.\quad x - 2)2x^4 - 32\,\dagger(2x^3 + 4x^2 + 8x + 16 \\
\qquad\qquad \underline{2x^4 - 4x^3} \\
\qquad\qquad\qquad 4x^3 \\
\qquad\qquad\qquad \underline{4x^3 - 8x^2} \\
\qquad\qquad\qquad\qquad 8x^2 \\
\qquad\qquad\qquad\qquad \underline{8x^2 - 16x} \\
\qquad\qquad\qquad\qquad\qquad 16x - 32 \\
\qquad\qquad\qquad\qquad\qquad \underline{16x - 32}
\end{array}$$

$$\begin{array}{l}
5.\quad 4x^2 - 7x)12x^5 - 13x^4 - 14x^3 + 3x^2 + 1(3x^3 + 2x^2 + 2 + \dfrac{14x + 1}{4x^2 - 7x} \\
\qquad\qquad\qquad \underline{12x^5 - 21x^4} \\
\qquad\qquad\qquad\qquad 8x^4 - 14x^3 \\
\qquad\qquad\qquad\qquad \underline{8x^4 - 14x^3} \\
\qquad\qquad\qquad\qquad\qquad 8x^2 + 1 \\
\qquad\qquad\qquad\qquad\qquad \underline{8x^2 - 14x} \\
\qquad\qquad\qquad \text{Remainder,} \qquad 14x + 1
\end{array}$$

EXAMPLES FOR EXERCISE.

1. Divide $x^2 - 2x - 35$ by $x - 7$
2. Divide $x^2 - x - 12$ by $x + 3$
3. Divide $6x^2 + 13x + 6$ by $3x + 2$
4. Divide $12x^3 + 29x^2 + 14x$ by $3x^2 + 2x$‡
5. Divide $18x^3 - 33x^2 + 44x - 35$ by $3x^2 - 2x + 5$
6. Divide $x^4 - y^4$ by $x - y$
7. Divide $x^4 - ax^3 - 7ax^2 + 8a^2x - a^3$ by $x - a$
8. Divide $x^2 + (a + b)\,x + ab$ by $x + a$
9. Divide $8x^4y + 2x^3y - 2x^2 - 3x^2y + x$ by $4x^2y + 3xy - 1$
10. Divide $x^6 - x^4 + x^3 - x^2 - 1$ by $x^2 + x - 1$
11. Divide $3\,(2x^2 + 3)\,x^2 - 20x$ by $3\,(x - 1)\,x$
12. Divide $x^2 + px + q$ by $x - a$
13. Divide $x^3 + px^2 + qx + r$ by $x - a$

[It is worthy of notice, that in each of the last two examples, the final *remainder* is the very same as the *dividend*, when the x in it is removed and a is written instead.]

ON EXPONENTS, ROOTS, SURDS.

We have already stated (page 458) that there are two ways of indicating a root of a quantity: one way by means of the *radical sign* $\surd$, placed before the quantity, and another by the introduction of a fraction, written in smaller character, over the right-hand corner of the quantity proposed—this corner fraction being called an *exponent* or *index.* The radical sign is used exclusively for *roots;* exponents are used alike for *roots* and for *powers*—thus, a^4 is the fourth *power* of a, and $a^{\frac{1}{4}}$ is the fourth *root* of a. But exponents or indices have a wider application still. As yet we have had to deal only with *positive* exponents; algebraists, however, have introduced *negative* exponents. We must give some account of these—showing how they have arisen, and what meaning is attached to them.

Your attention has already been drawn to the fact (page 458), that when a quantity with an exponent denoting a power, is to be divided by the same quantity with a smaller exponent, the subtraction of the latter exponent from the former is all that is necessary; thus

---

* Whether one quantity be divided by another, or *minus* the former by *minus* the latter, the result is the same; for $\frac{a}{b}$ is the same as $\frac{-a}{-b}$ whatever a and b may stand for; it is of course the same with multiplication: the factors a, b, give the same product as the factors $-a$, $-b$.

† This is evidently the same as $2x^4 + 0x^3 + 0x^2 + 0x - 32$; so that the -32 need not be brought down till we arrive at the concluding step of the work.

‡ In exercises in division, always expunge, before you begin the operation, whatever factor is obviously common to both dividend and divisor, as you would do if you had to deal with a *fraction*, the dividend being the numerator, and the divisor the denominator. In the example above, the factor x obviously enters all the terms of both dividend and divisor; it is therefore a useless encumbrance, and should be expunged; the division will then be $12x^2 + 29x + 14$ by $3x + 2$. Example 11 admits of a like simplification.

$$\frac{a^5}{a^2}=a^{5-2}=a^3\ ;\ \ \frac{a^3}{a^2}=\underline{a}^{3-2}=\underline{a}^1=\underline{a},\ \&c.$$

Now, this mode of proceeding has suggested the extension of notation adverted to above, giving rise to such expressions as a^0, a^{-1}, a^{-2}, &c.: thus, carrying out the foregoing principle, we have

$$\frac{a^1}{a^1}=a^{1-1}=a^0\ ;\ \text{but}\ \frac{a^1}{a^1}\ \text{or}\ \frac{a}{a}=1,\ \therefore a^0=1,\ \text{a remarkabie result.}$$

$$\text{In like manner,}\ \frac{a^0}{a^1}a^{0-1}=a^{-1}\ ;\ \text{but}\ \frac{a^0}{a}=\frac{1}{a^1}\ \therefore a^{-1}=\frac{1}{a}$$

$$\text{Similarly,}\ \frac{a^{-1}}{a^1}=a^{-1-1}=a^{-2}\ ;\ \text{but}\ \frac{a^{-1}}{a}=\frac{1}{a^2},$$

$$\therefore a^{-2}=\frac{1}{a^2}$$

And in the same way, $a^{-3}=\frac{1}{a^3}$, $a^{-4}=\frac{1}{a^4}$; and *generally*, $\frac{1}{a^n}=a^{-n}$; whatever whole number n may stand for. We thus see that without making any inquiry as to the particular values of m and n, we may always write $\frac{a^m}{a^n}=a^{m-n}$; if $m=3$ and $n=5$, then $\frac{a^3}{a^5}=a^{-2}$, which, as seen above, is only another way of writing $\frac{1}{a^2}$. It may here be observed that *unity* or 1, divided by any quantity, is called the *reciprocal* of that quantity; thus, $\frac{1}{a^2}$ is the reciprocal of a^2; $\frac{1}{a}$ is the reciprocal of a; and so on. And any quantity with a *negative exponent* stands for the reciprocal of that quantity with a *positive exponent*; thus, $a^{-\frac{1}{2}}$ means $\frac{1}{a^{\frac{1}{2}}}$, $a^{-\frac{1}{3}}$ means $\frac{1}{a^{\frac{1}{3}}}$, &c.; so that not only powers and roots, but also the reciprocals of powers and roots, are represented by exponents.

In the instances hitherto given of *fractional* exponents, the numerator of the fraction has always been *unit* or 1, the notation implying a *root* of the quantity to which the exponent is attached. When a *power* of this root is to be indicated, or the *root* of a power, the somewhat cumbersome form used at page 458—namely, $(a^4)^{\frac{1}{3}}$ for the third root of the fourth power of a, or $(a^{\frac{1}{3}})^4$ for the fourth power of the third root of a, is not the notation usually employed; a single fraction is made to serve; the *numerator* of the fraction denoting the *power*, and the *denominator* the *root; thus* $a^{\frac{4}{3}}$ would stand indifferently for the third root of the fourth power of a, or for the fourth power of the third root of a. Whether you regard the power to be taken first and then the root, or the root first and then the power, is of no moment; the *result* is the same. Thus suppose you have $8^{\frac{2}{3}}$; if you regard this as the second power (or square) of the cube or third root of 8, then since the cube root of 8 is 2 (seeing that $2^3=8$), you have $8^{\frac{2}{3}}=2^2=4$; but if, on the contrary, you regard it as the cube root of the square of 8, then since the square of 8 is 64, you have $8^{\frac{2}{3}}=64^{\frac{1}{3}}=4$, as before (seeing that $4^3=64$). Or take the more general case noticed above; namely, $a^{\frac{4}{3}}$. If you regard this as $(a^4)^{\frac{1}{3}}$, you consider it the same as $(aaaa)^{\frac{1}{3}}$. And if you regard $a^{\frac{4}{3}}$ as $(a^{\frac{1}{3}})_4$, you consider it the same as $a^{\frac{1}{3}}a^{\frac{1}{3}}a^{\frac{1}{3}}a^{\frac{1}{3}}$. Now these two results differ only in appearance; for let $a^{\frac{1}{3}}$, that is, the cube root of a, whatever it be, be denoted by c; then, of course, a is c^3; and it is plain that $(c^3c^3c^3c^3)^{\frac{1}{3}}=cccc$; the first side of this *identical equation* being the former of the above expressions, and the second side the latter. It is therefore matter of choice whether you call $a^{\frac{m}{n}}$ the nth root of a^m, or the mth power of $a^{\frac{1}{n}}$; and, in actual numbers, whichever of these two views is most convenient for the purposes of arithmetic, may be taken.

Whenever an exponent in the form of a fraction is such that the numerator and denominator are *the same*, as in $a^{\frac{m}{m}}$, that exponent may be replaced by unit, or 1; because if the mth *power* of any quantity be taken, and then the mth *root* of the result, the original quantity (in this case a) is of course brought back again.

The second operation merely undoes what the first does; the two operations mutually destroy one another, and are $\therefore$ of no effect, so that $a^{\frac{m}{m}}=a$. In consequence of this, such an expression as $a^{\frac{p}{q}\cdot\frac{m}{m}}$ is the same as $a^{\frac{p}{q}}$, since the former means the mth root of the mth power of *this.* When a fractional exponent, therefore, has a factor common to both numerator and denominator, the common factor may be expunged. All that is said above applies as well to negative as to positive exponents, as each expression there considered may be equally regarded as the denominator of a fraction whose numerator is 1. The following is a view of the principal operations with exponents when they are attached to the same quantity:—

$a^{\frac{pm}{qm}}=a^{\frac{p}{q}}$; for example, $a^{\frac{4}{6}}=a^{\frac{2}{3}\cdot\frac{2}{2}}=a^{\frac{2}{3}}$; $a^{\frac{4}{2}}=a^{2\cdot\frac{2}{2}}=a^2$; &c.

$a^m\times a^n=a^{m+n}$; for example, $a^3\times a^2=a^5$; $a^{\frac{1}{3}}\times a^{\frac{1}{2}}=a^{\frac{1}{3}+\frac{1}{2}}=a^{\frac{5}{6}}$

$a^m\div a^n=a^{m-n}$; for example, $a^5\div a^2=a^3$; $a^{\frac{1}{2}}\div a^{\frac{1}{3}}=a^{\frac{1}{2}-\frac{1}{3}}=a^{\frac{1}{6}}$

$(a^m)^n=a^{mn}$; for example, $(a^3)^2=a$; $(a^{\frac{1}{3}})^{\frac{1}{2}}=a^{\frac{1}{6}}$; &c.

That is—

To MULTIPLY. *Add the exponents.*

To DIVIDE. *Subtract the exp. of divisor from exp. of dividend.*

To EXPRESS A POWER OR ROOT. *Multiply the exp. of the quantity, by the exp. of the power or root of it which is proposed.*

In *evolution*, or the *extraction of roots*, there are some particulars respecting *signs* which require to be especially mentioned. In *involution*, or the raising of powers, you have seen that the sign of the result is always fixed by the rule of signs; it is not so in the reverse operation of extraction. For instance, the square of 4 is 16, the 16 being *plus*, whether the 4 be *plus* or *minus;* but the square root of 16 is *ambiguous* as to sign; the numerical value of the root is, of course, 4; but we have as much right to prefix a *minus* to this 4 as a *plus;* since $(-4)^2$ and 4^2 are equally 16. Hence $\sqrt{16}=\pm 4$; that is *plus* or *minus* 4. And there is a like ambiguity, as to sign, in every *even root* of a positive quantity; because the corresponding *even power* of that root would be the same whether a + or a — be prefixed to it: $\sqrt{4}$ or $4^{\frac{1}{2}}$ is ± 2; $\sqrt[4]{16}$ or $16^{\frac{1}{4}}$—is ± 2, and so on. As to an *even root* of a *negative* quantity, the thing is *impossible.* Such an expression as $\sqrt{-4}$ implies an impossible operation; for the *square root* of a quantity is that which, when squared, reproduces the quantity. Now a quantity squared, whether its sign be + or —, is always +; it is impossible $\therefore$ that -4 can be the *square* of anything. Such expressions as $\sqrt{-4}$, $\sqrt{-9}$, $\sqrt{-1}$, &c., are $\therefore$ called *imaginary* or *impossible* quantities; and they answer this purpose, namely—whenever they occur in the solution of a problem, you may take it as a sure indication that the problem implies some impossibility or contradiction. You thus see that the numbers of arithmetic, when introduced into algebra, divide themselves not only into *positive* and *negative*, but also into *real* and *imaginary.* Real numbers, too, are separated into two classes; namely, *rational* and *irrational*, or *surd.* The following are examples of *surds;* namely, $\sqrt{2}$, $\sqrt{3}$, $\sqrt{5}$, $\sqrt{7}$, $\sqrt{10}$, &c. Surds, you see, are *roots;* but roots of numbers that are not themselves the reverse *powers:* 3, 5, 7, 10, &c., are not *squares;* they have $\therefore$ no *exact square roots.* Nevertheless, either of these numbers being proposed, we can always find another number, such that its square shall approach as near to the proposed number as we please; we can thus *approximate*, as it is called, to the square root of 3, or 5, or 7, &c., to any degree of nearness, as was shown in the operation for the square root in decimal arithmetic. There is thus a marked difference between $\sqrt{3}$ and $\sqrt{-3}$; the value of the former can be approximated to, to any degree of nearness; the value of the latter cannot be approached to at all—it has no existence. It may be noticed, however, that both *surds* and *imaginary quantities* may sometimes be simplified in appearance. Thus, $\sqrt{8} = \sqrt{4\cdot2} = 2\sqrt{2}$; $\sqrt{27} = \sqrt{9\cdot3} = 3\sqrt{3}$; $\sqrt{-8} = \sqrt{-2\cdot4} = 2\sqrt{-2}$; $\sqrt{-27} = \sqrt{-3\cdot9} = 3\sqrt{-3}$; $\sqrt{-4} = 2\sqrt{-1}$, &c. This can always be done when the number under $\sqrt{\ }$ can be separated into two factors, one of which is a square; the operation implied in $\sqrt{\ }$ being actually *performed* on this square, it becomes freed from the radical, which then applies only to the other factor. You should never leave under the radical, in any final result, a factor upon which the operation indicated by the radical can be actually performed. Thus, such an expression as $\sqrt{a^2b}$ should be reduced to the simpler form $a\sqrt{b}$. In like manner, $\sqrt[3]{a^3x^3y} = ax\sqrt[3]{y}$; $\sqrt[3]{16ax^3} = \sqrt[3]{8\cdot2ax^3} = 2x\sqrt[3]{2a}$; and so on. It is customary to call such forms as $\sqrt{b}$, $\sqrt[3]{y}$, $\sqrt[3]{2a}$, &c., in which the operation under the radical cannot be performed, *algebraical surds*; although, if the letters were interpreted, it is quite possible that the algebraical surd might prove a *rational number*. Thus, if b were 4, then $\sqrt{b}$ would be ± 2; which is rational, though ambiguous as to sign.

We shall now give you a few examples on the *evolution* of simple quantities, or quantities consisting of but *one term*. It has been stated (p. 461) that quantities consisting of *two* terms are called *binomials*; you will be prepared to expect, therefore, that those of *one* term are often called *monomials*, those of *three* terms *trinomials*, those of four *quadrinomials*; a quantity consisting of more terms comes under the general name of *polynomial* or *multinomial*.

To extract a proposed root of a simple or monomial quantity.

RULE 1. Write the root of the *coefficient* with its proper sign, remembering that an *odd* root, like an *odd* power of any quantity, has the *same sign* as that quantity; but that an *even* root of a *positive* quantity takes the *double sign* $\pm$.

2. *Divide* the exponent of each letter by the exponent of the radical; or, which is the same thing, *multiply* by the fractional index, by which the radical may be replaced; and the proposed root will be obtained.

1. $\sqrt{16a^4x} = 4a^2\sqrt{x}$, or $4a^2x^{\frac12}$. Here the square root of the coefficient 16 is 4; the letters with their exponents are a^4x^1, the index or exp. of the radical is 2; ∴ dividing the exponents by this, the *letters* of the result are $a^{\frac42}x^{\frac12} = a^2x^{\frac12}$. Or replacing the radical by the equivalent exponent, the ex. is $(16a^4x)^{\frac12} = 4(a^4x^1)^{\frac12}$; and *multiplying* the exponents *within* the vinculum, by the exp. *without*, we have $4(a^4x^1)^{\frac12} = 4a^{\frac42}x^{\frac12} = 4a^2\sqrt{x}$. The double sign is not placed before the 4: the reason is, that the extraction is not completed; $\sqrt{x}$ is a still unperformed operation, and the double sign is regarded as still implied in $\sqrt{\ }$.

2. $\sqrt{9a^2x^6} = 3a^{\frac22}x^{\frac62} = \pm 3ax^3$

3. $\sqrt{2a^3x^4} = \sqrt{2a^2ax^4} = ax^2\sqrt{2a}$

4. $\sqrt[3]{-8a^6x^3} = -2a^{\frac63}x = -2a^2x$

5. $\sqrt[3]{27ab^2x^3} = 3a^{\frac13}b^{\frac23}x = 3x\sqrt[3]{ab^2}$

It is to be observed, that when an irrational or surd quantity occurs among the factors of a term, the *letters* composing that term are not arranged in alphabetical order except when the surd is expressed by a fractional exponent; when it is denoted by the sign $\sqrt{\ }$, it is always placed *last*, to prevent all mistake as to the extent of influence of this sign. If the result in the last ex. had been written $3\sqrt[3]{ab^2x}$, it would evidently have conveyed a wrong meaning; it is true this might have been remedied by marking the extent to which $\sqrt[3]{\ }$ reaches by a bar-vinculum, thus, $3\sqrt[3]{\overline{ab^2}}.\,x$; but superfluous marks and signs are always to be avoided, so that the form $3x\sqrt[3]{ab^2}$ is to be preferred; a bar over ab^2 is not required, when it is understood that $\sqrt{\ }$ covers, or extends to, *all* the factors which follow it. We have, indeed, put a bar over similar expressions at page 455, but did so for fear that *you* should limit the influence of the radical; it is best omitted when there is no danger of such mistake being made.

6. $\frac{1}{\sqrt{a^3b^4}} = \frac{1}{ab^2\sqrt{a}}$ or $= a^{-\frac32}b^{-2}$, or $= a^{-1}a^{-\frac12}b^{-2}$.

The first of these forms, namely $\frac{1}{ab^2\sqrt{a}}$, is that which would, in general, be employed; negative indices, though of much importance in certain general investigations, being seldom used in particular expressions. But we must tell you that algebraists do not like to leave surd quantities in the *denominators of fractions*; for as has been said before (page 460), they wish their final results to be in a form the best suited for arithmetical computation. Now, suppose you had to compute $\frac{1}{\sqrt{a}}$, a being interpreted to you;—say $a = 11$. You would have first to find the square root of 11, to several places of decimals; suppose *four* places were considered sufficient, you would then have $\frac{1}{\sqrt{a}} = \frac{1}{\sqrt{11}} = \frac{1}{3\cdot3166}$, and the *division* here indicated would have to be performed. But instead of taking this course, let numerator and denominator of $\frac{1}{\sqrt{a}}$ be multiplied by $\sqrt{a}$, which, from the first principles of arithmetical fractions, you know to be allowable, $\frac{1}{\sqrt{a}}$ would thus be changed into $\frac{\sqrt{a}}{a}$; and you would have to compute $\frac{\sqrt{a}}{a} = \frac{\sqrt{11}}{11} = \frac{3\cdot3166}{11}$. You can *now*, in a moment, pronounce the final result to be ·3015 . . . , which, of course, is the same as the result of $\frac{1}{3\cdot3166}$, but it would have taken you much longer to discover it. Ex. 6 therefore should not be left in the state in which we have left it above; the steps should be:—

$$\frac{1}{\sqrt{a^3b^4}} = \frac{1}{ab^2\sqrt{a}} = \frac{\sqrt{\ }}{ab^2a} = \frac{\sqrt{a}}{a^2b^2}.$$

EXAMPLES FOR EXERCISE.

1. $\sqrt{a^4x^6y}$ 2. $\sqrt[4]{2^4a^4b^8}$ 3. $\sqrt[3]{8a^3x^6z}$
4. $\sqrt[3]{-8a^4x^3y^2}$ 5. $\sqrt{-2a^4y^6z^8}$ 6. $\sqrt{3a^5y^4x}$
7. $(a^2b^3x^4)^{\frac12}$ 8. $\sqrt{x^{\frac13}y^2z^2}$ 9. $\sqrt{\frac{a^2}{bx^2}}$
10. $\sqrt{a^3x^{-4}}$ 11. $\sqrt{a^{-3}x^{-4}y^{-5}}$ 12. $\sqrt{\frac{8a^3}{27x^3y^4}}$
13. $(-8a^3x^2y^6)^{\frac13}$ 14. $(9b^4x^2y^3)^{-\frac12}$ 15. $x^2(81x^6y^7z^8)^{-\frac14}$
16. $\sqrt[3]{-16a^5x^6y^{-9}}$ 17. $(32a^{\frac12}x^2y^4)^{-\frac15}$ 18. $(32a^{-3}x^{-6}y^3)^{-\frac15}$

FRACTIONS.

Algebraic fractious are treated exactly the same as numerical fractions in common arithmetic; the only difference being in the symbols, and not in the operations performed.

To reduce a mixed quantity to an improper fraction.

A quantity is called a mixed quantity when it is partly integral and partly fractional; such a quantity may always be changed into an equivalent one, wholly fractional in form; the result is called an *improper* fraction, as well in arithmetic as in algebra, because an integral quantity is really absorbed into it. The rule for reducing a quantity partly integral and partly fractional to a form wholly fractional, is as follows:—

RULE.—Multiply the integral part by the denominator of the fractional part; connect the product with the numerator, by the sign of that numerator, and place the denominator underneath.

1. $a+\frac{x}{b}=\frac{ab+x}{b}$. Here nothing more is done than replacing a by $\frac{ab}{b}$, which is, of course, equivalent to it. The integral part a is converted into a fractional form, by multiplying it by the *given* denominator b, and dividing the result by the same letter, thus destroying the effect of the multiplication. And this is all that is done in operations of this kind.

2. $a+b-\frac{c}{x}=\frac{(a+b)x-c}{x}$ 3. $a-\frac{b}{x-y}=\frac{a(x-y)-b}{x-y}$

4. $a-\frac{x-y}{b}=\frac{ab-x+y}{b}$

5. $2+\frac{x^2+y^2}{xy}=\frac{2xy+x^2+y^2}{xy}=\frac{(x+y)^2}{xy}$*

6. $\frac{(x+y)^2}{xy}-2=\frac{(x-y)^2}{xy}$ 7. $a+b+\frac{b^2}{a-b}=\frac{a^2}{a-b}$

8. $\sqrt{x}-\frac{x-1}{\sqrt{x}}=\frac{1}{\sqrt{x}}=\frac{\sqrt{x}}{x}$†

To reduce an improper fraction to a mixed quantity.

RULE.—Divide the numerator by the denominator, as far as the division can be carried, and to the quotient annex the *remainder* with the denominator underneath. If there be no remainder, the quotient, which will then be wholly integral, will be the complete value; showing that the so-called improper fraction is an integral quantity disguised under a fractional form.

This operation, you see, is nothing but that of *division:* the examples at page 463, serve as well as any to illustrate the present rule; but a few others may be added here.

1. $\frac{12a^2-4a+3b}{4a}=3a-1+\frac{3b}{4a}$

2. $\frac{a^2-x^2+1}{a-x}=a+x+\frac{1}{a-x}$

3. $\frac{4x^3-25x^2+20x+25}{4x+3}=x^2-7x+10+\frac{x-5}{4x+3}$

4. $\frac{x^4-8x+7}{x^2-3x+2}=x^2+3x+7+\frac{7x-7}{x^2-3x+2}$

EXAMPLES FOR EXERCISE IN THE TWO PRECEDING RULES.

Prove that the following are IDENTICAL EQUATIONS:—

1. $a+x+\frac{x^2}{a-x}=\frac{a^2}{a-x}$

2. $3-y-\frac{2-y^2}{3+y}=\frac{7}{3+y}$

3. $\left(\frac{b+c}{b-c}\right)^2-1=\frac{4bc}{(b-c)^2}$

4. $\frac{a^3+x^3}{a-x}=a^2+ax+x^2+\frac{2x^3}{a-x}$

5. $\frac{a^3-x^3}{a^2+ax+x^2}=a-x$

6. $x^2-a^2+\frac{x^4+a^4}{x^2+a^2}=\frac{2x^4}{x^2+a^2}$

7. $\frac{(x+y+z)(x+y-z)}{2xy}-1=\frac{x^2+y^2-z^2}{2xy}$

8. $\frac{(x+y+z)(x+y-z)}{2xy}-2=\frac{(x-y)^2-z^2}{2xy}$

9. $\frac{x^2+y^2-z^2}{2xy}-1=\frac{(x-y-z)(x-y+z)}{2xy}$

10. $x^2-3x-\frac{3x(3-x)}{x-2}=\frac{x\{(x-1)^2-4\}}{x-2}$

To reduce fractions to a common denominator.

Before fractions can be either added or subtracted they must be reduced to a common denominator. No two quantities can be actually added together, or subtracted the one from the other, so long as the *denominations* of the quantities are different. We cannot *add* 4 shillings to 2 pounds; but can only connect them together as distinct quantities, till both are brought to the same denomination. It is only then that they can be actually incorporated in one sum; 40*s.* and 4*s.* make 44*s.*; the 2 and the 4 make 6; but these are neither pounds nor shillings, and have no meaning in reference to the things proposed. A fraction, like a concrete quantity, denotes a stated number of things of a stated denomination; the *number* is expressed by the *numerator*, the *denomination* by the *denominator;* and ∴ so long as the denominators are different, two fractions can no more be added or subtracted than pounds and shillings. It follows, therefore, that before fractions can be fitted for addition or subtraction, they must be prepared for these operations by a previous reduction of them to common denominators. The rule for this reduction is given below; it is founded upon the obvious principle that a fraction is not altered in value, though the numerator be multiplied by any quantity whatever, provided only that the denominator be multiplied by the same thing; since the new factor in the denominator just counteracts the influence of the same factor in the numerator: a multiplication, and then a division by the same thing, leaves the quantity operated upon, whatever it may be, virtually untouched.

RULE 1.—Multiply *each* numerator by the product of all the denominators *except its own;* the results will be the numerators of the changed fractions.

2. The product of *all* the denominators will be the denominator common to all the changed fractions.

This rule will effect the reduction of fractions to a common denominator in all cases; but sometimes the desired change may be brought about in an easier way. The common denominator, found by the rule, is evidently such that each of the proposed denominators is always *a factor* of it. It is the object of the rule to make sure of such a number in every case; but it often happens that a *smaller* number exists, such that each denominator is a factor of it; and whenever such smaller number can be discovered with little trouble, it is of course better to use *it*, than a larger number. The smallest number possible is called the *least common multiple* of the denominators; and a little examination of the denominators will often enable us to arrive at it very readily, as will be seen in some of the following examples:—

1. $\frac{a}{x}+\frac{b}{y}+\frac{c}{z}=\frac{ayz}{xyz}+\frac{bxz}{xyz}+\frac{cxy}{xyz}$

Here the three fractions on the right of the sign of equality are respectively the same, in value, as those on the left; and the denominator xyz is common to all.

2. $\frac{x+a}{2}+\frac{b}{3}+\frac{1}{5}=\frac{15(x+a)}{30}+\frac{10b}{30}+\frac{6}{30}$

3. $\frac{2x+3}{x}-\frac{5x+1}{3}=\frac{6x+9}{3x}-\frac{5x^2+x}{3x}$

4. $\frac{2x+1}{6a}+\frac{5x}{4}$. Here it is plain that 12 is a number, and the *least* number, such that 6 and 4 are each a factor of it, ∴ $12a$ is the least common multiple of $6a$ and 4, so that the common denominator need be no higher than $12a$; this $12a$ is the first denominator above multiplied by 2, ∴ multiplying the numerator also by 2, the changed fraction is $\frac{2(2x+1)}{12a}$. Again, the same $12a$ is the second denominator multiplied by $3a$, ∴ multiplying the numerator also by $3a$, the second changed fraction is $\frac{15ax}{12a}$; so that $\frac{2x+1}{6a}+\frac{5x}{4}=\frac{2(2x+1)}{12a}+\frac{15ax}{12a}$ By the *rule* the common denominator would have been twice as great.

5. $\frac{2x}{x^2-a^2}+\frac{3}{x+a}$ Here, since we know that $(x+a)$

---

* See *ante*, p. 460.   † See p. 465.

$(x-a)=x^2-a^2$, the second fraction will be converted into one with a denominator the same as the first, by merely multiplying numerator and denominator of the second by $x-a$, $\therefore$ the fractions are $\frac{2x}{x^2-a^2}+\frac{3(x-a)}{x^2-a^2}$.

6. $\frac{2x}{3ab^3}+\frac{x}{2a^2b^2}+\frac{5}{6ab}$. Here the *coefficient* of the common denominator is 6, the least number divisible by coefficients 3, 2, and 6; the letters are a^2b^3, the least quantity divisible by a^2b^3, a^2b^2, and ab, $\therefore$ the changed fractions are $\frac{4ax}{6a^2b^3}+\frac{3bx}{6a^2b^3}+\frac{5a^2b^2}{6a^2b^3}$; each fraction *here* differing from that which it replaces only in appearance —it is the original fraction with numerator and denominator multiplied by the same thing.

It will not be necessary that we should give any exercises expressly for practice in the preceding rule. The examples furnished in addition and subtraction— the rule for which we are now about to give, will equally afford practice in the foregoing operation; for, as you have already seen, all fractions must have a common denominator before they can be either added or subtracted. We shall therefore at once proceed to

ADDITION AND SUBTRACTION OF FRACTIONS.

Rule.—*Addition.*—Reduce the fractions to equivalent ones with a common denominator, which place under the *sum* of the changed numerators.

Subtraction.—Reduce the fractions to equivalent ones with a common denominator, which place under the *difference* of the changed numerators.

1. $\frac{x+a}{2}+\frac{b}{3}+\frac{1}{5}=\frac{15(x+a)+10b+6}{30}$

2. $\frac{2x+3}{x}-\frac{5x+1}{3}=\frac{9+5x-5x^2}{3x}=\frac{9+5x(1-x)}{3x}$

3. $\frac{a+b}{a-b}+\frac{a-b}{a+b}=\frac{(a+b)^2+(a-b)^2}{a^2-b^2}=\frac{2(a^2+b^2)}{a^2-b^2}$

4. $\frac{a+b}{a-b}-\frac{a-b}{a+b}=\frac{(a+b)^2-(a-b)^2}{a^2-b^2}=\frac{4ab}{a^2-b^2}$

5. $\frac{2x-3}{3x}-\frac{4x+2}{3}=\frac{2x-3-(4x+2)x}{3x}=-\frac{4x^2+3}{3x}$

6. $\frac{1}{a^n}+\frac{1}{a^n+1}=\frac{a+1}{a^n+1}$

7. $1-\frac{x^2-y^2}{x^2+y^2}=\frac{x^2+y^2-(x^2-y^2}{x^2+y^2}=\frac{2y^2}{x^2+y^2}$

8. $\frac{x^2+y^2}{xy}-2=\frac{x^2+y^2-2xy}{xy}=\frac{(x-y)^2}{xy}$

In this example, as well as in the preceding, an *integer* occurs in connection with a fraction; and it may here be noticed, that an integer may always be put in the form of a fraction by simply giving to it 1 for denominator: thus, in the present example, the 2 may be regarded as $\frac{2}{1}$.

EXAMPLES FOR EXERCISE.

Note.—It sometimes happens that the sum or difference of fractions is a fraction such that numerator and denominator have a factor common to both. Such common factors should always be expunged from the final result, whenever they are seen to enter: they only serve to give to the fraction an appearance unnecessarily complicated. A fraction thus deprived of all common factors in numerator and denominator is said to be in its *lowest terms*, the numerator and denominator being called *the terms of the fraction*.

1. $\frac{2x-5}{3}+\frac{x-1}{2x}$
2. $\frac{x}{x-3}+\frac{x}{x+3}$
3. $\frac{10x-9}{8}-\frac{3x-5}{7}$
4. $\frac{2x-3}{7x}-\frac{x-5}{8x}$
5. $\frac{x-a}{x^2-ax+a^2}+\frac{1}{x+a}$
6. $1-\frac{x-a}{x+a}$
7. $\frac{a^2x}{xy}-\frac{b^2x}{yz}$
8. $\frac{1}{x}+\frac{1}{x^2}-\frac{1}{x^n}$
9. $\frac{1}{2x-a}+\frac{1}{2x+a}-\frac{4x^2}{4x^2-a^2}$
10. $\frac{1+x}{1+x+x^2}-\frac{1-x}{1-x+x^2}$
11. $\frac{a^2+b^2}{a^2-b^2}+\frac{a+b}{a-b}-\frac{a-b}{a+b}+2$
12. $\frac{y}{y-3}-\frac{y-3}{y}+\frac{y}{y+3}-\frac{y+3}{y}$
13. Show that $\frac{x}{x+y}+\frac{y}{x-y}=\frac{x}{x-y}-\frac{y}{x+y}$
14. $\frac{x}{x+z}-\frac{y}{y+z}=\frac{z}{y+z}-\frac{z}{x+z}$

Note.—The student may obtain considerable assistance in the study of the addition, &c., of algebraic fractions, by combining with it that of the arithmetical branch of the same subject.*—Ed.

MULTIPLICATION OF FRACTIONS.

If a fraction $\frac{a}{b}$ is to be multiplied by an integer c, we have to take a things, of denomination b, c times; the product is therefore $\frac{ac}{b}$; that is, ac of those things, just as if we had to multiply a pounds, or a ounces, by c, the product would be ac of those pounds or ounces. But, if instead of c, we are to multiply only by the dth part of c, then, of course, the product will be only the dth part of the former; that is, it will be $\frac{ac}{b}\div d$, or $\frac{ac}{bd}$, $\therefore \frac{a}{b}\times\frac{c}{d}=\frac{ac}{bd}$. This suggests the rule, which is as follows:

Rule 1.—Multiply the numerators together, the result will be the *numerator of the product.*

2 Multiply the denominators together, and the result will be the *denominator of the product.*

Note.—Before performing the operation, see whether either of the fractions can be reduced to *lower terms;* if so, reduce the fraction. And after the operation, see whether a like reduction can be easily made in the result; if so, reduce accordingly. (See preceding Note).

It is of importance, in dealing with algebraic fractions, that we always keep in remembrance the factors of such expressions as a^2-b^2, a^4-b^4, a^6-b^6, &c.; as also of $a^2+2ab+b^2$, and $a^2-2ab+b^2$. You have seen at page 460, that the *difference* of the *squares* of two quantities is the *product of the sum and difference* of the quantities; so that $a^2-b^2=(a+b)(a-b)$; $a^4-b^4=(a^2-b^2)(a^2-b^2)$; $a^6-b^6=(a^3+b^3)(a^3-b^3)$, &c.; also that $a^2+2ab+b^2=(a+b)(a+b)$, or $(a+b)^2$; and that $a^2-2ab+b^2=(a-b)(a-b)$, or $(a-b)^2$. As there will be frequent occasion to apply these truths in operations with fractions, we repeat them here, that you may have full warning of what you will be expected to remember.

1. $\frac{3x}{x-1}\times\frac{2x}{x+1}=\frac{6x^2}{(x-1)(x+1)}=\frac{6x^2}{(x-1)^2}$

2. $\frac{3x^2-x}{5}\times\frac{10}{2x^2-3x}$. Here it is easy to see that the factor x will enter into both numerator and denominator of the product: it is useless to allow it thus to enter, and afterwards to expunge it; we, therefore, silently suppress or *cancel* this common factor, and so preclude its appearance altogether. In like manner, the factor 5, foreseen to enter numerator and denominator of the product, is, at the outset, *cancelled;* so that, before actually multiplying, we imagine the factors changed for $\frac{3x-1}{1}\times\frac{2}{2x-3}=\frac{2(3x-1)}{2x-3}$, the product in its lowest terms. You are aware that all this is exactly what we should do in common arithmetic: and have, in fact, nothing to learn in the management of algebraic fractions that is not equally necessary in the fractions of pure arithmetic. Suppose the example here commented upon had been $\frac{3x^2-x}{5}\times\frac{10}{2x^2-4x}$; then, seeing that the second fraction has the factor 2 common to numerator and denominator, you would here, as in arithmetic,

---

* See *ante*, p. 443, *et seq.*

expunge or cancel that factor; and, to make each step perfectly plain, might write—

$$\frac{3x^2-x}{5}\times\frac{10}{2x^2-4x}=\frac{3x^2-x}{5}\times\frac{5}{x^2-2x}=\frac{3x-1}{1}\times\frac{1}{x-2}=\frac{3x-1}{x-2}$$

EXAMPLES FOR EXERCISE.

1. $\frac{4x}{7}\times\frac{5}{9x}$ 2. $\frac{4x+1}{3}\times\frac{6x}{7}$ 3. $\frac{4x+2}{3}\times\frac{5x}{2x+1}$

4. $\frac{2x-1}{x+2}\times\frac{3x+1}{x-3}$ 5. $\frac{a+b}{b}\times\frac{b^2x}{a^2-b^2}$

6. $\frac{x^3-a^2x}{a^2}\times\frac{x}{ax-a^2}$ 7. $\frac{x^n}{y^m}\times\frac{x^m}{y^n}$ 8. $\frac{x^n}{y^m}\times\frac{y^n}{x^m}$

9. $\frac{3\sqrt{x}}{y}\times\frac{2y^2}{5\sqrt{x}}$ 10. $\frac{x^2-4a^2}{x-a}\times\frac{x^2-a^2}{x+2a}$

11. $\frac{2x}{7}\times\frac{4x}{9}\times\frac{7}{4x}\times\frac{9x}{5}$ 12. $\frac{4x+2}{3}\times\frac{5x}{2x+1}\times\frac{9x-3}{x}$

13. $\frac{(x-y)^2}{x^2-y^2}\times\frac{x+y}{x-y}$ 14. $\frac{(x-y)^2}{x^4-y^4}\times\frac{x+y}{x-y}$

15. $\left(a-\frac{b^2}{a}\right)\left(\frac{a}{b}+\frac{b}{a}\right)$

DIVISION OF FRACTIONS.

If a fraction $\frac{a}{b}$ is to be divided by an integer c, the result is of course $\frac{a}{bc}$; but if it is to be divided, not by c, but by only the dth part of c, that is, by $\frac{c}{d}$, then the quotient will be d times the former quotient, as is obvious; that is to say, the quotient will be $\frac{a}{bc}\times d$, or $\frac{ad}{bc}$. Hence division is converted into multiplication, as directed in the following rule:—

RULE.—Invert the terms of the *divisor*, or turn it upside down, and proceed as in multiplication.

1. $\frac{3x-2}{2x}\div\frac{5x+1}{7x}=\frac{3x-2}{2x}\times\frac{7x}{5x+1}=\frac{7(3x-2)}{2(5x+1)}$

2. $\frac{x^4-y^4}{(x-y)^2}\div\frac{x^2+xy}{x-y}=\frac{x^4-y^4}{(x-y)^2}\times\frac{x-y}{x(x+y)}=\frac{(x^2+y^2)(x^2-y^2)}{x-y}\times\frac{1}{x(x+y)}=\frac{(x^2+y^2)(x^2-y^2)}{x^2-y^2}\times\frac{1}{x}=\frac{x^2+y^2}{x}$

3. $\left(\frac{a^2}{x}-\frac{x^3}{a^2}\right)\div\left(\frac{a}{x}+\frac{x}{a}\right)=\frac{a^4-x^4}{a^2x}\times\frac{ax}{x^2+x^2}=\frac{a^2-x^2}{a}$

EXAMPLES FOR EXERCISE.

NOTE.—*Before* inverting the divisor, you may always expunge factors common to either *both numerators*, or to *both denominators:* thus, the x in the denominators of example worked in the last page, might have been omitted, as also $x-y$ in each denominator of Example 1.

1. $\frac{x}{x-2}\div\frac{x-1}{x^2+2}$ 2. $\frac{a+1}{a}\div\frac{a^2-1}{a}$

3. $\frac{x^2-9}{5}\div\frac{x+3}{4}$ 4. $\frac{6x^2-2x}{4-x^2}\div\frac{x^2}{2-x}$

5. $\frac{9x^2-4y^2}{x+y}\div\frac{3x-2y}{x^2-y^2}$ 6. $\frac{x^3-y^3}{x^2-2xy+y^2}\div\frac{x^2+xy}{x-y}$

CHAPTER III.

ALGEBRA.—EQUATIONS.

AT page 456, a rule was given for the solution of a simple equation, and several examples were proposed to show its practical application. These examples, however, were selected with a view to your acquaintance with the operations of algebra at that stage of your progress. You may now attempt equations of a higher order of difficulty, and apply the following more general rule for that purpose.

GENERAL RULE *for the solution of a simple equation with one unknown quantity.*

1. Clear the equation of fractions, if there be any. This may be done by multiplying *each* numerator by *all* the denominators except its own; or by taking a common multiple of the denominators and then multiplying *each numerator* by this multiple, after suppressing that factor in it which is equal to the *denominator.*

2. Clear the equation of radical signs, if there be any. This is done by causing the quantity under the radical we wish to remove, to stand *alone* on one side of the equation, and then performing the operation the *reverse* of that indicated by the radical, on *both* sides of the equation. Thus, if the radical be $\sqrt{\ }$, we must *square* both sides; if it be $\sqrt[3]{\ }$, we must *cube* both sides; and so on. This reverse operation evidently disengages the quantity from the radical; if *two* radicals enter, the operation must be repeated in reference to the *second* radical. Transposing, collecting, &c., are sufficiently explained in the former rule. It need only be added here, that the example itself must suggest the order in which the precepts given in either rule should follow one another.

1. $\frac{x}{5}+\frac{x}{4}=\frac{x}{2}-\frac{x}{3}+17$. Here, if each numerator be multiplied by the product of the denominators of all the *other* fractions (regarding 17 as $\frac{17}{1}$), we shall have $24x+30x=60x-40x+2040$, $\therefore 24x+30x+40x-60x=2040$; that is, $34x=2040$, $\therefore x=\frac{2040}{34}=60$.

But if we take the least common multiple of 5, 4, 2, 3, which is easily seen to be 60, we shall have to multiply the first numerator by $\frac{60}{5}$ or 12, the second by $\frac{60}{4}$ or 15, the third by $\frac{60}{2}$ or 30, the fourth by $\frac{60}{3}$ or 20, and the last (17) by $\frac{60}{1}$ or 60. The equation cleared of fractions in this way will be—

$$12x+15x=30x-20x+1020,\ \therefore 12x+15x+20x-30x=1020.$$

$$\text{That is, } 17x=1020,\ \therefore x=\frac{1020}{17}=60.$$

It is plain, that, whichever method be used, the equation free from fractions always arises from multiplying both sides of the original equation by the same quantity; thus, in the first way, each side is multiplied by 120, the product of the denominators; in the second way, each side is multiplied by 60, the least common multiple of the denominators.

2. $x+\sqrt{6x+x^2}=3$. Transposing the x, agreeably to precept 2, of the rule, $\sqrt{6x+x^2}=3-x$; and squaring both sides, $6x+x^2=9-6x+x^2$

$$\therefore 6x=9-6x,\ \therefore 12x=9,\ \therefore x=\frac{9}{12}=\frac{3}{4}.$$

3. $\sqrt{x+7}-\sqrt{x}=1$. Transposing, $\sqrt{x+7}=\sqrt{x}+1$. Squaring both sides, $x+7=x+2\sqrt{x}+1$. Transposing again, to get the radical *alone* on one side, $x-x+7-1=6=2\sqrt{x}$, $\therefore 3=\sqrt{x}$, $\therefore$ (squaring) $9=x$.

4. $\frac{1}{a^2-x^2}-a=\frac{ax}{a-x}+\frac{a}{a+x}$. Here it is evident that $(a-x)(a+x)$, or a^2-x^2 is the least common multiple of the denominators.

$$\therefore 1-a(a^2-x^2)=ax(a+x)+a(a-x),$$

that is, $1-a^3+ax^2=a^2x+ax^2+a^2-ax$. Transposing the unknown terms to the left, $\therefore ax-a^2x=a^3+a^2-1$, that is, $(1-a)ax=a^3+a^2-1$.

$$\therefore x = \frac{a^3 + a^2 - 1}{(1-a)a}, \text{ or } \frac{(a+1)a^2 - 1}{(1-a)a}.$$

As already remarked at page 467, we may, if we please, always *change the signs* of numerator and denominator of a fraction, so that it would be equally correct to write the preceding expression for x thus: $x = \frac{1-(a+1)a^2}{(a-1)a}$.

5. $\sqrt{a+x} + \sqrt{x} + b = c$. Transposing, $\sqrt{a+x} = c - b - \sqrt{x}$.
Squaring, $a + x = (c-b)^2 - 2(c-b)\sqrt{x} + x$.
Transposing, $2(c-b)\sqrt{x} = (c-b)^2 - a$.
Squaring. $4(c-b)^2 x = \{(c-b)^2 - a\}^2$.

$$\therefore x = \left\{\frac{(c-b)^2 - a}{2(c-b)}\right\}^2.$$

This example is in appearance difficult, but in reality it is easy. If you look at the operations actually *performed*, you will see that they are very trifling; the work is for the most part merely *indicated*, not *executed*; and such, in general, is the case when we have to deal exclusively with *literal*, and not with *numerical* quantities. The work of an algebraic problem is usually the greater, as the merely numerical operations are greater; because these must be actually performed: it is the *arithmetic*, not the algebra, that occasions the labour. An example purely algebraical, like that above, requires only a little address in the deduction of one step from another; a little caution in the management of signs, and some care in *indicating* processes, which arithmetic must *perform* when the symbols are interpreted by numbers. It is not easy, however, to embody in a *rule* all the expedients and artifices which may with advantage be resorted to in the solution of a simple equation; these must be acquired by observation and experience, by the exercise of your own ingenuity, and the suggestions of common sense. A little thought and reflection will often do more than the most elaborate *rule*. The following example will serve to illustrate these remarks:—

6. $\frac{\sqrt{a^2+x^2}+x}{\sqrt{a^2+x^2}-x} = \frac{b}{c}$. In this example, the removal of the radicals is evidently the first thing we should try to effect; and it is easy to see that if we were to attempt this by implicitly following the precepts in the rule, we should soon have to deal with complicated expressions. Let us try to evade these by a little ingenuity. You see that if we were at liberty to subtract the denominator of the first member from the numerator, the upper radical would be removed at once: this suggests the subtracting 1 from each side; we therefore make the following the first step, namely—

$$\frac{\sqrt{a^2+x^2}+x}{\sqrt{a^2+x^2}-x} - 1 = \frac{b}{c} - 1\text{; that is, } \frac{2x}{\sqrt{a^2+x^2}-x} = \frac{b-c}{c}.$$

And as it is in general less inconvenient to have a radical in the numerator than in the denominator of a fraction, we shall take the *reciprocals* of these fractions; that is, shall simply turn them upside down, writing the equation thus—

$$\frac{\sqrt{a^2+x^2}-x}{2x} = \frac{c}{b-c} \therefore \sqrt{a^2+x^2} = \left(\frac{2c}{b-c}+1\right)x$$
$$= \frac{b+c}{b-c}x \ldots [\text{A}]$$

$$\therefore \text{squaring each side, } a^2 + x^2 = \left(\frac{b+c}{b-c}\right)^2 x^2 \therefore \frac{a^2}{x^2} + 1$$
$$= \left(\frac{b+c}{b-c}\right)^2$$

$$\therefore \frac{a^2}{x^2} = \left(\frac{b+c}{b-c}\right)^2 - 1 = \frac{4bc}{(b-c)^2} \therefore \frac{x^2}{a^2} = \frac{(b-c)^2}{4bc}$$
$$\therefore x = \frac{a(b-c)}{2\sqrt{bc}}, \text{ or } = \frac{a(b-c)\sqrt{bc}}{2bc}.$$

The step marked [A] may be reached a little differently by help of a property of *two equal fractions*, which you will do well to remember, and apply in examples like that above. Let $\frac{p}{q}, \frac{b}{c}$ be two equal fractions ($\frac{p}{q}$ may stand for the first member of the given equation above); then *subtracting* 1 from each, we have—

$$\frac{p-q}{q} = \frac{b-c}{c}.$$

Also, *adding* 1 to each, we have—

$$\frac{p+q}{q} = \frac{b+c}{c}.$$

Now divide these results by the former, and we get—

$$\frac{p+q}{p-q} = \frac{b+c}{b-c}.$$

By applying this property to the given equation, we get at once—

$$\frac{\sqrt{a^2+x^2}}{x} = \frac{b+c}{b-c}, \text{ and thence } \sqrt{a^2+x^2} = \frac{b+c}{b-c}x.$$

EXAMPLES FOR EXERCISE.

NOTE.—Examples 8, 9, 10, 11, and 16, have been selected with a view to the application of the principle just explained. Remember, in Ex. 15, that *sum.* × *diff.* = *diff. of squares.*

1. $\frac{2x}{5} + \frac{x}{2} = 22 + \frac{x}{6}$ 2. $\frac{x}{2} + \frac{x}{3} + \frac{x}{4} = 6\tfrac{1}{2}$

3. $\frac{x}{2} - \frac{x}{4} = \frac{x}{3} - \frac{x}{6} + 1$ 4. $\frac{18+x}{x} = \frac{6}{x} + 5$

5. $21 + \frac{3x-11}{16} = \frac{5(x-1)}{8} + \frac{97-7x}{2}$

6. $\sqrt{x^2+7} + x = 7$ 7. $\sqrt{x-a} - b = 0$

8. $\frac{\sqrt{x}+2}{\sqrt{x}-2} = \frac{3}{2}$ 9. $\frac{\sqrt{x}+28}{\sqrt{x}+4} = \frac{\sqrt{x}+38}{\sqrt{x}+6}$

10. $\frac{\sqrt{x}+2a}{\sqrt{x}+b} = \frac{\sqrt{x}+4a}{\sqrt{x}+3b}$ 11. $\frac{\sqrt{ax}-a}{\sqrt{ax}+a} = \frac{3\sqrt{ax}-2a}{3\sqrt{ax}+5a}$

12. $\sqrt{(x-24)} = \sqrt{x} - 2$ 13. $\sqrt{(4x+21)} = 2\sqrt{x} + 1$

14. $\sqrt[3]{(2x+3)} = 3$ 15. $\frac{5x-9}{\sqrt{5x}+3} = \frac{\sqrt{5x}-1}{2}$

16. $\frac{\sqrt{x+1}-\sqrt{x-1}}{\sqrt{x+1}+\sqrt{x-1}} = \frac{1}{2}$

Simple Equations with Two Unknown Quantities.

There are *three* methods of solving a pair of simple equations containing two unknown quantities. We shall illustrate them by an example:—

1. Find the values of x and y in the equations,

$$\begin{cases} 2x + 5y = 23, \\ 3x - 2y = 6. \end{cases}$$

From the first equa., by trans., $2x = 23 - 5y$ ∴

$$x = \frac{23-5y}{2}.$$

From the second equa., by trans., $3x = 6 + 2y$ ∴

$$x = \frac{6+2y}{3}.$$

Equating these two different expressions for x, we have $\frac{23-5y}{2} = \frac{6+2y}{3}$. ∴ (clearing) $69 - 15y = 12 + 4y$ ∴ trans. $-19y = -57$ ∴ $y = 3$. Substituting this value for y in either of the expressions for x, the second, for instance, we have $x = \frac{6+6}{3} = 4$ ∴ $x = 4$, $y = 3$. This method, you see, consists in equating the expressions for the *same* unknown quantity, as deduced from the two equations.

---

2. Having found an expression for x from *one* of the equations, as, for instance, $x = \frac{6+2y}{3}$, substitute it for x in the *other* equation, and we get $\frac{2(6+2y)}{3} + 5y = 23$; ∴ clearing and removing brackets,

$$12 + 4y + 15y = 69 \therefore 19y = 57 \therefore y = 3,$$

so that x or $\frac{6+2y}{3}=\frac{6+6}{3}=4 \mathrel{.\cdot.} x=4,\ y=3.$

This is called the method of substitution.

---

3. In the third method, the first object is to convert the proposed equations into forms such that one of the unknown quantities may have *the same coefficient* in each; thus:—multiplying the first equation by 3, and the second by 2, they become changed into

$$\begin{aligned} 6x+15y&=69\\ 6x-\ \ 4y&=12 \end{aligned}$$

By subtracting, $19y=57 \therefore y=3$

And this value put for y in one of the given equations, in the second for instance, there results, $3x-6=6 \therefore$

$$x=\frac{12}{3}=4.$$

Or without, in this way, borrowing from the method of substitution, multiply the first equation by 2, and the second by 5: they then change into

$$\begin{aligned} 4x+10y&=46\\ 15x-10y&=30 \end{aligned}$$

By adding, $19x=76 \therefore x=4$

This is the method of *equalising the coefficients* of the same unknown quantity in the two equations. When this equality is brought about, then addition or subtraction, according as the *signs* of the equal coefficients are unlike or like, will of course remove one of the unknown quantities altogether: when one of the unknown quantities is thus got rid of, it is said to be *eliminated*.

The operations by the three methods may be stated in a rule as follows:—

RULE 1. *By equating two expressions for the same unknown quantity.*—Find an expression for one of the unknown quantities from the first equation. Find an expression for the same from the second equation. Equate these two expressions, and you will then have but a single equation with one unknown quantity, the value of which may be found by the former rules. The value of the other is got by substituting the *value* just found in one of the expressions in place of its *symbols*.

2. *By substitution.*—Find an expression for one of the unknown quantities from either equation, and substitute this expression in place of that unknown in the other equation: an equation with but one unknown quantity will be the result.

3. *By equalising coefficients.*—Multiply the two equations by such numbers (or quantities), the smaller the better, as will cause the resulting coefficients of one of the unknown quantities to be *the same* in the two changed equations: then by addition or subtraction, according as the equal coefficients have unlike or like signs, an equation will arise having only one unknown quantity. *Both* may be *eliminated* one after the other in this way; or having eliminated one, and then found the value of the other from the resulting equation, the value of the former may then be got by substitution, as in the example above.

1. Find the values of x and y from the equations $\left\{\begin{aligned} \frac{x}{6}+\frac{y}{4}&=6\\ \frac{x}{4}+\frac{y}{6}&=5\tfrac{2}{3} \end{aligned}\right.$

Multiplying the first equation by 2 and the second by 3,

$$\begin{aligned} \frac{x}{3}+\frac{y}{2}&=12\\ \frac{3x}{4}+\frac{y}{2}&=17 \end{aligned}$$

Subtracting, $\frac{3x}{4}-\frac{x}{3}=5 \therefore 9x-4x=60 \therefore 5x=60 \therefore x=12$

$$\therefore \text{(equation 1) } 2+\frac{y}{4}=6 \therefore \frac{y}{4}=4 \therefore y=16.$$

2. $\left.\begin{aligned} \frac{x}{2}+\frac{y}{3}&=7\\ \frac{x}{3}+\frac{y}{2}&=8 \end{aligned}\right\} \therefore$ clearing, $\left.\begin{aligned} 3x+2y&=42\\ 2x+3y&=48 \end{aligned}\right\}$ . . . [A] $\therefore x=24-\frac{3y}{2}$

Substituting this value of x in the first equation,

$$72-\frac{9y}{2}+2y=42$$

$$\therefore 144-9y+4y=84 \therefore 60=5y \therefore 12=y$$

$$\text{And } x=24-\frac{3y}{2}=24-18=6.$$

Or, subtracting the upper from the lower of [A],

$$-x+y=6 \therefore y=6+x.$$

Substituting this in the former,

$3x+12+2x=42 \therefore 5x=30 \therefore x=6 \therefore y=6+x=12.$

This latter is the easier mode of proceeding: such slight departures from *rule*, as in equations with one unknown, may often be adopted with advantage.

EXAMPLES FOR EXERCISE.

1. $\left.\begin{aligned} 2x+3y&=23\\ 5x-2y&=10 \end{aligned}\right\}$ 2. $\left.\begin{aligned} 5x+4y&=58\\ 3x+7y&=67 \end{aligned}\right\}$

3. $\left.\begin{aligned} \frac{x}{8}+8y&=194\\ \frac{y}{8}+8x&=131 \end{aligned}\right\}$ 4. $\left.\begin{aligned} \frac{x+y}{3}&=5\\ \frac{y-x}{7}&=1 \end{aligned}\right\}$

5. $\left.\begin{aligned} \frac{3x-7y}{3}&=\frac{2x+y-1}{5}\\ 2-\frac{x-y}{5}&=0 \end{aligned}\right\}$ 6. $\left.\begin{aligned} \frac{x+2}{3}+8y&=31\\ \frac{y+5}{4}+10x&=192 \end{aligned}\right\}$

7. $\left.\begin{aligned} ax+by&=1\\ a'x-b'y&=1 \end{aligned}\right\}$ 8. $\left.\begin{aligned} ax+by&=c\\ a'x+b'y&=c \end{aligned}\right\}$

9. $\left.\begin{aligned} \frac{1}{x}-\frac{1}{y}&=12\\ \frac{3}{x}+\frac{5}{y}&=2\tfrac{4}{7} \end{aligned}\right\}$ Here the unknowns had better be regarded as $\frac{1}{x}, \frac{1}{y}$; when these are found, the reciprocals can be taken.

10. $\left.\begin{aligned} \frac{x-2}{5}-\frac{10-x}{3}-\frac{y-10}{4}&=0\\ \frac{2(y+2)}{3}-\frac{2x+y}{8}-\frac{x+13}{4}&=0 \end{aligned}\right\}$

11. $\left.\begin{aligned} \frac{x+6}{x+4}&=\frac{y+2}{y-2}\\ \frac{x+3}{x+1}&=\frac{y-7}{y-13} \end{aligned}\right\}$* 12. $\left.\begin{aligned} x+y&=19\\ x^2-y^2&=95 \end{aligned}\right\}$

Questions in Simple Equations with One or Two Unknown Quantities.

1. Find a number such that whether it be divided into two equal parts, or into three equal parts, the product of the parts shall be the same.

Let x be the number; then by the question

$$\frac{x}{2}\times\frac{x}{2}=\frac{x}{3}\times\frac{x}{3}\times\frac{x}{3}$$

that is $\frac{x^2}{4}=\frac{x^3}{27} \therefore \frac{1}{4}=\frac{x}{27} \therefore 27=4x \therefore \frac{27}{4}=6\tfrac{3}{4}=x.$

When the question implies *parts* of the unknown quantity, fractions may generally be avoided in the solution by representing the unknown not by x, but a multiple of x, such that the proposed parts may be integral: thus, in the present case—

Let $6x$ be the number; then by the question

$$3x\times 3x=2x\times 2x\times 2x$$

$$\text{that is } 9x^2=8x^3 \therefore 9=8x \therefore x=\frac{9}{8} \therefore 6x=\frac{27}{4}=6\tfrac{3}{4}.$$

2. A person after spending one-fifth of his income and £10 more, found that he had £35 more than half his income left; what was his income?

Let $10x$ represent his income; then by the question, the number of pounds he spent is $2x+10$, so that he had $10x-(2x+10)$ left; that is $8x-10$; but by the question he had $5x+35$ left,

$\therefore 8x-10=5x+35 \therefore 3x=45 \therefore x=15 \therefore 10x=150,$ so that his income was £150.

3. There is a fraction such that if 3 be added to the numerator, its value is $\frac{1}{3}$; and if 1 be subtracted from the denominator, its value is $\frac{1}{5}$: what is the fraction?

---

* See *ante*, p. 470.

Let x be the numerator and y the denominator; then the fraction is $\frac{x}{y}$; and by the question

$$\left.\begin{aligned}\frac{x+3}{y}&=\frac{1}{3}\\ \frac{x}{y-1}&=\frac{1}{5}\end{aligned}\right\}\text{ or }\left\{\begin{aligned}&3x+9=y\\ &5x=y-1,\text{ or }y=5x+1.\end{aligned}\right.$$

Hence, equating these two expressions for y, we have $5x+1=3x+9\;\therefore\;2x=8\;\therefore\;x=4$, the numerator.

And $y=5x+1=21$, the denominator, $\therefore\;\frac{4}{21}$ is the fraction.

4. A man and his wife could drink a barrel of beer in 15 days; but after drinking together 6 days, the woman alone drank the remainder in 30 days. In what time could either alone drink the whole barrel?

Suppose the man could drink it in x days, and the woman in y days; then in *one* day the man's share is $\frac{1}{x}$ of the whole, and the woman's $\frac{1}{y}$; so that 15 times the sum of these shares is 1 whole barrel: that is—

$$\frac{15}{x}+\frac{15}{y}=1.$$

But by the question

$$\frac{6}{x}+\frac{6}{y}+\frac{30}{y}=1;\text{ that is, }\frac{6}{x}+\frac{36}{y}=1.$$

So that dividing the first equation by 15, and this last by 6, we have

$$\frac{1}{x}+\frac{1}{y}=\frac{1}{15}.$$

$$\frac{1}{x}+\frac{6}{y}=\frac{1}{6}.$$

By subtracting

$$\frac{5}{y}=\frac{1}{6}-\frac{1}{15}=\frac{3}{30}=\frac{1}{10}\;\therefore\;y=50.$$

Also since, $\frac{5}{y}=\frac{1}{10}\;\therefore\;\frac{15}{y}=\frac{3}{10}\;\therefore\;\frac{15}{x}=1-\frac{15}{y}=1-\frac{3}{10}=\frac{7}{10}$

$$\therefore\;7x=150;\;\therefore\;x=\frac{150}{7}=21\tfrac{3}{7}.$$

Consequently, the man alone could drink it in $21\frac{3}{7}$ days, and the woman in 50 days.

In this example, $\frac{1}{x}$ and $\frac{1}{y}$ are regarded as the unknown quantities, as recommended at page 471, Example 9.

---

1. Find a number such that if it be increased by one-half, one-third, and one-fourth of itself, the sum shall be 50.

2. There is a fraction such that if 4 be added to the denominator the value is a $\frac{1}{2}$; and if 3 be added to the numerator, the value is $\frac{3}{4}$: required the fraction.

3. What number is that such that if it be increased by 7, the square root of the sum shall be equal to the square root of the number itself and 1 more?

4. Fifty labourers are engaged to remove an obstruction on a railway: some of them are by agreement to receive ninepence each, and the others fifteen pence. Just £2 are paid to them: but, no memorandum having been made, it is required to find how many worked for 9*d.*, and how many for 15*d.*

5. A person ordered a quantity of rum and brandy, for which he paid £19 4*s.*: the brandy was 9*s.* a quart, and the rum 6*s.* He has, however, forgotten the exact quantity of each he has to receive; but he remembers that if his brandy had been rum, and his rum brandy, his outlay would have been £1 13*s.* less. How many quarts of each did he buy?

6. A person has spirits at 12*s.* a gallon, and at £1 a gallon; how much of each sort must he take to make a gallon worth 14*s.*?

7. A merchant has spirits at *a* shillings a gallon, and at *b* shillings a gallon; how much of each must he take to make a mixture of *d* gallons worth *c* shillings a gallon?

8. In the composition of a certain quantity of gunpowder, two-thirds of the whole + 10lbs. was nitre; one-sixth of the whole — 4½lbs. was sulphur; and the charcoal was one-seventh of the nitre, all but 2lbs. How many lbs. of gunpowder were there?

9. A farmer wishes to mix 28 bushels of barley at 2*s.* 4*d.* a bushel with rye at 3*s.* a bushel, and wheat at 4*s.* a bushel, so that the whole may make 100 bushels worth 3*s.* 4*d.* a bushel; how much rye and wheat must he use?

10. Two persons, A and B, are engaged on a work which they can finish in 16 days; but after working together 4 days, A is called off; and B alone finishes it in 36 days more. In how many days could each do it separately?

11. A composition of copper and tin, containing 100 cubic inches, weighed 505 ounces; how many ounces of each metal did it contain, supposing a cubic inch of copper to weigh 5¼ oz., and a cubic inch of tin to weigh 4¼ oz.?

12. A cask is supplied by three spouts, which can fill it in *a* minutes, *b* minutes, and *c* minutes respectively; in what time will it be filled if all flow together?

Simple equations with three unknown quantities may be solved by imitating the operations in equations with two unknown; that is, by first eliminating one of the unknown from *two* of the equations, and then eliminating the *same* unknown from one of those two and the third; the results of the eliminations will be a pair of equations, with only two unknown quantities: for example,

A and B can perform a piece of work in 8 days; A and C in 9 days; and B and C in 10 days. In how many days can each alone perform it?

Suppose A, B, and C can do the xth part, the yth part, and the zth part respectively in *one* day: then by the question,

$8x+8y=1$ (*the whole*), $9x+9z=1$, $10y+10z=1$.

To equalise the coefficients of y, multiply the first by 5, and the third by 4; and we have

$$40x+40y=5$$

$$40x+40y=4$$

$\therefore$ Subtracting, $40x-40z=1$. Mult. this by 9, and the second equa. $9x+9z=1$ by 40:

$$360x-360z=9$$

$$360x+360z=40$$

Adding and subtracting, $720x=49$ and $720z=31$,

$$\therefore\;x=\frac{49}{720},\text{ and }z=\frac{31}{720},$$

$$\therefore\;10y+10z=10y+\frac{31}{72}=1\;\therefore\;10y=\frac{41}{72}\;\therefore\;y=\frac{41}{720}.$$

Hence A can do

$\frac{49}{720}$ of the whole in 1 day; B can do $\frac{41}{720}$; and C, $\frac{31}{720}$.

$\therefore$ A can do the whole in

$\frac{720}{49}$ days, B in $\frac{720}{41}$ days, and C in $\frac{720}{31}$ days.

That is, in $14\frac{34}{49}$ days, $17\frac{23}{41}$ days, and $23\frac{7}{31}$ days, respectively.

Equations which, like those considered in the preceding pages, imply distinct conditions, all existing together, are called *simultaneous equations:* the conditions of the foregoing problem are implied in the three simultaneous equations at the commencement of the solution.

Quadratic Equations with One Unknown Quantity.

A quadratic is an equation in which the *square* of the unknown quantity enters, and enters in such a way as to require a peculiar process for its removal. It is possible that even a simple equation may contain the square of the unknown; but then, in order that it may deserve the name of a *simple* equation, this square must be removable by transposition or division, or by some other of the operations common to simple equations in general; whereas a *quadratic*, properly so called, requires for its solution an additional principle; what this is, is now to be explained.

And first, you are to observe that the square of a quantity, consisting of but *one* term; that is, the square of a *monomial* is itself a monomial: thus the square of x is x^2; the square of ax is a^2x^2, and so on. But the square of a *binomial* consists of *three* terms; that is, it is a *trinomial:* thus, $(x+a)^2=x^2+2ax+a^2$, $(x-a)^2=x^2-2ax+a^2$, and so on.

The next thing to observe is, that if only the first and second terms of the square of a binomial, $x+a$, or $x-a$, be given, the *third* term of it can always be found; for you see that *this third term is nothing more than the square of half the coefficient in the second term.* Thus, if the first and second terms, viz., x^2+2ax, or x^2-2ax, be written down, we can complete the square to which these two terms belong, by dividing the coefficient of x, namely $2a$ or $-2a$, by 2; and then *adding* the square of the result. Thus, half the coefficient of x, in x^2+2ax, is a; the square of this is a^2; adding this $\therefore$ to the two terms proposed, we have $x^2+2ax+a^2$, for the complete square of $x+a$. In like manner, knowing the two terms x^2-2ax, we have only to add to them the square of half $-2a$, that is, $(-a)^2$, or a^2, to get $x^2-2ax+a^2$, the complete square of $(x-a)^2$. It follows from this, that whenever we have an expression of this form—namely, x^2+px, whether p be positive or negative, we can always add to it a term, easily found, that will make the expression a complete square; this term being no other than the square of $\frac{1}{2}p$; that is $\frac{1}{4}p^2$; and moreover, that the root of the square may at once be pronounced to be $x+\frac{1}{2}p$. In fact, common multiplication shows that $x^2+px+\frac{1}{4}p^2=(x+\frac{1}{2}p)^2$, whether p be + or —.

We shall give you an example or two of *completing the square*, as it is called—

1. Having the two terms x^2+6x, complete the square to which these two terms belong, and express the root of that square. Here half the coefficient of x is 3, $\therefore$ the wanting term is $3^2=9$, $\therefore$ the square is x^2+6x+9, and the root being x, with the half coefficient taken with its own sign added, we have $x^2+6x+9=(x+3)^2$.

2. Given x^2-8x to complete the square. Here the half coefficient is -4, of which the square is 16, $\therefore$ the complete square is $x^2-8x+16$, the root of which being x, together with the half coefficient, we have $x^2-8x+16=(x-4)^2$.

3. Given x^2-3x to complete the square. Here the half coefficient is $-\frac{3}{2}$, $\therefore$ its square is $\frac{9}{4}$, $\therefore$ the complete square is $x^2-3x+\frac{9}{4}=(x-\frac{3}{2})^2$.

You can now find no difficulty in rendering an expression of the form x^2+px, in which the coefficient of x^2 is *unity*, and that of x *anything*, a complete square. It is the accomplishment of this single matter that constitutes the whole mystery of quadratic equations.

To solve a Quadratic Equation.

RULE 1.—As in a simple equation dispose all the unknown terms on one side of the equation, and all the known on the other; the unknown side, when the terms are collected, will then consist of but *two* terms—the first containing x^2, and the second x simply.

2. If x^2, in the first term, have a coefficient other than unity, divide both sides by that coefficient; the equation will thus be reduced to the form $x^2+px=a$, where a is the *known* side, and p a known coefficient.

+3. Add the square of half this coefficient to both sides; *the unknown side will then be a complete square*, viz., the square of $x+\frac{1}{2}p$, the *sign* of p being the same as that in the above reduced form; and the *known side* will be $a+\frac{1}{4}p^2$.

4. Extract the square root of each side, and the result will be a *simple equation*, viz., $x+\frac{1}{2}p=\surd(a+\frac{1}{4}p^2)$.

You will observe, that although we *extract the square root of each side*, yet as far as the unknown side is concerned, there is, in reality, *no actual extraction performed*; you have nothing to do but to write down x *together with* half the coefficient of x, in the reduced form x^2+px; but, as respects the *known* side, when this is a *number*, the square root is actually found by common arithmetic, unless it is seen to be a surd, when we may leave it under the sign $\surd$, the extraction being merely *indicated*. You must remember, however, that when the square root of a number is actually *determined*, the *sign* to be prefixed to that root is *ambiguous*;* it may be either + or —.

1. Find the values of x in the equation $x^2+6x=55$.
Completing the square, $x^2+6x+9=64$.
Extracting the square root, $x+3=\pm 8$.
$$\therefore x=-3\pm 8=5, \text{ or } -11.$$
If 5 be put for x, the proposed equation is $25+30=55$.
If -11 be put for x, the equation is $121-66=55$.

2. $3x^2+2x-9=76$. Transposing, and then dividing by 3, the coefficient of x^2, $x^2+\frac{2}{3}x=\frac{85}{3}$.
Completing the square, $x^2+\frac{2}{3}x+\frac{1}{9}=\frac{85}{3}+\frac{1}{9}=\frac{256}{9}$.
Extracting the root, $x+\frac{1}{3}=\surd\frac{256}{9}=\pm\frac{16}{3}$.
$$\therefore x=-\tfrac{1}{3}\pm\tfrac{16}{3}=5 \text{ or } -\tfrac{17}{3}.$$

3. $3x^2-9x-4=80$. Transposing and dividing by 3, $x^2-3x=28$.
Completing the square, $x^2-3x+\frac{9}{4}=28+\frac{9}{4}=\frac{121}{4}$.
Extracting the root, $x-\frac{3}{2}=\surd\frac{121}{4}=\pm\frac{11}{2}$.
$$\therefore x=\tfrac{3}{2}\pm\tfrac{11}{2}=7, \text{ or } -4.$$

4. $\frac{x}{5}+\frac{5}{x}=5\frac{1}{5}$. Multiplying by $5x$, to clear fractions,
$$x^2+25=26x, \therefore x^2-26x=-25.$$
Completing the square, $x^2-26x+13^2=169-25=144$.
Extracting the root, $x-13=\surd 144=\pm 12$.
$$\therefore x=13\pm 12=25, \text{ or } 1.$$

5. $\frac{7}{x+1}+\frac{2}{x}=5$. Clearing fractions,
$$7x+2x+2=5x^2+5x.$$
Transposing, $5x^2-4x=2 \therefore x^2-\frac{4}{5}x=\frac{2}{5}$.
Completing the square, $x^2-\frac{4}{5}x+\frac{4}{25}=\frac{2}{5}+\frac{4}{25}=\frac{14}{25}$.
Extracting the root, $x-\frac{2}{5}=\surd\frac{14}{25}=\frac{1}{5}\surd 14$.
$$\therefore x=\frac{2}{5}+\frac{1}{5}\surd 14.$$

The square root of 14 is found, by arithmetic, to be 3·742; and $\frac{1}{5}$ of this is ·748; also since $\frac{2}{5}=\cdot4$, we have $x=\cdot4\pm\cdot748=1\cdot148$, or $-\cdot348$.

6. $\frac{x+11}{x}+\frac{9+4x}{x^2}=7$. Multiplying by x^2, to clear fractions, $x^2+11x+9+4x=7x^2 \therefore 6x^2-15x=9$.
Or dividing by 6, $x^2-\frac{5}{2}x=\frac{3}{2}$.
Completing the square, $x^2-\frac{5}{2}x+\frac{25}{16}=\frac{3}{2}+\frac{25}{16}=\frac{49}{16}$.
Extracting the root, $x-\frac{5}{4}=\surd\frac{49}{16}=\pm\frac{7}{4}$.
$$\therefore x=\frac{5}{4}\pm\frac{7}{4}=3, \text{ or } -\frac{1}{2}.$$

7. $\frac{2\surd x+2}{4+\surd x}=\frac{4-\surd x}{\surd x}$. Clearing fractions, and remembering that sum × dif. = dif. sqrs.
$$2x+2\surd x=16-x \therefore 2\surd x=16-3x.$$
Squaring, to remove the radical,
$$4x=256-96x+9x^2 \therefore 9x^2-100x=-256.$$
Dividing by 9, $x^2-\frac{100}{9}x=-\frac{256}{9}$.
Completing the square,
$$x^2-\frac{100}{9}x+\frac{2500}{81}=\frac{2500}{81}-\frac{256}{9}=\frac{196}{81}$$
Extracting the root, $x-\frac{50}{9}=\surd\frac{196}{81}=\pm\frac{14}{9}$
$$\therefore x=\frac{50}{9}\pm\frac{14}{9}=\frac{64}{9}, \text{ or } 4.$$

---

* See *ante*, p. 466.

We might have completed the solution without clearing the radical from the equation $2x + 2\sqrt{x} = 16 - x$, thus: by transposing,

$$3x + 2\sqrt{x} = 16 \therefore x + \frac{2}{3}\sqrt{x} = \frac{16}{3}.$$

Now, since x in the first term is the *square* of $\sqrt{x}$ in the second, it is plain that we may treat this as a quadratic equation, regarding $\sqrt{x}$ as the unknown quantity $\therefore$ completing the square,

$$x + \frac{2}{3}\sqrt{x} + \frac{1}{9} = \frac{16}{3} + \frac{1}{9} = \frac{49}{9}$$

Extracting the root,

$$\sqrt{x} + \frac{1}{3} = \sqrt{\frac{49}{9}} = \pm\frac{7}{3}$$

$$\therefore \sqrt{x} = -\frac{1}{3} \pm \frac{7}{3} = 2, \text{ or } -\frac{8}{3}; \quad \therefore x = 4, \text{ or } \frac{64}{9}.$$

NOTE.—And in a similar way may any equation of the form $x^{2n} + px^n + a$, in which the exponent of x in the first term is double that of x in the second, be solved as a quadratic; the equation just considered is $x + \frac{2}{3}x^{\frac{1}{2}} = \frac{16}{3}$, where the exp. 1 of x, in the first term, is double $\frac{1}{2}$, the exp. of x in the second.

EXAMPLES FOR EXERCISE.

1. $x^2 - 4x = 45.$ 2. $x^2 + 8x = 33$
3. $x^2 - 8x = 9.$ 4. $3x^2 + 2x = 161.$
5. $7x^2 - 20x = 32.$ 6. $x^2 - x - 170 = 40.$
7. $5x^2 + 4x = 273.$ 8. $\frac{4x^2 - x}{3} = 11.$
9. $x + \frac{7x - 8}{x} = 9.$ 10. $5x^2 + 3 = 4x + 159.$
11. $6x + \frac{35 - 3x}{x} - 44 = 0.$ 12. $\frac{x-2}{x+2} + \frac{x+2}{x-2} = 14.$
13. $\frac{48}{x^2} + \frac{32}{x} = 11$ or $48x^{-2} + 32x^{-1} = 11.$*
14. $x^4 - 40x^2 + 39 = 0.$ 15. $x^2 + ax + b = 0.$
16. $\frac{x+a}{x-a} + \frac{x-a}{x+a} = b.$ 17. $\frac{x}{2} - \frac{1}{5}\sqrt{x} = 22\frac{1}{2}.$
18.† $(3x - 2)(1 - x) = 4.$ 19. $15x^2 - 48x + 45 = 0.$
20. $\sqrt{\frac{x-2}{x+2}} + \sqrt{\frac{x+2}{x-2}} = 4.$

The preceding method of solving a quadratic equation is that which is usually employed for the purpose; in certain cases, however, it is attended with inconvenience; in those cases, namely, where the completion of the square introduces numerical *fractions* into the work. We shall now show you an improvement upon the common rule; by adopting which, in practice, you will prevent the introduction of fractions.

The most general form of the quadratic equation, after the proper preliminary reductions, is $ax^2 + bx = c$. Let each side be multiplied by $4a$; the equation will then be $4a^2x^2 + 4abx = 4ac$, or, which is the same thing,

$$(2ax)^2 + 2b(2ax) = 4ac.$$

The first member of this, you will observe, consists of two terms—namely, the *square* of $2ax$ and $2b$ times $2ax$; so that, regarding $2ax$ as the unknown quantity, we shall *complete the square* by adding b^2; and the root of that square will be $2ax + b$: we therefore proceed thus—

Completing the square, $(2ax)^2 + 2b(2ax) + b^2 = 4ac + b^2$.

Extracting the root, $2ax + b = \sqrt{(4ac + b^2)}$.

Hence any quadratic may be reduced to a simple equation, of which this is the general model, without the introduction of any fractions. The steps from the proposed quadratic $ax^2 + bx = c$, to the simple equation $2ax + b = \sqrt{(4ac + b^2)}$, need not be gone through in each particular example; the reduced equation may be derived at once as follows:—

Rule II.—Take twice the coefficient of x^2 in the proposed quadratic; this will be the coefficient of x in the derived simple equation.

To the first term thus found, connect with its own sign the coefficient of x in that proposed: and the first member of the derived simple equation will be obtained.

To form the second member, multiply the second member of the proposed, by four times the coefficient of x^2, add the square of the next coefficient (that of x) to the result, and cover the whole with the radical sign.

This is the *rule* for the solution of any quadratic; it is a mere translation in words of the *formula* for the solution; namely,

Proposed quadratic.	*Derived simple equation.*
$ax^2 + bx = c.$	$2ax + b = \sqrt{(4ac + b^2)}.$

You may either commit the *rule* to memory, or keep the *formula* before your mind's eye; remembering that, as a *square* is always *plus*, b^2 is to take the *positive* sign, whether b, in the quadratic, is + or —. Thus (see Ex. 6, p. 473),

Quadratic. *Simple equation.*

$6x^2 - 15x = 9$

or

$2x^2 - 5x = 3$ . . . . $4x - 5 = \sqrt{(24 + 25)} = \sqrt{49} = \pm 7.$

Again, Ex. 5, p. 473,

$5x^2 - 4x = 2$ . . . . $10x - 4 = \sqrt{(40 + 16)} = \sqrt{56} = 2\sqrt{14}.$

Also Ex. 3, p. 473,

$x^2 - 3x = 28$ . . . . $2x - 3 = \sqrt{(112 + 9)} = \sqrt{121} = \pm 11.$

And from each of these simple equations you may deduce the value of x, at a single step: thus—

$$\text{Ex. 3. } x = \frac{3 \pm 11}{2} = 7, \text{ or } -4;$$

$$\text{Ex. 5. } x = \frac{4 + 2\sqrt{14}}{10} = \frac{2}{5} + \frac{1}{5}\sqrt{14};$$

$$\text{Ex. 6. } x = \frac{5 \pm 7}{4} = 3, \text{ or } -\frac{1}{2},$$

as at the pages referred to. All the examples worked by the common method you may re-solve in this way, which will be much the shorter and easier, whenever fractions are unavoidable by the former rule. We refrain from giving additional examples here, solely because we expect you to act upon this recommendation.

To solve a pair of Equations with Two Unknown Quantities, when one is a Simple Equation and the other a Quadratic.

The mode of proceeding in this case scarcely requires any formal directions. From the simple equation an expression for one of the unknowns may be easily found in terms of the other and *known* quantities, as at page 471; and this expression substituted in the quadratic will, of course, give an equation with only one unknown quantity; the other being *eliminated* in consequence of the substitution. Thus—

1. $\left.\begin{array}{c} x + 2y = 7 \\ x^2 + 3xy - y^2 = 23 \end{array}\right\}$ From the first equation $x = 7 - 2y$. Substituting this in the second, it becomes—

$$(7 - 2y)^2 + 3(7 - 2y)y - y^2 = 23; \text{ that is, } 49 - 28y + 4y^2 + 21y - 6y^2 - y^2 = 23, \text{ or } 3y^2 + 7y = 26$$

$$\therefore \text{ Rule II., } 6y + 7 = \sqrt{(312 + 49)} = \sqrt{361} = \pm 19$$

$$\therefore y = \frac{-7 \pm 19}{6} = 2, \text{ or } -\frac{13}{3} \therefore x = 7 - 2y = 3, \text{ or } 15\frac{2}{3};$$

so that the two values of x and y which satisfy the proposed pair of simultaneous equations are either—

$$\left.\begin{array}{l} x = 3 \\ y = 2 \end{array}\right\} \text{ or } \left\{\begin{array}{l} x = 15\frac{2}{3} \\ y = -4\frac{1}{3} \end{array}\right.$$

2. $\left.\begin{array}{c} 2x - 3y = 1 \\ 2x^2 + xy - 5y^2 = 20 \end{array}\right\}$ From the first equation $x = \frac{1 + 3y}{2}$.

Substituting this in the second, it becomes—

$$2\left(\frac{1 + 3y}{2}\right)^2 + \frac{1 + 3y}{2}y - 5y^2 = 20; \text{ that is, } \frac{1 + 6y + 9y^2}{2} + \frac{y + 3y^2}{2} - 5y^2 = 20,$$ or, multiplying by 2, and transposing,

$2y^2 + 7y = 39$

---

* See *ante*, p. 465.

† The roots of this equation, and also those of equation 19, are imaginary; that is, the values of x in each will be found to involve the square root of a negative number; we may conclude, therefore, that it is not possible to satisfy either of these equations by any real value of x (see p. 465).

$$\therefore \text{ Rule II., } 4y+7=\surd(312+49)=\surd 361=\pm 19$$

$$\therefore y=\frac{-7\pm 19}{4}=3, \text{ or } -\frac{13}{2} \therefore x=\frac{1+3y}{2}=5, \text{ or } -9\tfrac{1}{4},$$

so that the values of x and y are either—

$$\left.\begin{matrix} x=5 \\ y=3 \end{matrix}\right\} \text{ or } \left\{\begin{matrix} x=-9\tfrac{1}{4} \\ y=-6\tfrac{1}{2} \end{matrix}\right.$$

Sometimes pairs of equations, coming under the present head, may be most conveniently solved, independently of *rule*, by exercising a little ingenuity. Here is an example :—

3. $\left.\begin{matrix} x+y=12 \\ x^2+y^2=74 \end{matrix}\right\}$ By squaring the first equation, and then subtracting the second, $2xy=70 \therefore 4xy=140$.

$$\begin{array}{llcl} \text{From the sq. of the first, viz.} & x^2+2xy+y^2 & = & 144 \\ \text{Subtract} & 4xy & = & 140 \\ \hline & \therefore x^2-2xy+y^2 & = & 4 \\ \text{Extracting the square root,} & x-y & = & \pm 2 \\ \text{But,} & x+y & = & 12 \\ \hline \end{array}$$

$$\therefore \text{ adding and subtracting, } 2x=12\pm 2, \text{ and } 2y=12\mp 2$$

$$\therefore x=7, \text{ or } 5; \text{ and } y=5, \text{ or } 7$$

that is, the values of x and y are either—

$$\left.\begin{matrix} x=7 \\ y=5 \end{matrix}\right\} \text{ or } \left\{\begin{matrix} y=7 \\ x=5 \end{matrix}\right.$$

4. In a similar way you may treat the equations $x-y=6$, $x^2+y^2=50$; and you will find that the values of x and y are either $x=7$, $y=1$; or $x=-1$, $y=-7$.

Questions requiring the Solution of Quadratic Equations.

1. The fore-wheel of a carriage makes 6 revolutions more than the hind-wheel in going 120 yards; but it is found that if the circumference of each wheel be increased 1 yard, it will make only 4 revolutions more than the hind-wheel in the same distance; required the circumference of each wheel.

Let $x=$ No. of yards in circ. of larger wheel,
$y=$ . . . . smaller wheel,

then $\frac{120}{x}=$ No. of revolutions of the former, and $\frac{120}{y}=$ No. of revolutions of latter; and by the question, $\frac{120}{x}=\frac{120}{y}-6 \therefore 20y=20x-xy \therefore xy=20x-20y$. . [A].

Also by the question, $\frac{120}{x+1}=\frac{120}{y+1}-4 \therefore 30(y+1$ $=(x+1)(29-y)$, that is, $30y+30=29x+29-xy-y \therefore xy=29x-31y-1$.

Substituting this expression for xy in the equation [A], we have—

$$29x-31y-1=20x-20y \therefore 9x=11y+1 \text{ . . . . [B].}$$

This equation [B] is a simple equation, and [A] is a quadratic, or an equation of *two dimensions*, because of the term xy.

From [A] we have $x=\frac{11y+1}{9}$; this substituted in [B] gives—

$$\frac{11y^2+y}{9}=\frac{220y+20}{9}-20y \therefore 11y^2+y=220y+20-180y$$

$$=40y+20 \therefore 11y^2-39y=20$$

$$\therefore \text{ Rule II., } 22y-39=\surd(880+39^2)=\surd 2401=\pm 49.$$

$$\therefore y=\frac{39+49}{22}=4, \text{ or } -\frac{5}{11} \therefore x=\frac{11y+1}{9}=5, \text{ or } -\frac{1}{9}.$$

From the nature of the question, it is plain that the *negative* values of x and y are inadmissible; they fulfil the *algebraical* conditions [A] and [B], as well as the *positive* values, for there is nothing in those conditions to exclude them; and it will often be found that the algebraic translation is free from the particular restrictions embodied in the question itself. The algebra furnishes *all* the values of the symbols, whether positive or negative, real or imaginary; and those of them are afterwards to be rejected which the restrictions of the question necessarily exclude. In the present case the only answers to the question are $x=5$, and $y=4$

2. A company at a tavern had £8 15*s*. to pay; but before the bill was settled, two of them left; in consequence of which, those who remained had each 10*s*. more to pay. How many persons were in company at first?

Let x represent the number: then $\frac{175}{x}$ is the share of each in shillings, and $\frac{175}{x-2}$ the portion each paid, after two had left: the difference is $\frac{175}{x-2}-\frac{175}{x}=10$ by the question, $\therefore$ clearing fractions,

$$175x-175x+350=10x(x-2);$$

or, dividing by 10, $35=x^2-2x$, or $x^2-2x=35$,

$$\therefore 2x-2=\surd(140+4)=\pm 12 \therefore x=\frac{2\pm 12}{2}$$

$$=1\pm 6=7, \text{ or } -5.$$

Consequently they were 7 persons at first.

3. What number is that which, being divided by the product of its two digits, the quotient is 2; and if 27 be added to it, the digits will be inverted or transposed?

Let x and y be the digits, then the number is $10x+y$; and when the digits are inverted or transposed, the number is $10y+x$.

By the question, $\frac{10x+y}{xy}=2 \therefore 10x+y=2xy$ . . . . [A]

and $10x+y+27=10y+x \therefore 9x+27=9y \therefore x+3=y$.

Substituting this value of y in [A], we have—

$$11x+3=2x^2+6x \therefore 2x^2-5x=3$$

$$\therefore 4x-5=\surd(24+25)=\surd 49=\pm 7.$$

$$x=\frac{5\pm 7}{4}=3, \text{ or } -\tfrac{1}{2} \therefore y=x+3=6, \text{ or } 2\tfrac{1}{2}.$$

The only admissible values are $x=3$, and $y=6$, $\therefore$ the number is 36.

---

1. Divide the number 33 into two such parts, that their product may be 162.

2. Find two numbers whose difference is 9, and which are also such that their sum multiplied by the greater gives 266 for the product.

3. A company at a tavern had £7 4*s*. to pay; but two of them having left, the others had each 1*s*. more to pay than his fair share; how many persons were there at first?

4. A purse contains 24 coins of silver and copper; each copper coin is worth as many pence as there are silver coins, and each silver coin is worth as many pence as there are copper coins: and the whole is worth 18*s*. How many are there of each?

5. Two messengers, A and B, were dispatched to the same place, 90 miles distant. A, by riding one mile an hour more than B, arrives at his destination an hour before him. How many miles an hour did each travel?

6. A grocer sold 80lbs. of mace and 100lbs. of cloves for £65; but he sold 60lbs. more of cloves for £20 than he did of mace for £10. What was the price of 1lb. of each?

7. The product of two numbers is 240, and they are such, that if one of them be increased by 4, and the other diminished by 3, the product of the results is still 240. Find the numbers.

8. A and B set out at the same time for a place 150 miles distant. A travels 3 miles an hour faster than B, and arrives at the place 8_3 hours before him. How many miles did each travel per hour?

9. What number is that the sum of whose digits is 15, and if 31 be added to their product, the digits will be transposed?

10. There is a certain number consisting of two digits. The left-hand digit is equal to three times the right-hand one; and if 12 be subtracted from the number, the remainder will be equal to the square of the left-hand digit. What is the number?

A pair of simultaneous equations, with two unknown quantities, cannot in general be solved without the aid of higher equations, when the proposed ones are *both* quadratics. There are only two particular classes of such simultaneous equations to which general methods of solution, capable of being explained here, apply. These classes are called respectively *homogeneous equations*, and *symmetrical equations*. We shall very briefly consider them in the present article.

Homogeneous Quadratics.—A pair of quadratics is said to be a pair of homogeneous equations when each unknown term in both is of *two dimensions*; that is, when no term occurs without either the *square* of one of the unknown quantities, or the *product* of both; the presence of *two* unknown factors—whether equal or unequal—in a term, being the circumstance that renders that term of *two* dimensions. The following is a pair of homogeneous quadratics, each unknown term being of two dimensions:

$$\left.\begin{array}{l} x^2+xy=77 \\ xy-y^2=12 \end{array}\right\}$$

The following is the general way of solving such equations:—Put zy for x, and the equations become

$$z^2y^2+zy^2=77, \text{ and } zy^2-y^2=12.$$

From the first, $y^2=\frac{77}{z^2+z}$; from the second, $y^2=\frac{12}{z-1}$ . . . . [A]

$$\therefore \frac{77}{z^2+z}=\frac{12}{z-1} \therefore 12z^2-65z=-77.$$

By means of this contrivance; viz., the putting z times one of the unknown quantities for the other, we easily obtain a quadratic equation involving z only: solving this, we have

$$24z-65=\surd(-77\times48+65^2)=\surd529=\pm23$$

$$z=\frac{65\pm23}{24}=\frac{11}{3}, \text{ or } \frac{7}{4}.$$

Substituting each of these in equation [A], we have

$$y^2=\frac{12}{2\frac{2}{3}}, \text{ or } \frac{12}{\frac{3}{4}}; \text{ that is, } y^2=\frac{9}{2}, \text{ or } 16 \therefore y=\frac{3}{\surd2}=\frac{3}{2}\surd2, \text{ or } \pm4$$

$$\therefore x=zy=\frac{11}{2}\surd2, \text{ or } \pm7.$$

You see that each of the unknown quantities has *four* values; for $\surd2$ is either + or −: such is usually the case when the proposed equations are each of *two* dimensions. From the first equation above $y=\frac{77-x^2}{x}$; and if this be put for y in the second, the result, cleared of fractions, would evidently be an equation of the *fourth* degree; and it is proved, in the *Theory of Equations*, that an equation always has as many roots as there are units in the number which marks its degree: this is the reason that the values of x and y above are four in number.

Symmetrical Quadratics.—An equation is said to be symmetrical, in reference to the unknown quantities which enter it, when they so enter that they may be interchanged without producing any alteration in the equation: thus $x+y=a$; $x^2+3xy+y^2=b$; $2x^3-3x^2y^2+2y^3=c$, &c., are all symmetrical equations; because for every x you may put y, and for every y, x, without altering either of the equations. The following is a pair of symmetrical quadratics; namely,

$$\left.\begin{array}{r} x^2+y^2-x-y=18 \\ xy+x+y=19 \end{array}\right\}$$

The *general* method of dealing with such equations is as follows:—Put $u+v$ for x, and $u-v$ for y, and the equations become

$$\left.\begin{array}{r} (u+v)^2+(u-v)^2-2u=18 \\ (u+v)(u-v)+2u=19 \end{array}\right\} \text{or} \left\{\begin{array}{l} u^2+v^2-u=9 \\ u^2-v^2+2u=19 \end{array}\right. \quad . \ . \ . \ [A]$$

By adding $2u^2+u=28 \therefore 4u+1=\surd(224+1)=\pm15 \therefore$

$$u=\frac{-1\pm15}{4}=\frac{7}{2}, \text{ or } -4$$

$$\therefore [A], \frac{49}{4}+v^2-\frac{7}{2}=9 \therefore v^2=\frac{1}{4} \therefore v=\pm\frac{1}{2}$$

$$16+v^2+4=9 \therefore v^2=-11 \therefore v=\surd-11$$

$$\therefore x=u+v=\frac{7}{2}\pm\frac{1}{2}, \text{ or } -4\pm\surd-11; \text{ that is, } x=4, 3, \text{ or, } -4\pm\surd-11$$

$$y=u-v=\frac{7}{2}\pm\frac{1}{2}, \text{ or } -4\pm\surd-11; \text{ that is } y=3, 4, \text{ or } -4\pm\surd-11$$

The two classes of equations here exemplified will always yield to the foregoing methods: but particular cases of these, as also of other kinds of simultaneous equations for the solution of which no general rules can be given, may often be solved more easily by the exercise of a little tact and ingenuity: for instance, you would not think of applying the first method to such a pair of equations as $x^2+xy=9$, $y^2+xy=16$; because the slightest inspection of them would suggest to you the better way of *adding* them together, which would give you $x^2+2xy+y^2=25$, whence $x+y=\pm5$; and since the first is $(x+y)x=9$, you would have at once $\pm5x=9$; and thence $x=\pm\frac{9}{5} \therefore y=\pm5-x=\pm5\pm\frac{9}{5}=\frac{\pm25\pm9}{5}=\pm\frac{16}{5}$. Or you may proceed thus: the two equations give $x+y=\frac{9}{x}$, and $x+y=\frac{16}{y} \therefore 9y=16x \therefore y=\frac{16}{9}x \therefore$ by substitution in the given equations, you would have

$$\frac{25}{9}x^2=9, \text{ and } \frac{400}{81}x^2=16.$$

These equations give no *different* values for x, since the second is nothing but $\frac{16}{9}$ times the first: hence the only values of x are $x=\pm\frac{9}{5} \therefore y=\frac{16}{9}x=\pm\frac{16}{5}$.

CHAPTER IV.

ALGEBRA.—RATIO AND PROPORTION.

THE abstract number which arises from dividing one quantity by another of the same kind, is called the *ratio* of the former to the latter. *Ratio*, therefore, is only another name for the *quotient* of one quantity by another of the same kind:—the first quantity (the dividend) is called the *antecedent* of the ratio, and the second (the divisor) the *consequent:* these are the *terms* of the ratio. Thus, of the two quantities a, b, the ratio is $\frac{a}{b}$; or, which is the same thing, $a\div b$; but the little mark between the two dots, in the symbol for division, is usually omitted in expressing a ratio; so that the *ratio of a to b* would be denoted by $a:b$. Thus, the ratio of 8 to 4, that is $8:4$ is $\frac{8}{4}$ or 2; this ratio is of course the same as the ratio $4:2$, or the ratio $2:1$.

When there are four quantities such that the ratio of the first to the second is equal to the ratio of the third to the fourth, the four quantities are said to be in proportion: thus, if the four quantities, a, b, c, d, be such that $\frac{a}{b}=\frac{c}{d}$, or, which is the same thing, $a:b=c:d$, then a, b, c, d are in proportion; and we express this by *saying* that a is to b as c is to d; or by *writing* $a:b::c:d$. Of these four *terms*, the first and last (a and d) are called the *extremes*; and the intermediate terms (b and c) the *means*.

From what is here said, you see that two equal fractions may always be converted into a proportion, and a proportion into two equal fractions. All the properties of proportional quantities may therefore be derived from those of equal fractions: the following are the most useful :—

1. In four proportional numbers, $a : b :: c : d$, the product of the extremes is equal to the product of the means: for since $\frac{a}{b} = \frac{c}{d}$ $\therefore ad = bc$.

Conversely, if the product of one pair of factors be equal to the product of another pair, the four factors are in proportion: the factors of one product being the means, and those of the other the extremes: thus, if $ad = bc$, then $a : b :: c : d$; because from $ad = bc$, we get, by dividing each side by db, $\frac{a}{b} = \frac{c}{d}$.

3. If four quantities are proportional, they are proportional when taken *inversely*; that is, the second is to the first as the fourth to the third: thus, if $a : b :: c : d$, then $b : a :: d : c$; because from $\frac{a}{b} = \frac{c}{d}$ we get, by taking the reciprocals, $\frac{b}{a} = \frac{d}{c}$.

4. They are also proportional if taken alternately, provided the four quantities are all of the same kind; that is, the first is to the third, as the second to the fourth: thus, if $a : b :: c : d$ then $a : c :: b : d$ if the quantities are alike in kind; because from $\frac{a}{b} = \frac{c}{d}$ we get, by mutiplying by $\frac{b}{c}$, $\frac{a}{c} = \frac{b}{d}$. If a and c were quantities of different kinds, as for instance, pounds and yards, they could of course have no ratio; *ratio* being always an *abstract* number expressing how many times the antecedent is contained in the consequent.

5. *Three* quantities a, b, c are in proportion when they supply the equality $\frac{a}{b} = \frac{b}{c}$; that is, when $a : b :: b : c$. It is plain that three such quantities must always be of the same kind; the first of them is to the third as the square of the first to the square of the second; that is, $a : c :: a^2 : b^2$; because from $\frac{a}{b} = \frac{b}{c}$, we get, by multiplying by $\frac{b}{c}$, $\frac{a}{c} = \frac{b^2}{c^2} = \frac{a^2}{b^2}$.

6. It is further obvious that you may multiply or divide the first and second terms of a proportion by any number, and the third and fourth by any number, without disturbing the proportion; for $\frac{a}{b} = \frac{c}{d}$ is the same as $\frac{ma}{mb} = \frac{nc}{nd}$. And that the first and third may be multiplied or divided by any number, as also the second and fourth; for from $\frac{a}{b} = \frac{c}{d}$ we get $\frac{ma}{nb} = \frac{mc}{nd}$. Moreover, since $\frac{a}{b} = \frac{c}{d}$ leads to $\frac{a^m}{b^m} = \frac{c^m}{d^m}$, whatever be m, it follows that the same powers or roots of four proportional numbers are also in proportion.

7. The terms of two proportions, when they are numbers, may also be multiplied together; that is if—

$$a : b :: c : d$$
and $$e : f :: g : h$$
then $$ae : bf :: cg : dh$$

for this is only multiplying the equations $\frac{a}{b} = \frac{c}{d}$, $\frac{e}{f} = \frac{g}{h}$, together.

8. If $\left.\begin{array}{l} a : b :: c : d \\ \text{and } b : e :: d : f \end{array}\right\}$ then $a : e :: c : f$. This follows from multiplying together the equations $\frac{a}{b} = \frac{c}{d}$, $\frac{b}{e} = \frac{d}{f}$ which give $\frac{ab}{be} = \frac{cd}{df}$, or $\frac{a}{e} = \frac{c}{f}$.

By thus deducing different equations from the equal fractions or ratios $\frac{a}{b} = \frac{c}{d}$ an endless variety of sets of proportionals may be obtained; but the most general of these deductions is derived from the following principle, namely :—

If two fractions, $\frac{a}{b}$, $\frac{c}{d}$ are equal, then we may replace the terms a, b of the first by any expressions involving a and b that are *homogeneous* in reference to these quantities, provided we also replace the terms c, d by expressions involving c and d in the same manner. For instance—

$2a^2 - 3ab + b^2$ is homogeneous as respects a and b: each term being of two dimensions; so also is $5ab + 4a^2 - 2b^2$; we may therefore substitute these for a and b, provided we put the similar expressions $2c^2 - 3cd + d^2$ and $5cd + 4c^2 - 2d^2$ for c and d; that is, we may infer that because—

$$\frac{a}{d} = \frac{c}{d} \therefore \frac{2a^2 - 3ab + b^2}{5ab + 4a^2 - 2b^2} = \frac{2c^2 - 3cd + d^2}{5cd + 4c^2 - 2d^2}.$$

The reason of this is pretty obvious; two fractions cannot be *equal* unless one is convertible into the other by multiplying num. and den. of the former by some factor (m); so that in the above, c must be $= ma$ and $d = mb$. Now, if in the *second* of the changed fractions above, you put ma, mb for their equals c and d, you will see at once that that fraction will be nothing but the *first* fraction with its num. and den. multiplied by m^2. If the homogeneous expressions chosen for the terms of the first fraction had been of *three* dimensions, then after the substitution of ma, mb, for c, d in the similar terms of the second fraction, the result would have differed from the first fraction only by the num. and den. being multiplied by m^3, and so on, as is obvious. The particular case of this general theorem which is most frequently employed is this, namely :—

$$\frac{a}{b} = \frac{c}{d} \therefore \frac{a \pm mb}{a \pm nb} = \frac{c \pm md}{c \pm nd}.$$

or, from $a : b :: c : d$

$$\therefore a \pm mb : a \pm nb :: c \pm md : c \pm nd$$

where the values of m and n are arbitrary. In most applications they are chosen each equal to 1, or one equal to 0, and the other equal to 1. We need scarcely mention, that when any of the conditions of a question are expressed by a *proportion*, the product of the extremes equated to the product of the means converts the proportion into an *equation*.

ARITHMETICAL AND GEOMETRICAL PROGRESSIONS.

Arithmetical Progression.

An arithmetical progression is a row, or *series* of quantities, such, that each quantity, after the first, is merely the *preceding* quantity with some invariable value added to it, or subtracted from it: thus, 1, 3, 5, 7, &c., and 1, −1, −3, −5, &c., are arithmetical progressions; the terms after the first in the former are obtained, each from the preceding, by adding 2; and in the latter by subtracting 2. The constant quantity thus added or subtracted is called the common difference: it is usually denoted by d; and as d may stand for a quantity either positive or negative, the following will be the *general way* of expressing an arithmetical progression—viz.:

$$a,\ a + d,\ a + 2d,\ a + 3d,\ a + 4d,\ \cdots\ a + (n - 1)d;$$

where n stands for the number of the terms: the last term being evidently derived from the first by adding to it as many times d as there are terms *after* the first; that is $n - 1$ times d; so that calling the last term l, we have $l = a + (n - 1)d$. You thus see that the problem—Given the first term, the common difference and the number of terms, to find the last term, is one of very easy solution. We shall therefore proceed to the next, which is this :—

Given the first term (a) the com. diff. (d), and the number of terms (n) to find the sum of the series (S).

$$S=a+(a+d)+(a+2d)+(a+3d)+\ldots\ldots l,$$

or writing the terms in reverse order,

$$S=l+(l-d)+(l-2d)+(l-3d)+\ldots\ldots a,$$

$$\therefore \text{adding, } 2S=(a+l)+(a+l)+(a+l)+(a+l)+\ldots\ldots a+l.$$

And as there are n terms in each series for S, there must be n *equal* terms in this last series; that is to say,

$$2S=n\,(a+l)\ \therefore S=\tfrac{1}{2}n\,(a+l);\ \text{but } l=a+(n-1)d$$

$$\therefore S=\tfrac{1}{2}n\,\{2a+(n-1)d\}$$

The foregoing expressions for l and S will enable you to determine any two of the five quantities concerned when the other three are given; as shown in the following examples.

1. The first term of an arithmetical progression is 5, and the ninth term 37; what is the common difference of the terms?

For the particular numbers here given, the formula

$$l=a+(n-1)d$$

$$\text{is } 37=5+8d\ \therefore d=\frac{37-5}{8}=4.$$

Therefore, the series is 5, 9, 13, 17, 21, 25, 29, 33, 37.

2. Required $1+3+5+7+9+$ &c., to twenty terms.

$$S=\tfrac{1}{2}n\,\{2a+(n-1)d\}$$

$$=10\ \{2+19\times 2\}=400.$$

3. How many terms of the series $\frac{1}{2}+\frac{1}{3}+\frac{1}{6}+$ &c. (where $d=-\frac{1}{6}$) must be taken so that the sum may be *nothing*?

$$S=\frac{1}{2}n\left\{2a+(n-1)d\right\}$$

$$\therefore 0=\frac{1}{2}n\ \left\{1-\frac{1}{6}(n-1)\right\}$$

$$=\frac{1}{2}n\left(\frac{7}{6}-\frac{n}{6}\right)\therefore 0=7n-n^2\ \therefore 0=7-n$$

$$\therefore n=7$$

therefore, the series is $\frac{1}{2}+\frac{1}{3}+\frac{1}{6}+0-\frac{1}{6}-\frac{1}{3}-\frac{1}{2}$.

4. Insert four *arithmetical means* between 2 and 17. Here 2 is the first, and 17 the *sixth* term of an arithmetical progression, and we have to find the common difference.

$$l=a+(n-1)d$$

$$17=2+5d\ \therefore d=\frac{15}{5}=3$$

∴ the means are, 5, 8, 11, 14; which evidently fill up the gap between the first term and the sixth; the series being 2, 5, 8, 11, 14, 17.

5. How many terms of the series $9+7+5$, &c., will give 24?

$$S=\tfrac{1}{2}n\ \{\ 2a+(n-1)d\ \}$$

$$\therefore 24=\tfrac{1}{2}n\ \{\ 18-2(n-1)\ \}=10n-n^2$$

$$\therefore n^2-10n=-24\ \therefore 2n-10=\sqrt{100-96}=\pm 2$$

$$\therefore n=4 \text{ or } 6.$$

Consequently, whether we take *four* terms of the proposed series or *six*, the sum in either case will be 24; thus—

four terms $9+7+5+3=24.$
six terms $9+7+5+3+1-1=24.$

EXAMPLES FOR EXERCISE.

1. Find the sum of sixteen terms of the series—

$$1+2+3+4+\text{\&c.}$$

2. Find the sum of fourteen terms of the series—

$$4+3+2+1+0-1-2-\text{\&c.}$$

3. Sum the series $\frac{1}{2}+1\frac{1}{3}+2\frac{1}{6}+$ &c., to twenty terms.

4. Insert three arithmetical means between 2 and 6.

5. Insert five arithmetical means between $\frac{1}{2}$ and $-\frac{1}{2}$.

6. The first term is 5, and the fifteenth 47; what is the common difference?

7. How many terms of the series $12+11\frac{1}{2}+11+10\frac{1}{2}$, &c., must be taken to make 55?

8. The first term of an arithmetical progression is 7, the common difference $-\frac{2}{3}$: required the ninth term.

9. The sum of eight terms of an arithmetical series is 2, and the common difference $-1\frac{1}{2}$: required the first term.

10. The first term of an arithmetical series is $-3\frac{1}{3}$, the common difference $\frac{1}{3}$: required the sum of twenty-one terms.

Geometrical Progression.

In an arithmetical progression, the several terms give equal *differences*; in a geometrical progression they give equal *quotients*; and this constant quotient, arising from dividing any term by that which immediately precedes it, is called the *common ratio*. The general form for a geometrical series, continued as far as n terms, is

$$a,\ ar,\ ar^2,\ ar^3,\ ar^4,\ \ .\ \ .\ \ .\ \ .\ \ .\ ar^{n-1}$$

where a is the first term, and r the common ratio; the last, or nth term, being $l=ar^{n-1}$; which formula enables us readily to find any remote term (the nth term) when the first term and the common ratio are given.

By glancing at the above general form for a geometrical series, you will at once see that the product of any two terms is always equal to the product of any other two equidistant from them; and that if the number of terms be *odd*, the product of the *extreme* terms is always equal to the square of the middle or *mean* term. Thus:—the product of the first and fifth terms is equal to that of the second and fourth, as also to the square of the third: that is—

$$ar^4\times a=ar^3\times ar=(ar^2)^2=a^2r^4.$$

When the first term of a geometrical progression is given, it is plain that we only require to know the common ratio in order to write down the succeeding terms to any extent; and from this it follows that when the leading term and any remote term are given, we may always find the intervening terms, and thus fill up the gap: for instance, if a and ar^4 be given, to find the *three* intervening terms, we should divide ar^4 by a; and knowing—from the fact that there are *five* terms altogether—that the quotient would be the *fourth* power of the ratio, we should obtain the ratio itself by taking the fourth root of that quotient: by help of the ratio, the wanting terms may be easily supplied, as noticed above. These intervening terms are called *geometrical means* between the given extremes; if only *one* mean is to be inserted between two extremes, it is found by taking the square root of the product of the extremes. Suppose, for example, it were required to find a geometrical mean between 2 and 8: then, since the square root of 8 × 2, or 16, is 4, we know the mean to be this number; the progression being 2, 4, 8: if the proposed extremes had been −2, −8, we should have taken the *minus* root of 16, and have written the progression thus, −2, −4, −8: nevertheless, whether the given extremes be both *plus* or both *minus*, the square root of their product with *either* sign may be truly regarded as a *mean*, for the following are geometrical progressions, as well as those above, 2, −4, 8; −2, 4, −8: the common ratio *here* being −2; in the sets above it was + 2.

Again, suppose we had to insert *two* geometrical means between 3 and 81: then, as there are *four* terms altogether, the exponent $n-1$ above, is here 3, $\therefore 81\div 3=27=r^3\ \therefore r=3$. Hence the progression is 3, 9, 27, 81; the required *means* being 9 and 27.

To find the sum (S) *of n terms of a geometrical progression.*

$$\text{Since } S=a+ar+ar^2+ar^3+ar^4+\ .\ .\ .\ ar^{n-2}+ar^{n-1}$$

$$\therefore Sr=ar+ar^2+ar^3+ar^4+\ .\ .\ .\ ar^{n-2}+ar^{n-1}+ar^n.$$

Subtracting the first expression from the second—

$$Sr-S+ar^n-a\ \therefore S=\frac{ar^n-a}{r-1},\ \text{or}=a\,\frac{r^n-1}{r-1}.$$

We have already seen that the last term l is ar^{n-1}, so that $rl = ar^n$, ∴ the first expression for S may be written

$$S = \frac{rl-a}{r-1} \quad . \quad . \quad . \quad . \quad (1),$$

and this formula, expressed in words, furnishes the following rule to obtain the sum.

Rule.—Multiply the last term by the ratio; from the product subtract the first term, and divide the remainder by the ratio minus 1.

This rule applies, of course, whether the ratio be whole or fractional, positive or negative. When it is a *proper fraction*, the series is a *decreasing* one; and if carried on to an unlimited extent, must supply terms approaching nearer and nearer to zero or nothing, the terms at length differing from 0 by quantities too small to be assigned. Although we cannot *write down* such an infinite number of terms, yet we may affirm, with confidence, that they are all comprehended between these extreme limits, namely, the first term a, and 0; with these limits included; for including the 0 in the series cannot affect the value of the *sum*. In finding this sum we may therefore regard 0 as the *last* term of the infinite decreasing series; so that, for all such series, the formula above, l being 0, will be—

$$S = \frac{a}{1-r} \quad . \quad . \quad . \quad . \quad (2);$$

and from this you see—strange as the thing may appear—that it is *easier* to find the entire sum of an *infinite* geometrical decreasing series, than to find the sum of three or four of its leading terms; because the formula (1) involves more calculation than the formula (2). For distinction sake, it is usual to replace the symbol S, for the sum of a *finite* series, Σ when the series is infinite; that is, to write the formulæ (1) and (2) thus:—

$$S = \frac{rl-a}{r-1}, \quad \Sigma = \frac{a}{1-r}.$$

1. Required the sixth term and the sum of six terms of the series $1+2+4+$ &c., in which $a = 1$, $r = 2$, and $n = 6$, $l = ar^{n-1} = 2^5 = 32$; $S = \frac{rl-a}{r-1} = 2 \times 32 - 1 = 63$.

2. Required the sum of five terms of the series $1 - 4 = 16 - 64 +$ &c., in which $r = -4$.

$$\text{Here } l = 256; \; S = \frac{rl-a}{r-1} = \frac{-1024-1}{-5} = 205.$$

3. Required the sum to seven terms, as also to infinity of each of the series, $1 + \frac{1}{2} + \frac{1}{4} +$ &c., and $1 - \frac{1}{2} + \frac{1}{4} -$ &c. In the first series $r = \frac{1}{2}$, $n = 7$ ∴ $l = ar^{n-1} = (\frac{1}{2})^6 = \frac{1}{64}$.

$$\therefore S = \frac{rl-a}{r-1} = \left(\frac{1}{128} - 1\right) \div -\frac{1}{2} = \frac{127}{128} \times 2 = 1\frac{63}{64}.$$

This is the sum of seven terms. When the number of terms is infinite, that is when $n = \infty$,* the sum is—

$$\Sigma = \frac{a}{1-r} = 1 \div \tfrac{1}{2} = 2;$$

so that the sum of the *infinite* series is just double of the first term; and you see how much more easily the sum of an infinite number of terms is found than the sum of seven terms.

In the second series $r = -\frac{1}{2}$, ∴ for the seventh term

$$\text{we have } l = ar^{n-1} = \left(-\frac{1}{2}\right)^6 = \frac{1}{64} \therefore S = \frac{rl-a}{r-1}$$

$$= \left(\frac{1}{128} - 1\right) \div -\frac{3}{2} = \frac{127}{128} \times \frac{2}{3} = \frac{127}{192}$$

$$\text{And when } n = \infty, \; \Sigma = \frac{a}{1-r} = 1 \div \frac{3}{2} = 1 \times \frac{2}{3} = \frac{2}{3}.$$

4. Insert five geometrical means between 2 and $\frac{1}{32}$.

Here, when the means are supplied, there will be *seven* terms ∴ $n = 7$; also $a = 2$, and $l = \frac{1}{32}$; but $l = ar^{n-1}$

$$= 2r^6 \therefore 2r^6 = \frac{1}{32} \therefore r^6 = \frac{1}{64} \therefore r = \pm\frac{1}{2}.$$

Consequently the five means are ± 1, $\frac{1}{2}$, $\pm \frac{1}{4}$, $\frac{1}{8}$ $\pm \frac{1}{16}$, so that the complete seven terms are either $2 + 1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16} + \frac{1}{32}$, or $2 - 1 + \frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16} + \frac{1}{32}$.

---

[*] This symbol stands for the word *infinite*.

EXAMPLES FOR EXERCISE.

1. Required the sum of five terms of the series $1 + 2^2 + 2^4 + 2^6 +$ &c.
2. Eight terms of $1 - \frac{1}{2} + \frac{1}{4} - \frac{1}{8} +$ &c.
3. Ten terms of $1 + 2 + 4 + 8 +$ &c.
4. What is the geometrical mean between 6 and 54?
5. Insert two geometrical means between 2 and 54.
6. Sum the series $\frac{1}{10} + \frac{1}{10^2} + \frac{1}{10^3} +$ &c., to affinity; that is, find the true fractional value of the recurring decimal ·1111. . .
7. The first term of a geometrical series is 3, the common ratio 5, and the last term 375: find the sum.
8. The first term of a geometrical series is $\frac{5}{6}$, and the common ratio $-\frac{1}{5}$: find the sum to infinity.
9. Insert three geometrical means between $\frac{1}{3}$ and $\frac{2}{3}$.
10. Required the sum of the infinite series,

$$1 + \frac{1}{x} + \frac{1}{x^2} + \frac{1}{x^3} + \text{\&c.}$$

and thence deduce the values of Σ in the particular cases of $x = 2$, and $x = -2$.

Besides the two classes of progressions just treated of, there is a third kind which may here be briefly adverted to, namely, *harmonical progression*. This name is given to every series of which the terms are the *reciprocals* of those of an arithmetical progression. Thus the reciprocals of the terms of the arithmetical series $1 + 2 + 3 + \;.\;.\;.\;.\; n$ give the harmonical series $1 + \frac{1}{2} + \frac{1}{3} + \;.\;.\;.\;.\; \frac{1}{n}$. It has been found that musical strings, of equal thickness and tension, when their lengths are as the numbers 1, $\frac{1}{2}$, $\frac{1}{3}$, &c., are in harmony when sounded together; and hence the term *harmonical progression*.

There is no general formula for the *sum* of an harmonical series, but any number of harmonical *means* may be inserted between two given extremes by help of the corresponding problem in arithmetical progression. Thus:—

Insert four harmonical means between 2 and 4.

First insert four arithmetical means between $\frac{1}{2}$ and $\frac{1}{4}$, from the formula $l = a + (n-1)d$, where $a = \frac{1}{2}$, $n = 6$, and $l = \frac{1}{4}$: we thus get $\frac{1}{4} = \frac{1}{2} + 5d$; ∴ $d = (\frac{1}{4} - \frac{1}{2}) \div 5 = -\frac{1}{20}$ ∴ since $\frac{1}{2} = \frac{10}{20}$, by applying the constant difference $-\frac{1}{20}$, we have, for the four *arithmetical* means, the quantities $\frac{9}{20}$, $\frac{8}{20}$, $\frac{7}{20}$, $\frac{6}{20}$; that is $\frac{9}{20}$, $\frac{2}{5}$, $\frac{7}{20}$, $\frac{3}{10}$; and, taking the reciprocals of these, the required *harmonical* means are

$$2\tfrac{2}{9},\; 2\tfrac{1}{2},\; 2\tfrac{6}{7},\; 3\tfrac{1}{3}.$$

And in this way you will find that two harmonical means, between 1 and 2, are $1\frac{1}{5}$ and $1\frac{1}{2}$; and that four, between 2 and 12, are $2\frac{2}{5}$, 3, 4 and 6.

Questions in which Proportion and Progression are concerned.

1. Divide 18 into two parts so that the squares of those parts may be the one to the other, as 25 to 16.

Let x be one part, then $18 - x$ is the other, and by the question,

$$\begin{aligned} & x^2 : (18-x)^2 :: 25 : 16 \\ \therefore \text{(Theo. 6, p. 477)}\; & x : 18 - x :: 5 : 4 \\ \text{or (p. 477)}\; & x : 18 :: 5 : 9 \\ \therefore \text{(Theo. 6, p. 477)}\; & x : 2 :: 5 : 1 \end{aligned}$$

∴ (Theo. 1, p. 477) $x = 10$ ∴ the parts are 10 and 8.

2. A merchant sold some brandy for £39, and gained as much per cent. as the brandy cost him. What was the original price?

Let £x = the cost price, then the gain was £x per £100,

$$\therefore 100 : x :: x : \frac{x^2}{100},$$ the number of pounds gained.

But the number of pounds gained was also $39 - x$

$$\therefore \frac{x^2}{100} = 39 - x$$

$$* \therefore x^2 + 100x = 3900 \therefore x^2 + 100x + 50^2$$
$$= 3900 + 2500 = 6400.$$
$$\therefore x + 50 = \pm 80 \therefore x = 30 \text{ or } -130.$$

∴ the cost price was £30; the negative value of x, though satisfying the algebraical conditions, being excluded by the nature of the question.

3. The sum of three numbers in arithmetical progression is 9, and the sum of their cubes 153. What are the numbers?

Let $x - y$, x, $x + y$ represent the numbers; then

$$x - y + x + x + y = 3x = 9 \therefore x = 3$$
$$(x-y)^3 + x^3 + (x+y)^3 = 3x^3 + 6xy^2 = 153 \therefore y^2 = \frac{153 - 3x^3}{6x} = 4 \therefore y = \pm 2,$$ ∴ the numbers are either 1, 3, 5; or 5, 3, 1; being the same set, whether the common difference y be taken positively or negatively.

4. A person travels a distance of 198 miles as follows: namely, 30 miles the first day, 28 the second, 26 the third, and so on: in how many days will he have finished the journey?

Here we have an arithmetical progression, in which $a = 30$, $d = -2$, and $S = 193$, to find n, the number of terms or days.

By the formula, p. 478, $S = \frac{1}{2} n \left\{2a + (n-1)d\right\}$, that is,

$$198 = \frac{1}{2} n \left\{60 - (n-1)2\right\} = 31n - n^2 \therefore n^2 - 31n = -198.$$
$$\dagger \therefore 2n - 31 = \sqrt{(31^2 - 792)} = \sqrt{169} = \pm 13.$$
$$\therefore n = \frac{31 \pm 13}{2} = 22 \text{ or } 9.$$

It would seem from this result, that he might arrive at his journey's end either in 9 days, or in 22 days. But you must always remember, in solving particular questions by algebra, that the equation which embodies the conditions of the question is not necessarily *restricted* to those conditions. The solution will furnish *all* the values which can satisfy the *equation;* whereas, from the limited nature of the question, some of these may be inadmissible. You perceive, in a moment, that the question solved above is of wider meaning than that proposed: it includes the proposed and something more; for it is this—namely, The sum of an arithmetical series is 198, the first term is 30, and the common difference —2: find the number of terms. The answer is perfectly general; for the series consists of either the *nine* terms $30 + 28 + 26 + 24 + 22 + 20 + 18 + 16 + 14 = 198$, or of the twenty-two terms furnished by extending the series to the thirteen additional terms $+ 12 + 10 + 8 + 6 + 4 + 2 + 0 - 2 - 4 - 6 - 8 - 10 - 12$; for you see that these additional terms amount to 0; and therefore that the sum of *nine* terms, or of *twenty-two*, equally amounts to 198. It is plain, therefore, that the algebra would have been imperfect if $n = 22$ had not been contained in the result, though the limitation of the question excludes it: this limitation evidently is, that each day's travel *adds* to the distance from the starting-point: the traveller is presumed not to go back, so that a *subtractive* day's journey is forbidden.

5. The sum of three numbers in geometrical progression is 13; and the product of the mean and sum of the extremes is 30; required the numbers.

Let the numbers be represented by $\frac{x}{y}$, x, and xy; the condition that they are to form a geometrical progression being thus secured.

Then the other two conditions are as follow—namely,

$$\frac{x}{y} + x + xy = 13$$
$$\text{and } \left(\frac{x}{y} + xy\right) x = 30$$

From the first of these equations

$$\frac{x}{y} + xy = 13 - x \ldots\ldots (A).$$

From the second $\frac{x}{y} + xy = \frac{30}{x}$, $\therefore 13 - x = \frac{30}{x}$,

$$\therefore 13x - x^2 = 30, \text{ or } x^2 - 13x = -30,$$

Consequently, by Rule II. of quadratic equations, page 474,

$$2x - 13 = \sqrt{(-120 + 13^2)} = \sqrt{49} = \pm 7,$$
$$\therefore x = \frac{13 \pm 7}{2} = 10, \text{ or } 3.$$

Therefore, substituting 3 for x in equation (A), we have $\frac{3}{y} + 3y = 13 - 3 = 10 \therefore 3 + 3y^2 = 10y$, or $3y^2 - 10y = -3$;

$$\ddagger\ 6y - 10 = \sqrt{(-36 + 100)} = \sqrt{64} = \pm 8.$$
$$\therefore y = \frac{10 \pm 8}{6} = 3, \text{ or } \frac{1}{3}$$

Hence, putting 3 for x, and 3 for y, in $\frac{x}{y}$, x, xy, the numbers are 1, 3, 9; or putting 3 for x, and $\frac{1}{3}$ for y, the numbers are 9, 3, 1; forming the same geometrical progression written in reverse order. If, instead of $x = 3$, the other value $x = 10$ had been taken, the corresponding values of y would have been imaginary, or impossible: thus, putting 10 for x in (A), the equation becomes

$$\frac{10}{y} + 10y = 13 - 10 = 3 \therefore 10 + 10y^2 = 3y,$$
$$\text{or } 10y^2 - 3y = -10,$$
$$\therefore 20y - 3 = \sqrt{(-400 + 9)} = \sqrt{-391},$$
$$\therefore y = \frac{3 \pm \sqrt{-391}}{20}$$

These two values of y are imaginary; so that the three numbers, 1, 3, 9, determined above, are the only *real* numbers that fulfil the conditions of the question.

---

1. Divide 49 into two parts such, that the greater increased by 6 may be to the less diminished by 11 as 9 to 2.

2. Two hundred stones are placed in a straight line at intervals of 2 feet, the first stone being 20 yards in advance of a basket: suppose a person starting from the basket collects the stones, and returns them one by one to the basket. How much ground does he go over?

3. The sum of four numbers in geometrical progression is equal to 1 added to the common ratio; and $\frac{1}{16}$ is the first term: required the numbers.

4. From two towns 165 miles apart, A and B set out to meet each other. A travels 1 mile the first day, 2 the second, 3 the third, and so on: B travels 20 miles the first day, 18 the second, 16 the third, and so on: in how many days will they meet?

5. The sum of the first and second of four numbers in geometrical progression is 15, and the sum of the third and fourth 60: what are the numbers?

6. The sum of three numbers in geometrical progression is 35; and the mean term is to the difference of the extremes as 2 to 3: what are the numbers?

CHAPTER V.

ALGEBRA.—MISCELLANEOUS INVESTIGATIONS.

A FEW particulars connected with the elements of algebra remain to be noticed. These might have been introduced earlier, and are so introduced in most books on the subject. We have thought it expedient, however, with a view to facilitate the progress of the student, to postpone them to this place.

To Extract the Square Root of a Polynomial

When we set about extracting the square root of a quantity, whether a number or an algebraical expression, we proceed on the supposition that the proposed quantity is really a *square;* that is, that it is capable of being produced from two *equal* factors. You know, that in *numbers*, this is not always the case; 2, 7, 8, 10, &c., are not *squares*, and therefore, in strictness, have no *square roots;* by the aid of decimals, however, we can *approximate*, as it is called, to the square root of any of these numbers; that is, we can find a number such that the square of it shall differ from the number proposed by as small a decimal as we please; so, that for all *practical* purposes, the root, thus determined, may be used for that of the proposed number; since it is the *exact* root of a number differing from the proposed one, only by a decimal too minute to be appreciated. The difference here spoken of would be actually exhibited by the *remainder* left at the close of the operation; for, by subtracting this remainder from the number proposed, we should convert that number into a complete square; we always take care, in such arithmetical operations, to push the approximative process sufficiently far to render the correctional remainder of no moment, in reference to the practical inquiry in hand.

It is the same with algebraical expressions or *polynomials;* we proceed (by the rule presently to be given) on the supposition that the square root actually exists, carrying on the process, as in arithmetic, till the terms of the polynomial have all been used up. If a remainder be left, we conclude that the polynomial is not a square, and can assign the correction necessary to make it a square; for this correction, as in arithmetic, is the *remainder.* In algebra, it is usual to stop as soon as the proposed polynomial is exhausted; the object being, in general, more to ascertain whether the expression submitted to the process is a square or not, than to seek algebraical approximations to imperfect squares. Indeed, the term *algebraical* approximation would be meaningless, as you must see; for, in the absence of all *numerical* interpretation of our symbols, how could we speak of a set of symbolical expressions *approximating*, as to value, to any other such expression? When numerical values are given to the letters, we may with propriety speak of such approximations; but, even then, what are *approximations* for some numerical values, will be *departures* for others.

Let us now take a complete algebraic square, and try to discover by what process its root may be evolved. And first, let the square be that of a binomial; namely, the square of $a + b$, which is $a^2 + 2\,ab + b^2$.

$$\begin{array}{rl} & a^2 + 2ab + b^2\,(a + b \\ & a^2 \\ \cline{2-2} 2a + b\,] & 2ab + b^2 \\ & 2ab + b^2 \\ \cline{2-2} \end{array}$$

Now write down this expression as in the margin, and mark off a place for the root, to the right. The square root of the first term is a, which we know to be the first term of the sought root; and subtracting a^2 from the given expression, we get $2ab + b^2$ for a remainder. Consider this remainder as a *dividend*, and let us see whether, by help of the term a, already in the root, we cannot discover the leading term of a *divisor* for this dividend, suited to give b, the other term of the root. A glance at the dividend shows that the proper leading term is just double the partial root a, already obtained; we therefore write $2a$ for the first term of the divisor we are seeking to form; and as, in algebra, the *first term* of a divisor is all we want, to get a term of the quotient, we at once pronounce b to be the second term of the quotient or root; and, to *complete* the divisor, we put this b, not only in the quotient, but *also* in the divisor; and we find that b times the complete divisor, $2a + b$, equals the dividend; and thus the operation terminates, and the required root is discovered.

Guided by this easy process, let us now endeavour to evolve the root from the square of a trinomial; namely, from the square of $a + b + c$, which is $(a + b)^2 + 2(a + b)c + c^2$; this being evidently the square of $(a + b) + c$. Writing the polynomial in the usual way, it would be $a^2 + 2ab + b^2 + 2(a + b)\,c + c^2$; and the following method, for discovering the terms a, b, c, of the root, one after another, is in exact imitation of the operation above.

$$\begin{array}{rll} & a^2 + 2\,ab + b^2 + 2\,(a + b)\,c + c^2\,[a + b + c & \\ & a^2 & \\ \cline{2-2} 2a + b\,] & 2\,ab + b^2 & \\ & 2\,ab + b^2 & \\ \cline{2-2} 2(a + b) + c\,] & & 2\,(a + b)\,c + c^2 \\ & & 2\,(a + b)\,c + c^2 \\ \cline{3-3} \end{array}$$

Here the first term a of the root is found as before: we then get the remainder or *dividend* $2ab + b^2$; the double of the known portion a of the root furnishes the *trial* or *incomplete* divisor $2a$, by help of which the second term b, of the root is found; after which the divisor is completed by joining this b to the incomplete form: we then get a second remainder or *dividend* $2(a + b)\,c + c^2$, and take the double of what is now in the root for the corresponding incomplete divisor: this gives for quotient c the third term of the root; and the addition of this c completes the divisor, the multiplication of which by the quotient-term c, finishes the process, as no remainder is left.

In like manner, by applying the same proceeding to the square of a quadrinomial $a + b + c + d$, we should obtain the several terms of the root, one after another; the polynomial whose root is sought being written in the form

$$a^2 + (2\,a + b)\,b + (2(a + b) + c)\,c + d^2,$$

as a mere contemplation of this form, in connection with the above process, makes sufficiently evident. And as the square of *any* polynomial $(a + b + c + d + .\ . + l)^2$, may be written

$$a^2 + (2a + b)\,b + (2(a + b) + c)\,c + (2(a + b + c) + d)\,d + \ldots. + l^2,$$

the process is general: it is expressed in words as follows:—

RULE 1.—Arrange the terms of the proposed polynomial as if for division, marking off a place as for quotient.

2.—Find the square root of the leading term, put it in the quotient's place, and the square of it under the leading term, which will of course be equal to it. Draw a line, as if for subtraction, and bring down, under it, the next *two* terms of the polynomial: these will form a *dividend*, and a place, to the left of it, is now to be marked off, for a *divisor.*

3.—Put *twice* the root-term, just found, in the divisor's place: see how often this *incomplete* divisor is contained in the leading term of the dividend, and connect the quotient, with its proper sign, both to the root-term, and to the incomplete divisor: the divisor will thus be *completed.*

4.—Multiply the complete divisor by the root-term just found, subtract the product from the dividend, and to the remainder unite the two next terms of the polynomial; and a *second* dividend will be obtained.

Proceed with this as with the former, marking off a place for a new divisor, and putting in that place *twice* the root-quantity already found, for an *incomplete* divisor, by aid of which the third root term may be found, which, added to the incomplete divisor, renders it *complete*. And this uniform process is to be continued till all the terms of the polynomial have been brought down, as in the following examples :—

$$\begin{array}{rl}
1. & 9x^4-12x^3+16x^2-8x+4\;(3x^2-2x+2 \\
 & 9x^4 \\
6x^2-2x] & -12x^3+16x^2 \\
 & -12x^3+\;\;4x^2 \\
6x^2-4x+2] & \qquad\qquad 12x^2-8x+4 \\
 & \qquad\qquad 12x^2-8x+4
\end{array}$$

$$\begin{array}{rl}
2. & 4x^6-24x^5+60x^4-80x^3+60x^2-24x+4\,(2x^3-6x^2+6x-2 \\
 & 4x^6 \\
4x^3-6x^2] & -24x^5+60x^4 \\
 & -24x^5+36x^4 \\
4x^3-12x^2+6x] & \qquad 24x^4-80x^3+60x^2 \\
 & \qquad 24x^4-72x^3+36x^2 \\
4x^3-12x^2+12x-2] & \qquad\qquad -8x^3+24x^2-24x+4 \\
 & \qquad\qquad -8x^3+24x^2-24x+4.
\end{array}$$

$$\begin{array}{rl}
3. & a^{4m}-4a^{3m+n}+6a^{2m+2n}-4a^{m+3n}+a^{4n}\;(a^{2m}-2a^{m+n}+a^{2n}. \\
 & a^{4m} \\
2a^{2m}-2a^{m+n}] & -4a^{3m+n}+6a^{2m+2n} \\
 & -4a^{3m+n}+4a^{2m+2n} \\
2a^{2m}-4a^{m+n}+a^{2n}] & \qquad 2a^{2m+2n}-4a^{m+3n}+a^{4n} \\
 & \qquad 2a^{2m+2n}-4a^{m+3n}+a^{4n}
\end{array}$$

$$\begin{array}{rl}
4. & 4x^4-4x^3-3x^2+2x+4\;(2x^2-x-1 \\
 & 4x^4 \\
4x^2-x] & -4x^3-3x^2 \\
 & -4x^3+x^2 \\
4x^2-2x-1] & \quad -4x^2+2x+4 \\
 & \quad -4x^2+2x+1 \\
 & \qquad\qquad\qquad 3
\end{array}$$

In this example there is a *remainder*, after all the terms of the proposed polynomial have been used: we infer therefore that the polynomial is not a complete square; but that it would be made one, by subtracting 3 (the remainder) from it: the expression $2x^2-x-1$ is the complete square root of $4x^4-4x^3-3x^2+2x+1$: the polynomial proposed cannot be produced from two *equal* factors: it is the product of the unequal factors $(2x^2-x-1+\surd-3)\,(2x^2-x-1-\surd-3)$.

EXAMPLES FOR EXERCISE.

Extract the square root of each of the following expressions :—

1. $x^2+4bx+4b^2$. *Root*, $x+2b$.
2. $9x^4+12x^3+10x^2+4x+1$. *Root*, $3x^2+2x+1$.
3. $9x^4+12x^3+34x^2+20x+25$. *Root*, $3x^2+2x+5$.
4. $x^6+4x^5+2x^4+9x^2-4x+4$. *Root*, x^3+2x^2-x+2.
5. $x^6-4x^5+10x^4-4x^3-7x^2+24x+16$. *Root*, x^3-2x^2+3x+4.
6. $4x^4+6x^3+\frac{89}{4}x^2+15x+25$. *Root*, $2x^2+\frac{3}{2}x+5$.

In this last example you may, if you please, multiply the polynomial by 4, in order to get rid of the fraction: the square root of the result will, of course, be the square root of the given expression, multiplied by the square root of 4: that is, by 2; you must, therefore, remember to divide the root by 2.

The above general rule, for the square root of an algebraical expression, applies, of course, to *numbers*; and suggests the arithmetical operation given at page 449, in the Arithmetic. The first step in this operation, is to separate the figures of the number into periods, by marking off two figures, commencing at the units' place, then two to the left of these, and so on. This enables us to determine the *local value* of the leading figure of the root, and thence the number of integer-places in the complete root. Thus, taking for example the number 76807696, we see, by help of the periods, that the first figure of the root must be in the place of *thousands*, the *square* of it being so many millions, like the 76 in the first period. The detailed operation, as suggested by the Algebra, is therefore as follows :—

$$\begin{array}{rll}
 & 76\;80\;76\;96(8000+700+60+4= & \\
 & 64\;00\;00\;00 & 8700+60+4= \\
16000+700=16700) & 12\;80\;76\;96 & 8760+4=8764 \\
 & 11\;69\;00\;00 & \\
17400+60=17460) & \;\;1\;11\;76\;96 & \\
 & \;\;1\;04\;76\;00 & \\
17520+4=17524) & \qquad 7\;00\;96 & \\
 & \qquad 7\;00\;96 &
\end{array}$$

The above operation is the same, in principle, as that at page 449 of the Arithmetic; by a reference to which you will see that the more compact form, which the work assumes in the place referred to, arises merely from the suppression of the useless *ciphers* or *noughts*, and the postponement of the successive periods till they are actually wanted in the several dividends.

To Extract the Square Root of a Binomial, one of whose terms is Rational, and the other a Quadratic Surd.

It sometimes happens that expressions of the form

$\sqrt{(a+\sqrt{b})}$ occur in the results of algebraical problems: if they be left in this form, and then when a and b are interpreted, the operations of arithmetic be applied to them, you see that if b be irrational, we shall have to find the square root of b to a certain number of decimals, and then to extract the square root of $a+\sqrt{b}$, a quantity *necessarily* involving decimals. The square root of b, may be taken out of a table of square roots to several decimal places, when b consists of not more than four or five figures; but the square root of a number consisting of three or four figures, followed by five or six decimals, cannot be found to any degree of nicety by existing tables; so that, in such a case, the arithmetical operation must be executed. As we have told you before, algebraists seek such a form for their results as will give arithmeticians the least trouble in the numerical computation of them; and this is one reason why they have sought to convert $\sqrt{(a+\sqrt{b})}$, into the simpler form $\sqrt{a'}+\sqrt{b'}$.

In order to show how this is done, a theorem or two respecting binomial surds must first be established.

1. The square root of a quantity cannot be *partly* rational and *partly* a quadratic surd: that is to say, the condition $\sqrt{p}=q+\sqrt{r}$ is impossible, provided p and r are not themselves squares.

For, assuming this equation to be possible, we should have, by squaring each side $p=q^2+2q\sqrt{r}+r$, so that $\sqrt{r}=\frac{p-q^2-r}{2q}$, a rational quantity, which is contrary to the supposition, as it shows that r must be the *square* of the second member of this equation.

2. In every equation of the form $a+\sqrt{b}=x+\sqrt{y}$, where a and x are *rational* quantities, and $\sqrt{b}$ *irrational* or *surd*, a must be equal to x, and therefore b will equal y. For if a and x had any difference, then by transposing the a, we should have the square root of a quantity, not itself a square, expressed either by a rational quantity, which is absurd, or by a quantity partly rational and partly irrational, which has been shown above to be impossible. It follows that $\sqrt{y}$ must be irrational as well as $\sqrt{b}$.

3. If $\sqrt{(a+\sqrt{b})}=x+y$: then must $\sqrt{(a-\sqrt{b})}=x-y$; where $\sqrt{b}$ is a quadratic surd, and x, y, one or both, also quadratic surds.

For by squaring the first equation $a+\sqrt{b}=x^2+2xy+y^2$, where x^2+y^2 is necessarily *rational*, and $\therefore 2xy$ irrational (by 2 above) being equal to $\sqrt{b}$: that is (by 2),

$$a=x^2+y^2,\ \sqrt{b}=2xy,\ \therefore a-\sqrt{b}=x^2-2xy+y^2,\ \therefore \sqrt{(a-\sqrt{b})}=x-y.$$

By help of this latter principle, combined with theo. 2 above, the extraction of the square root of a binomial surd consisting of a rational term, and of a quadratic irrational term, may be effected, as in the following examples:—

1. Extract the square root of $7+2\sqrt{10}$.

$$\text{Put } \sqrt{(7+2\sqrt{10})}=x+y,\ \therefore \sqrt{(7-2\sqrt{10})}=x-y;$$

$$\therefore \text{taking the product, } \sqrt{(49-40)}=x^2-y^2,\ \therefore 3=x^2-y^2.$$

$$\text{But } 7+2\sqrt{10}=x^2+2xy+y^2,\ \therefore 7=x^2+y^2,\ \therefore 10=2x^2,\ 4=2y^2$$

$$\therefore x=\sqrt{5},\ y=\sqrt{2},\ \therefore \sqrt{(7+2\sqrt{10})}=\sqrt{5}+\sqrt{2}.$$

You will at once see that the change of $\sqrt{(7+2\sqrt{10})}$ into $\sqrt{5}+\sqrt{2}$ facilitates the arithmetical computation: a table of square roots gives us $\sqrt{5}=2{\cdot}2360680$, and $\sqrt{2}=1{\cdot}4142136$; so that the root sought is $3{\cdot}6502816$. If the unchanged form be used, we should have, from the table, $\sqrt{10}=3{\cdot}1622777$; twice this increased by 7 is $13{\cdot}3245554$, and the square root of this we should have to find by actual extraction, on account of the necessarily limited extent of the tables.

2. Find the square root of $10-\sqrt{96}$.

$$\text{Put } \sqrt{(10+\sqrt{96})}=x+y,\ \therefore \sqrt{(10-\sqrt{96})}=x-y.$$

$$\left.\begin{aligned}\therefore \sqrt{(100-96)}=x^2-y^2=2.\\ \text{Also } x^2+2xy+y^2=10+\sqrt{96},\ \therefore x^2+y^2=10\end{aligned}\right\}$$

$$\because x^2=6,\ y^2=4,\ \therefore \sqrt{(10-\sqrt{96})}=\sqrt{6}-2.$$

3. Find general expressions for the square roots of $a+\sqrt{b}$, and $a-\sqrt{b}$.

Putting $x+y$, and $x-y$, for the required roots, we have—

$$\left.\begin{aligned}a+\sqrt{b}=x^2+2xy+y^2\\ a-\sqrt{b}=x^2-2xy+y^2\end{aligned}\right\}\ \therefore x^2+y^2=a$$

$$\text{Also } x^2-y^2=\sqrt{(a^2-b)}$$

By adding and subtracting

$$x^2=\frac{a+\sqrt{(a^2-b)}}{2},\ y^2=\frac{a-\sqrt{(a^2-b)}}{2}$$

therefore $x+y$, $x-y$, that is $\sqrt{(a+\sqrt{b})}$ and $\sqrt{(a-\sqrt{b})}$ are respectively

$$\sqrt{(a+\sqrt{b})}=\sqrt{\frac{a+\sqrt{(a^2-b)}}{2}}+\sqrt{\frac{a-\sqrt{(a^2-b)}}{2}}$$

$$\sqrt{(a-\sqrt{b})}=\sqrt{\frac{a+\sqrt{(a^2-b)}}{2}}-\sqrt{\frac{a-\sqrt{(a^2-b)}}{2}}$$

These general expressions show that, whenever a^2-b is not *a square*, nothing is gained by changing $\sqrt{(a+\sqrt{b})}$ into the new form, but in fact something lost in the way of simplification: the changed form is less complex than the original only when a^2-b is a square: it is prudent, therefore, to ascertain whether or not this be the case, before entering upon the proposed transformation; and to leave the form unchanged if a^2-b be not a square.

EXAMPLES FOR EXERCISE.

1. $\sqrt{(19+8\sqrt{3})}=4+\sqrt{3}$
2. $\sqrt{(12-\sqrt{140})}=\sqrt{7}-\sqrt{5}$
3. $\sqrt{(7-2\sqrt{10})}=\sqrt{5}-\sqrt{2}$
4. $\sqrt{(8+\sqrt{39})}=\frac{1}{2}(\sqrt{26}+\sqrt{6})$
5. $\sqrt{(76-32\sqrt{3})}=8-2\sqrt{3}$
6. $\sqrt{(31+12\sqrt{-5})}=6+\sqrt{-5}$.

On Multipliers which render Binomial Surds rational.

It has already been noticed (page 466), that it is in general inconvenient to have the result of an algebraic operation in the form of a fraction with a surd denominator; and when the surd so occurring is *monomial*, the means of removing it have been explained. We are now to show how, in like manner, a fraction having a binomial surd $\sqrt{a}+\sqrt{b}$ or $\sqrt{a}-\sqrt{b}$ for denominator, may be converted into an equivalent fraction with a rational denominator; in other words, to explain the method of *rationalising* binomial surds of the above form. This is very easy, the rationalising multiplier being at once suggested from the binomial surd itself: if it be $\sqrt{a}+\sqrt{b}$, the multiplier is obviously $\sqrt{a}-\sqrt{b}$; and if it be $\sqrt{a}-\sqrt{b}$, the multiplier is $\sqrt{a}+\sqrt{b}$; and you thus have a useful application of the principle that the *sum* multiplied by the *difference* of two quantities gives the difference of their squares. Suppose, for example, our fraction is $\frac{3}{\sqrt{5}+\sqrt{7}}$, a form which is inconvenient for computation, because after getting $\sqrt{5}+\sqrt{7}$ we should have the troublesome operation of dividing 3 by a number consisting of many figures. But by multiplying numerator and denominator by $\sqrt{5}-\sqrt{7}$, we change the fraction into $\frac{3(\sqrt{5}-\sqrt{7})}{5-7}=\frac{3}{2}(\sqrt{7}-\sqrt{5})$, by which change the long division spoken of is avoided.

As a second example, let $\frac{\sqrt{3}+1}{5-\sqrt{3}}$ be proposed. The rationalising multiplier here is $5+\sqrt{3}$, and the changed fraction is $\frac{(\sqrt{3}+1)(5+\sqrt{3})}{25-3}=\frac{4+3\sqrt{3}}{11}$.

Sometimes the binomial surd to be rationalised is of the form $\sqrt[3]{a}\pm\sqrt[3]{b}$: in this case the suitable multiplier will be *trinomial*: it will consist of the *squares* of both the irrational terms, and of their product with changed sign, as actual multiplication will show; for

$$(\sqrt[3]{a}\pm\sqrt[3]{b})(\sqrt[3]{a^2}\mp\sqrt[3]{ab}+\sqrt[3]{b^2})=a\pm b.$$

The rationalising multiplier is therefore easily remembered: the following is an example of its application:—

Convert the fraction $\frac{5}{\sqrt[3]{5}-\sqrt[3]{2}}$ into an equivalent one with a rational denominator.

$$\frac{5}{\sqrt[3]{5}-\sqrt[3]{2}}=\frac{5(\sqrt[3]{25}+\sqrt[3]{10}+\sqrt[3]{4})}{5-2}=\frac{5}{3}(\sqrt[3]{25}+\sqrt[3]{10}+\sqrt[3]{4}).$$

And this form, though involving *three* cube roots, is of easier calculation than the original, if tables of cube roots are used; because there is no long-division operation.

EXAMPLES FOR EXERCISE.

Prove that—

1. $\frac{3}{2\sqrt{7}-3\sqrt{2}}=\frac{3}{10}(2\sqrt{7}+3\sqrt{2}).$
2. $\frac{2+\sqrt{3}}{3+\sqrt{3}}=\frac{3+\sqrt{3}}{6}$
3. $\frac{\sqrt{6}}{\sqrt{8}+\sqrt{3}}=\frac{4\sqrt{3}-3\sqrt{2}}{5}.$
4. $\frac{2}{\sqrt[3]{3}-\sqrt[3]{2}}=2(\sqrt[3]{9}+\sqrt[3]{6}+\sqrt[3]{4}).$
5. $\frac{5}{\sqrt[3]{7}-\sqrt[3]{5}}=\frac{5}{2}(\sqrt[3]{49}+\sqrt[3]{35}+\sqrt[3]{25}).$
6. $\frac{\sqrt{12}-\sqrt{10}}{\sqrt{6}+\sqrt{5}}=11\sqrt{2}-4\sqrt{15}.$

To Extract the Cube Root of a Compound Quantity.

In order to discover the means of arriving at the cube root of a polynomial, we may proceed in imitation of the course adopted for the determination of the square root. Thus, to begin with the simplest case, let us take the cube of $a+b$; that is, the expression $a^3+3a^2b+3ab^2+b^3$; and, availing ourselves of our previous knowledge of the cube root of this expression, let us inquire by what steps it may be evolved.

We see that the first term a of the root is at once obtained from the leading term of the polynomial; we thus have the step

$$\begin{array}{l} a^3+3a^2b+3ab^2+b^3(a \\ \underline{a^3} \\ \quad 3a^2b+3ab^2+b^3; \end{array}$$

and regarding the remainder, here exhibited, as a dividend, it remains to find a divisor of it, such that the quotient may be b. It is plain that three times the square of the root term a, just found, taken as a *trial* or incomplete divisor, suffices to suggest the second term b of the root; and we see, moreover, that if three times the product of the *two* root terms, a and b, as also the square of b, be added to the trial divisor $3a^2$, that the complete divisor, corresponding to the quotient b, will be obtained; hence the finished process is as follows:—

$$\begin{array}{rl} & a^3+3a^2b+3ab^2+b^3(a+b \\ & \underline{a^3} \\ 3a^2+3ab+b^2) & 3a^2b+3ab^2+b^3 \\ & \underline{3a^2b+3ab^2+b^3.} \end{array}$$

If the root consist of three terms, $a+b+c$, that is, if the polynomial be $(a+b+c)^3$, or $(a+b)^3+3(a+b)^2c+3(a+b)c^2+c^3$, then the portion $(a+b)^3$ of this polynomial may be exhausted, as above, and the first two terms $a+b$ of the root thus found. And, just as in the former case, b was derived from a, so here it is plain that c may be derived from $a+b$. From these considerations the following rule is suggested:—

RULE.—Arrange the terms according to the powers of one of the letters, as in the operation for the square root. Put the cube root of the leading term in the quotient's place, subtract the cube of it from the polynomial, bringing down the next *three* terms for a dividend, to the left of which mark off a place for the divisor. In this place put *three times* the square of the root term just found; this will be the *trial divisor*, and the quotient it suggests will be the second term of the root.

To *three times* the product of this new term and the preceding, add the square of the new term, and connect the result to the trial divisor; the whole will be the *complete divisor.*

Multiply the complete divisor by the new term, subtract the product from the dividend, and annex three more terms of the polynomial to the remainder; the whole will be the second dividend.

For the corresponding trial divisor put *three times* the square of the root-quantity now found, in the divisor's place; and with this trial divisor find the third term of the root; and then complete the divisor, by adding to what is already in the divisor's place *three times* the product of the new term and the preceding part of the root, and also the square of the new term; proceed then as in division, adding three new terms of the polynomial to the remainder; and so on, till all the terms of the polynomial have been brought down.

You will perceive that the principal part of the work consists in forming the successive divisors, each of which is made up of *three* portions—namely, thrice the square of the part of the root previously obtained, thrice the product of this part and the new term, and the square of that new term. The first of these portions is what we have called the *trial divisor;* but you will not fail to notice, that, as in the operation for the square root, the *leading term* of the *first* divisor is always sufficient to make known any subsequent term of the root; so that after the first divisor is obtained, every new term of the root may be discovered at once, without the aid of any special trial divisor; and therefore every subsequent divisor may be inserted at once, in its proper place, and in its complete form.

The following is an example of the operation:—

$$\begin{array}{ll} & x^6-6x^5+15x^4-20x^3+15x^2-6x+1\,(x^2-2x+1 \\ & \underline{x^6} \\ 3x^4-6x^3+4x^2) & -6x^5+15x^4-20x^3 \\ & \underline{-6x^5+12x^4-8x^3} \\ 3x^4-12x^3+15x^2-6x+1) & 3x^4-12x^3+15x^2-6x+1 \\ \text{This is made up of} & \underline{3x^4-12x^3+15x^2-6x+1} \\ 3(x^2-2x)^2+3(x^2-2x)+1 & \end{array}$$

As a second example the following may be taken:—

$$\begin{array}{ll} & 27x^6-54x^5+63x^4-44x^3+21x^2-6x+1\,(3x^2-2x+1 \\ & \underline{27x^6} \\ 27x^4-18x^3+4x^2) & -54x^5+63x^4-44x^3 \\ & \underline{-54x^5+36x^4-8x^3} \\ 27x^4-36x^3+21x^2-6x+1) & 27x^4-36x^3+21x^2-6x+1 \\ \text{This is made up of} & \underline{27x^4-36x^3+21x^2-6x+1} \\ 3(3x^2-2x)^2+3(3x^2-2x)+1 & \end{array}$$

The operation, as just conducted, is tolerably short; but there is some work, in finding the several divisors, which does not appear to the eye in looking at the finished form. We shall explain another mode of proceeding, much more complicated in appearance, but very simple indeed in the performance. It presents to the eye three columns of work, as below; they are formed thus:—

Write down 0, 0, and the given polynomial, as the leading quantities of three vertical columns of work; and then proceed to fill up the column thus:—Put the first term of the root not only in the quotient's place, but also under the first 0; to which, for uniformity sake, you may consider it to be *added*; multiply the sum by the same root-term, and add the product to the next 0; multiply the sum still by the same root-term, and *subtract* the product from the polynomial, bringing down, however, only *three* terms for remainder.

Return to the first column, and add the same term anew, multiplying the sum and carrying the product to the second column as before, but not extending the work to the third column. Return *again* to the first column, repeating the former operation, and there stop. With the last result in the second column, taken as a trial divisor, find the second term of the root; and go over with *this* exactly the same process, extending the several columns, by successive additions, till the polynomial is exhausted. As an inspection of the operation will convey a clearer idea of the several steps than words will do, we here give the work of the last example in the form proposed.

\end{array}
$$

NOTE.—It would be very easy to contrive means of abridging the work here exhibited in the fullest detail: but a learner will more clearly see the entire texture of the process by having every item of it thus put before him.

By the very same process, the fifth root, the seventh root, and indeed any root whatever of a polynomial, may be extracted: we have only to form, as above, as many columns of work as are sufficient to mark the number of the root; that is, five columns for the fifth root, seven for the seventh root, and so on; to construct the first column by that number of additions of the first root-term, of the second root-term, and so on; and to carry on the formation of the other columns as above. Whether you adopt this method of arranging the work of extracting the cube root of a *polynomial* or not, it is the arrangement we would recommend you always to observe, in extracting the cube root of a *number*; as it precludes the necessity of retaining in the memory a somewhat intricate rule: nothing can be more easy to remember than the very simple series of recurring operations of which the several steps of the following process are made up: the close of each of these steps we have marked by an Egyptian figure, in order that you may the more distinctly see where one step of the operation ends, and another begins. We call that a *step* which comprises the work between the determination of one root-figure and that of the immediately succeeding figure.

1. Required the cube root of 189119224.

It is easy to foresee, that after the step marked 4 (Ex. 3) is reached, the work of the subsequent steps can have little or no influence upon the *three* leading figures 6·23 of the forthcoming *divisors;* so that regarding these three figures as constant, and recognising the others, 8092, only for the sake of what is *carried* from them, we may, as above, make sure of at least *three* true decimals of the root, beyond the three already found, *by common division*, provided we reject a figure of the constant divisor, 6·23, at each step, taking care to secure accuracy in the carryings from the rejected figures.

Ex. 1. The cube root of $x^6 + 9x^5 + 6x^4 - 99x^3 - 42x^2 + 441x - 343$ is $x^2 + 3x - 7$.

2. The cube root of $x^6 + 6x^5 + 40x^3 - 96x - 64$, that is of $x^6 + 6x^5 + 0x^4 - 40x^3 + 0x^2 + 96x - 64$, is $x^2 + 2x - 4$.

3. The cube root of 12994449551 is 2351.

4. The cube root of 2 is 1·25992104989.

5. The cube root of 959 is 9·8614218.

6. The cube root of $x^6 - 15x^5y + 69x^4y^2 - 138x^2y^4 - 60xy^5 - 8x^6$ is $x^2 - 5xy - 2y^2$.

We here conclude the treatise on Elementary Algebra. The subject, in its widest acceptation, is one of very considerable extent—we might almost say of unlimited extent; as there are no definite bounds to its operations. In the preceding treatise, our object has been to unfold to you, fully and perspicuously, the leading principles of the science; and thus to lay a sufficiently secure basis for future researches. There is one department of the subject—the general theory of Logarithms and Series—which we have not touched upon here. It is a part of Algebra which is marked by peculiar features, and is occupied with investigations different in kind and in object from those necessary for the solution of an algebraical equation, or for the reduction of an algebraical expression; and is, moreover, of sufficient importance to merit distinct consideration. We shall, therefore, first give solutions to the various exercises contained in the foregoing chapters; and in the succeeding one, the subject of Series and Logarithms will be fully entered into. An extended Table of Logarithms of natural numbers will be also included.

SOLUTIONS TO THE EXERCISES IN THE CHAPTERS ON ALGEBRA.

At page 452 of the Algebra, a promise was given to furnish the Answers to all the Examples proposed for exercise in that subject. Considering for whom the work was expressly written—for persons not merely unacquainted with the very alphabet of Algebraical Science, but also precluded from the advantages of academical instruction—we have thought that more acceptable service would be rendered by supplying sketches of the solutions themselves, rather than a mere register of the *results*. You will therefore regard what follows as furnishing a Key to the unworked examples; showing briefly—but, we hope, clearly—the processes by which the answers are to be obtained.

In Addition and Subtraction, however, all that can here be done is to put down the totals; for the result of an addition or subtraction example exhibits, in itself, the whole work.

Exercises. Page 452.

1. $3a + 4c = 3.4 + 4.3 = 12 + 12 = 24$.
2. $5c - 2a = 5.3 - 2.4 = 15 - 8 = 7$.
3. $13n + b = 13.1 + 2 = 13 + 2 = 15$.
4. $21m - 9d = 21.8 - 9.5 = 168 - 45 = 123$.
5. $7d + 4n - 2a = 7.5 + 4 - 2.4 = 35 + 4 - 8 = 31$.
6. $3a + 4b - 5c = 3.4 + 4.2 - 5.3 = 12 + 8 - 15 = 5$.
7. $6m - 5n - 3b = 6.8 - 5 - 3.2 = 48 - 5 - 6 = 37$.
8. $14 - 3c + m = 14 - 3.3 + 8 = 14 - 9 + 8 = 13$.
9. $11b + n - 13 = 11.2 + 1 - 13 = 10$.
10. $-4d + 5m - 2n = -4.5 + 5.8 - 2 = 18$.
11. $\frac{3m}{4} + 6 - \frac{m}{2} = \frac{3.8}{4} + 6 - \frac{8}{2} = 6 + 6 - 4 = 8$.
12. $\frac{5a}{2} + \frac{4d}{5} - 2c = \frac{5.4}{2} + \frac{4.5}{5} - 2.3 = 10 + 4 - 6 = 8$.
13. $\frac{2a + 3b}{7} + m - n = \frac{2.4 + 3.2}{7} + 8 - 1 = 2 + 8 - 1 = 9$.
14. $\frac{3a - 4b + 6c - 2}{10} = \frac{3.4 - 4.2 + 6.3 - 2}{10} = \frac{20}{10} = 2$.
15. $3ab + dm - 5b + 6cn - 18 = 3.4.2 + 5.8 - 5.2 + 6.3 - 18 = 54$.
16. $2abm - 3cdm + \frac{3dm}{8} + ad = 2.4.2.8 - 3.3.5.8 + \frac{3.5.8}{8} + 4.5 = -197$.
17. $\frac{5am - 2bc + n - 49}{140} - n = \frac{5.4.8 - 2.2.3 + 1 - 49}{140} - 1 = -\frac{2}{7}$.
18. $\frac{24}{m} + \frac{5abc}{24} - \frac{60}{bcd} - \frac{m + n}{2b + d} = \frac{24}{8} + \frac{5.4.2.3}{24} - \frac{60}{2.3.5} - \frac{8 + 1}{2.2 + 5} = 5$.

Page 453. Ex. 1. $2xy - 4xy + 13xy + 3xy = 14xy$.
2. $-axz - 7axz + 11axz + axz = 4axz$.
3. $9mnx + 5mnx - 13mnx = mnx$.
4. $6\frac{a}{b} + 2\frac{a}{b} - 5\frac{a}{b} - 2\frac{a}{b} + \frac{a}{b} = 2\frac{a}{b}$.

SIMPLE EQUATIONS. EXAMPLES FOR EXERCISE. PAGE 457.

1. $2x-7=x+4$. Transposing, $2x-x=4+7$, that is, $x=11$.
2. $5x-3=3x+5$. Transposing, $5x-3x=5+3$, $\therefore 2x=8$ $\therefore x=4$.
3. $6x+2=4x+8$. Transposing, $6x-4x=8-2$, $\therefore 2x=6$ $\therefore x=3$.
4. $3x-1=x+7$. Transposing, $3x-x=7+1$, $\therefore 2x=8$ $\therefore =4$.
5. $8x-13=4x-1$. Transposing, $8x-4x=13-1$, $\therefore 4x=12$ $\therefore x=3$.
6. $2(x+3)=20$, that is, $2x+6=20$. Transposing, $2x=20-6=14$, $\therefore x=7$.
7. $3(x-4)=6$, that is, $3x-12=6$. Transposing, $3x=18$, $\therefore x=6$.
8. $4(x-1)=x+5$, that is, $4x-4=x+5$. Transposing, $3x=9$, $\therefore x=3$.
9. $5(x+2)=2(x+8)$, that is, $5x+10=2x+16$. Transposing, $3=6$, $\therefore x=2$.
10. $3(2x-3)=4(x-2)$, that is, $6x-9=4x-8$. Transposing, $2x=1$, $\therefore x=\frac{1}{2}$.

11. $\frac{x}{3}+\frac{x}{4}=7$. Multiplying by 3, to clear the first fraction,

$$x+\frac{3x}{4}=21.$$

Multiplying by 4, $4x+3x=84$, $\therefore 7x=84$, $\therefore x=\frac{84}{7}=12$.

12. $\frac{x}{3}-\frac{x}{4}=1$. Multiplying by 3, $x-\frac{3x}{4}=3$.

Multiplying by 4, $4x-3x=12$, $\therefore x=12$.

13. $\frac{2x}{3}-\frac{x}{4}=5$. Multiplying by 3, $2x-\frac{3x}{4}=15$.

Multiplying by 4, $8x-3x=60$, $\therefore 5x=60$, $\therefore x=12$.

14. $\frac{x}{2}+\frac{x}{3}=31-\frac{x}{5}$. Multiplying by 2,

$$x+\frac{2x}{3}=62-\frac{2x}{5}.$$

Multiplying by 3, $3x+2x=186-\frac{6x}{5}$.

" 5, $15x+10x=930-6x$, $\therefore 15x+10x+6x=930$.

That is, $31x=930$, $\therefore x=\frac{930}{31}=30$.

15. $\frac{x}{3}+\frac{x}{4}+\frac{x}{6}=1$. Multiplying by 3,

$$x+\frac{3x}{4}+\frac{3x}{6}=3.$$

Multiplying by 4, $4x+3x+2x=12$, $\therefore 9x=12$, $\therefore x=\frac{12}{9}=1\frac{1}{3}$.

16. $2x-(48-x)=x+12$, that is, $2x-48+x=x+12$, or transposing, $2x=12+48=60$, $\therefore x=30$

17. $\frac{5(3x+2)}{2}=35$. Multiplying by 2, and removing vinculum,

$$15x+10=70,\ \therefore 15x=60,\ \therefore x=4.$$

18. $\frac{x+3}{5}-1=2-\frac{x}{7}$, or $\frac{x+3}{5}=3-\frac{x}{7}$. Multiplying by 5,

$$x+3=15-\frac{5x}{7},\ \text{or}\ x=12-\frac{5x}{7}.$$

Multiplying by 7, $7x=84-5x$, $\therefore 12x=84$, $\therefore x=7$.

19. $\frac{x}{2}+\frac{x}{3}-\frac{x}{5}-1=0$. Multiplying by 2,

$$x+\frac{2x}{3}-\frac{2x}{5}-2=0.$$

$$\text{Multiplying by 3, } 3x+2x-\frac{6x}{5}-6=0, \text{ or } 5x-\frac{6x}{5}=6.$$

$$\text{,, by 5, } 25x-6x=30, \therefore 10x=30, \therefore x=\frac{30}{19}=1\tfrac{11}{19}.$$

20. $\frac{x}{2}+\frac{x}{3}-\frac{x}{4}-\frac{1}{2}=0$. Multiplying by 2,

$$x+\frac{2x}{3}-\frac{x}{2}-1=0.$$

$$\text{Multiplying by 3, } 3x+2x-\frac{3x}{2}-3=0, \text{ or } 5x-\frac{3x}{2}-3=0.$$

$$\text{,, by 2, } 10x-3x-6=0, \therefore 7x=6, \therefore, x=\frac{6}{7}.$$

21. $11-\frac{5x}{8}=\frac{x}{2}-\frac{2x}{3}$. Multiplying by 8,

$$88-5x=4x-\frac{16x}{3}.$$

$$\text{Multiplying by 3, } 264-15x=12x-16x, \therefore 264=11x, \therefore x=\frac{264}{11}=24.$$

22. $4x-2(3-x)=\frac{x+3}{2}$, that is, $4x-6+2x=\frac{x+3}{2}$, or $6x-6=\frac{x+3}{2}$.

$$\text{Multiplying by 2, } 12x-12=x+3, \therefore 11x=15, \therefore x=\frac{15}{11}=1\tfrac{4}{11}.$$

23. $6x-\frac{4-3x}{5}=\frac{29}{5}$. Multiplying by 5,

$$30x-4+3x=29, \therefore 33x=33, \therefore x=1.$$

24. $\frac{x-6}{5}+\frac{x}{3}=20-\frac{x-2}{2}$, that is, $\frac{x}{2}-3+\frac{x}{3}=20-\frac{x}{2}+1$, or by transposing, $x+\frac{x}{3}=24$, $\therefore$ mult. by 3, $3x+x=72$, $\therefore 4x=72$, $\therefore x=18$.

25. $\frac{3x-13}{7}+\frac{11-4x}{3}=0$. Multiplying by 7,

$$3x-13+\frac{77-28x}{3}=0.$$

$$\text{Multiplying by 3, } 9x-39+77-28x=0.$$

$$\text{Transposing, } 38=19x, \therefore x=2.$$

26. $6-\frac{x-1}{2}-\frac{x-2}{3}=\frac{3-x}{4}$. Multiplying by 4, in order that both the first and last fractions may be cleared at the same time, we have

$$24-2x+2-\frac{4x-8}{3}=3-x,$$

$$\text{Multiplying by 3, } 72-6x+6-4x+8=9-3x.$$

$$\text{Transposing, } 72+6+8-9=6x+4x-3x.$$

$$\text{Collecting, } 77=7x, \therefore x=11.$$

QUESTIONS TO BE SOLVED BY SIMPLE EQUATIONS.
PAGE 458.

1. There are two numbers of which the difference is 9, and the sum 43. What are the numbers?

Let x represent the smaller of the two numbers, then by the question, the other must be $x+9$, and their sum

$$x+x+9=43, \text{ that is, } 2x=43-9,$$

$$\therefore x=\frac{34}{2}=17,$$

the smaller number, and $\therefore 17+9=26$, the larger number.

2. From two places, 108 miles apart, two persons, A and B, set out at the same time, to meet each other. A travels 17 miles a-day, and B travels 18; in how many days will they meet?

Suppose they meet in x days: then by the question, the first, A, will have travelled $17x$ miles, and the second, B, $18x$ miles; and since the sum of these distances is the distance between the two places, we have the equation

$$17x+18x=108, \therefore 35x=108, \therefore x=3\tfrac{3}{35} \text{ days.}$$

3. Find two numbers of which the difference is 13, and which are such, that if 17 be added to their sum, the whole will amount to 62.

Let x be the greater number; then, by the question, $x-13$ is the less; also

$$x+x-13+17=62, \therefore 2x=62+13-17=58,$$

$\therefore x=29$, the greater number, and $\therefore 29-13=16$, the less number.

4. There are two numbers of which the difference is 15, and which are such that if 7 times the less be subtracted from 5 times the greater, the difference will be 19: what are the numbers!

Let x be the greater number; then, by the question, $x-15$ is the less; also

$$5x-(7x-105)=19, \text{ that is, } -2x+105=19,$$

$$\therefore -2x=-86,$$

$$\therefore x=\frac{-86}{-2}=43, \text{ the greater number, and}$$

$$\therefore 43-15=28, \text{ the less number.}$$

5. A person starts from a certain place, and travels at the rate of 4 miles an hour. After he has gone 10 hours, a horseman, riding 9 miles an hour, is dispatched after him: how many hours must the horseman ride to overtake him?

Suppose the horseman overtakes him after riding x hours; then, by the question, the pedestrian will have walked $40+4x$ miles, and the horseman will have ridden $9x$ miles; and since the distance travelled by each is the same, we have the equation

$$9x=40+4x, \therefore 5x=40, \therefore x=8;$$

hence the horseman has ridden 8 hours, so that each person must have travelled 9 × 8 = 72 miles.

6. A person has 264 coins—sovereigns and florins; he has $4\frac{1}{2}$ times as many florins as sovereigns: how many of each coin has he?

Suppose he had x sovereigns; then, by the question, he must have had $4\frac{1}{2}x$ florins; so that

$$x + 4\tfrac{1}{2}x = 264, \text{ that is, } 5\tfrac{1}{2}x = 264,$$
$$\text{or } 11x = 528, \therefore x = 48.$$

Consequently he had 48 sovereigns, and $\therefore 48 \times 4\frac{1}{2} = 216$ florins.

7. A person spends $\frac{1}{4}$th of his yearly income in board and lodging, $\frac{1}{7}$th in clothes and other expenses, and he lays by £85 a-year: what is his income?

To avoid fractions, suppose $28x$ to be the number of pounds he receives yearly, 28 being chosen because it is divisible by both 4 and 7: then, by the question, he spends in board and lodging $7x$ pounds, and in clothes, &c., $4x$ pounds. Consequently, since he lays by £85, we have the equation

$$7x + 4x + 85 = 28x, \text{ that is, } 11x + 85 = 28x.$$
$$\text{Transposing, } 85 = 17x, \therefore x = 5, \therefore 28x = 140.$$

Hence his yearly income was £140.

8. What number is that whose third part exceeds its fifth part by 72?

To avoid fractions, let $15x$ represent the number; then, by the question,

$$5x - 3x = 72, \therefore 2x = 72, \therefore x = 36,$$
$$\therefore \text{the number required is } 36 \times 15 = 540.$$

9. I have a certain number in my thoughts. I multiply it by 7, add 3 to the product, and divide the sum by 2. I then find that if I subtract 4 from the quotient I get 15: what number am I thinking of?

Let x represent the number; then, by the question,

$$\frac{7x + 3}{2} - 4 = 15, \text{ or } \frac{7x + 3}{2} = 19.$$

Multiplying by 2, $7x + 3 = 38$, $\therefore 7x = 35$, $\therefore x = 5$, the number thought of.

10. A man, 40 years old, has a son 9 years old: the father is therefore more than four times as old as his son. In how many years will the father be only twice as old as his son?

Suppose in x years: the father will then be $40 + x$ years old, and the son $9 + x$ years: by the question, the former number is to be double of the latter: hence the equation

$$40 + x = 18 + 2x, \therefore 40 - 18 = x = 22.$$

Therefore the father will be twice as old as his son in 22 years; in which time the father will be 62, and the son 31.

11. Two persons, A and B, 120 miles apart, set out at the same time to meet each other. A goes 3 miles an hour, and B 5 miles: what distance will each have travelled when they meet?

Suppose that A has travelled x *hours*, then B also must have travelled x *hours*. A must therefore have gone $3x$ miles, and B $5x$ miles; and since together they must have travelled 120 miles, we have the equation

$$3x + 5x = 120, \text{ that is, } 8x = 120, \therefore x = 15.$$

The *time* occupied by each is therefore 15 hours; so that A must have travelled 15 × 3 = 45 miles, and B 15 × 5 = 75 miles.

Otherwise.—Suppose A goes x miles, then B goes $120 - x$ miles: the time occupied by A, at 3 miles an hour, is therefore $\frac{x}{3}$ hours; and the time occupied by B, at 5 miles an hour, is $\frac{120 - x}{5}$ hours; but the times are *equal*. Hence the equation

$$\frac{x}{3} = \frac{120 - x}{5} = 24 - \frac{x}{5}.$$

$$\text{Multiplying by 3, } x = 72 - \frac{3x}{5}.$$

$$\text{Multiplying by 5, } 5x = 360 - 3x, \therefore 8x, = 360,$$
$$\therefore x = 45, \text{ A's distance.}$$
$$\therefore 120 - 45 = 75, \text{ B's distance.}$$

12. Divide £250 among A, B, and C, so that B may have £23 more than A, and C £105 more than B.

Let A's share be x pounds, then B's is $x + 23$; and C's $x + 23 + 105$; and the sum of the shares is 250: hence the equation

$$x + x + 23 + x + 23 + 105 = 250.$$

Collecting, and transposing, $3x = 99$, $\therefore x = 33$: hence the shares are as follow:—

A's share £33; B's £56; C's £161; and their sum is £250.

13. A can execute a piece of work in 3 days, which takes B 7 days to perform: in how many days can it be done if A and B work together?

Suppose they can do it in x days; then since A can do one-third of it in 1 day, he can do $\frac{x}{3}$ in x days: in like manner B can do $\frac{x}{7}$ of the whole in x days: hence, when working together, they do $\frac{x}{3} + \frac{x}{7}$ in x days; but these *parts* make up the whole work since they do it *all* in x days;

$$\therefore \frac{x}{3} + \frac{x}{7} = 1 \textit{ whole}$$

$$\text{Multiply by 3,} \quad x + \frac{3x}{7} = 3$$

$$\text{,,} \quad \text{by 7,} \quad 7x + 3x = 21, \therefore 10x = 21, \therefore x = 2\tfrac{1}{10}.$$

Hence they complete the work in two days and one-tenth.

14. A cistern can be filled by three pipes; by the first in 2 hours, by the second in 3, and by the third in 4; in what time can it be filled by all the pipes running together?

Suppose it can be filled in x hours; then since the first can supply one-half in 1 hour, it can supply $\frac{x}{2}$ in x hours; in like manner the second can supply $\frac{x}{3}$ in x hours, and the third $\frac{x}{4}$; and by the question the sum of these parts is the *whole*.

$$\therefore \frac{x}{2} + \frac{x}{3} + \frac{x}{4} = 1.$$

Multiplying by 4, in order that the first and third fractions may be removed at the same time, we have

$$2x + \frac{4x}{3} + x = 4, \text{ that is, } 3x + \frac{4x}{3} = 4.$$

Multiplying by 3, $9x + 4x = 12$, $\therefore 13x = 12$, $\therefore x = \frac{12}{13}$; hence, when they all run together, the pipes will fill the cistern in $\frac{12}{13}$h. = 55 min. $23\frac{1}{13}$ sec.

15. Solve the preceding question, when the first pipe fills the cistern in 1 hour 20 minutes; the second in 3 hours 20 minutes, and the third in 5 hours.

Imitating the foregoing solution, x being the required number of hours as before, the part of the whole supplied by the first pipe is $\frac{x}{1\frac{1}{3}}$, the part supplied by the second is $\frac{x}{3\frac{1}{3}}$, and the part supplied by the third is $\frac{x}{5}$, in x hours; hence, since these parts make up the whole, we have

$$\frac{x}{1\frac{1}{3}} + \frac{x}{3\frac{1}{3}} + \frac{x}{5} = 1.$$

Or, multiplying the terms of the first pair of fractions by 3, $\frac{3x}{4} + \frac{3x}{10} + \frac{x}{5} = 1$.

$$\text{Multiplying by 4, } 3x + \frac{6x}{5} + \frac{4x}{5} = 4, \text{ or } 3x + 2x = 4,$$

$$\text{that is, } 5x = 4, \therefore x = \frac{4}{5};$$

hence, the time is $\frac{4}{5}$ h. = 48 minutes.

16. After A has been working 4 days at a job, which he can finish in 10 days, B is sent to help him; they finish it together in 2 days: in what time could B alone have done the whole?

Suppose B can finish it in x days; then he can do $\frac{1}{x}$ of it in 1 day, so that in the 2 days he does $\frac{2}{x}$ of it. Now, as A does $\frac{1}{10}$ of it in a day, in the 4 days, working alone, he has done $\frac{4}{10}$ or $\frac{2}{5}$ of it; hence, when B commences there is only $\frac{3}{5}$ of it to be done, so that $\frac{2}{x} + \frac{2}{10} = \frac{3}{5}$, or $\frac{2}{x} + \frac{1}{5} = \frac{3}{5}$, $\therefore \frac{2}{x} = \frac{2}{5}$, $\therefore \frac{1}{x} = \frac{1}{5}$.

Multiplying by x, and then by 5, we have $5 = x$; hence, B can finish the work alone in 5 days.

17. Divide £143 among A, B, and C, so that A may receive twice as much as B, and B three times as much as C.

Suppose C's share to be x pounds
then B's ,, $3x$,,
and A's ,, $6x$,,

$\therefore$ the sum of the shares is $10x = 143$,

$$\therefore x = \frac{\overset{\pounds}{143}}{10} = \pounds 14\ 6s.$$

$\therefore$ C's share = £14 6*s.*; B's, £42 18*s.*; A's, £85 16*s.*; and the sum of which is the whole = £143.

18. A person has 40 quarts of superior wine worth 7*s.* a quart; he wishes, however, so to reduce its quality as that he may sell it at 4*s.* 6*d.* a quart; how much water must he add?

Suppose the water to be x quarts, then the entire number of quarts in the mixture will be $40 + x$, and by the question the worth of the pure wine is 280*s.*, and that of the reduced wine is $4\frac{1}{2}(40 + x)$ shillings. As the worth is to remain the same, we have the equation

$$4\tfrac{1}{2}(40 + x) = 280, \text{ or } 180 + 4\tfrac{1}{2}x = 280$$

$$\therefore 4\tfrac{1}{2}x = 100;\ \text{and} \therefore x = \frac{100}{4\frac{1}{2}} = \frac{200}{9} = 22\tfrac{2}{9};$$

hence, the quantity of water to be added is $22\frac{2}{9}$ quarts; so that the mixture will make $62\frac{2}{9}$ quarts. The value of this at $4\frac{1}{2}$*s.* a quart is found, as in the margin, to be 280*s.*, which is the value of the unreduced 40 quarts.

$$\begin{array}{r} 2)\,62\frac{2}{9} \\ 4\frac{1}{2} \\ \hline 248\frac{8}{9} \\ 31\frac{1}{9} \\ \hline 280s. \end{array}$$

19. Divide 90 into four parts, such, that if the first be increased by 2, the second diminished by 2, the third multiplied by 2, and the fourth divided by 2, the results may all be equal.

Let the first part be $x - 2$: this increased by 2, is x.
Then the second will be $x + 2$: ,, diminished by 2, is x.
,, third ,, $\frac{x}{2}$: ,, multiplied by 2, is x.
,, fourth ,, $\underline{2x}$: ,, divided by 2, is x.

$$\text{The sum of these is } 4x + \frac{x}{2} = 90.$$

Multiplying by 2, $8x + x = 180$, $\therefore 9x = 180$, $\therefore x = 20$; hence, the required parts are 18, 22, 10, and 40, which together make 90.

20. Divide 39 into four parts, such, that if the first be increased by 1, the second diminished by 2, the third multiplied by 3, and the fourth divided by 4, the results may all be equal.

Let the first part be $x - 1$: this increased by 1 is x.
Then the second will be $x + 2$: this diminished by 2 is x.
,, third ,, $\frac{x}{3}$: this multiplied by 3 is x.
,, fourth ,, $\underline{4x}$: this divided by 4 is x.

$$\text{The sum of these is } 6x + \frac{x}{3} + 1 = 39, \therefore 6x + \frac{x}{3} = 38.$$

Multiplying by 3, $18x + x = 114$, $\therefore 19x = 114$, $\therefore x = 6$; hence, the required parts are 5, 8, 2, and 24, the sum of which is 39.

From the last two examples you will perceive, that although, in general, the unknown quantity sought is best represented by a single symbol x, yet the conditions of the question may be such as to suggest a more convenient form for it: a judicious form of representation at the outset will often save several steps of work in the solution. When fractions are foreseen to enter the equation, when the symbol for the unknown quantity is x, it will always be better to use instead of x, such a multiple of x as will preclude their entrance, as in Examples 7 and 8, just given.

x^4-4x^3+6x^2-4x+1 \\
\hline
\end{array}$$

$$\therefore \{(x-1)^2\}^3 = x^6-6x^5+15x^4-20x^3+15x^2-6x+1.$$

NOTE.—In working the foregoing examples, it will be seen that frequent application has been made of the principles marked 1, 2, 3, at page 460. They should always be used in like manner whenever opportunity occurs. The Binomial Theorem, in the next article, is, however, of still wider application, and you should make yourself well acquainted with its form: the eleventh example here worked out in full, is solved in a moment by aid of the Binomial Theorem, as you will see by a reference to the table of developments at the middle of page 461. The example in question is to find the sixth power of $x-1$; for $\{(x-1)^2\}^3$ is the same as $(x-1)^6$. If you suppose a in the table to be -1, you will see that the development of $(x-1)^6$ is the same as that found above by actual multiplication; the directions at page 462 show how this development might have been written down at once.

BINOMIAL THEOREM. EXAMPLES FOR EXERCISE. PAGE 462.

1. To develop $(a+y)^4$. The terms without the coefficients are

$$a^4,\ a^3y,\ a^2y^2,\ ay^3,\ y^4.$$

The coefficients, as far as the third, are

$$1,\ 4,\ \frac{3\times 4}{2} = 6$$

$$\therefore (a+y)^4 = a^4+4a^3y+6a^2y^2+4ay^3+y^4.$$

Instead of finding the terms without the coefficients, and then the coefficients in a separate step, it is just as easy to write down each term in succession in its complete form, attending to the directions at page 461.

2. $(a-x)^5 = a^5-5a^4x+10a^3x^2-10a^2x^3+5ax^4-x^5$.

3. $(a+2x)^3 = a^3+3a^2(2x)+3a(2x)^2+(2x)^3$
$= a^3+6a^2x+12ax^2+8x^3$.

4. $(1-x)^6 = 1-6x+15x^2-20x^3+15x^4-6x^5+x^6$.

In this example the powers of 1, the first term of the binomial $1-x$, are, of course, suppressed; but the exponents of those powers are mentally employed, as in other cases, to form the coefficients.

5. $(1+3x)^4 = 1+4(3x)+6(3x)^2+4(3x)^3+(3x)^4$
$= 1+12x+54x^2+108x^3+81x^4$.

6. $(x+2y^2)^5 = x^5+5x^4(2y^2)+10x^3(2y^2)^2+10x^2(2y^2)^3+5x(2y^2)^4+(2y^2)^5$
$= x^5+10x^4y^2+40x^3y^4+80x^2y^6+80xy^8+32y^{10}$.

7. $(x^2+3y^2)^5 = (x^2)^5+5(x^2)^4(3y^2)+10(x^2)^3(3y^2)^2+10(x^2)^2(3y^2)^3+5(x^2)(3y^2)^4+(3y^2)^5$
$= x^{10}+15x^8y^2+90x^6y^4+270x^4y^6+405x^2y^8+243y^{10}$.

8. $(2a-x)^6 = (2a)^6-6(2a)^5x+15(2a)^4x^2-20(2a)^3x^3+15(2a)^2x^4-6(2a)x^5+x^6$
$= 64a^6-192a^5x+240a^4x^2-160a^3x^3+60a^2x^4-12ax^5+x^6$.

9. $(x-2y^2)^7 = x^7-7x^6(2y^2)+21x^5(2y^2)^2-35x^4(2y^2)^3+35x^3(2y^2)^4-21x^2(2y^2)^5+7x(2y^2)^6-(2y^2)^7$
$= x^7-14x^6y^2+84x^5y^4-280x^4y^6+560x^3y^8-672x^2y^{10}+448xy^{12}-128y^{14}$.

6. $\frac{-8b^6y^3z}{6b^3y^6z^2} = -\frac{4b^3}{3y^3z}$.
7. $\frac{24cy^3}{-21c^2y^2z} = -\frac{8y}{7cz}$.
8. $\frac{-36a^2x^2y^3}{2\times 7a^2x^4y} = -\frac{18y^2}{7x^2}$.
9. $\frac{5abx^2\sqrt{y}}{10ab^2x\sqrt{y}} = \frac{x}{2b}$.
10. $\frac{-3a^2c^3x^4}{-12ac^2x^5\sqrt{z}} = \frac{ac}{4x\sqrt{z}}$.
11. $\frac{-2mx^4y^3}{8m^2x^4y^6} = -\frac{1}{4my^3}$.
12. $\frac{-13x^2y^5z^{\frac{1}{2}}}{-26y^4\sqrt{z}} = \frac{x^2y}{2}$.

DIVISION. CASE II. PAGE 463.

1. $\frac{9a^2x^2-3a^3x^3+6a^4x}{3a^2x} = 3x-ax^2+2a^2$.

2. $\frac{12x^3yz^4+6x^2y^3z^3-3x^2y^3}{3x^2yz^2} = 4xz^2+2y^2-\frac{y}{z^2}$.

3. $$\frac{3ax(4xy - 8ay^2) + 12axy}{6axy} = \frac{12ax^2y - 24a^2xy^2 + 12axy}{6axy} = 2x - 4ay + 2.$$

4. $$\frac{8x^3y^4 - 4(4ax - 2y)x}{4x^2y} = \frac{8x^3y^4 - 16ax^2 + 8xy}{4x^2y} = 2xy^3 - \frac{4a}{y} + \frac{2}{x}.$$

The last two examples might have been treated somewhat more simply; thus, cancelling $3ax$ from dividend and divisor in Example 3, we have

$$\frac{4xy - 8ay^2 + 4y}{2y} = 2x - 4ay + 2$$

It is easy to see that instead of $3ax$, $6ax$ might have been cancelled. In like manner, in Example 4, by cancelling $4x$, we have

$$\frac{2x^2y^4 - 4ax + 2y}{xy} = 2xy^3 - \frac{4a}{y} + \frac{2}{x}.$$

5. Cancelling 2, from dividend and divisor, we have

$$\frac{4a^2x^2y^2 - 3ax^2y^2z^2 + 1}{2axy} = 2axy - \frac{3}{2}xy^2z^2 + \frac{1}{2axy}.$$

6. $$\frac{16a^4b^2x^3 - 8 + 3a^2bx^4}{4a^2bx^3} = 4a^2bx + \frac{3x^2}{4} - \frac{2}{a^2bx^3}.$$

DIVISION. CASE III. PAGE 464.

1. $$\begin{array}{l} x - 7)x^2 - 2x - 35(x + 5. \\ \quad \underline{x^2 - 7x} \\ \qquad 5x - 35 \\ \qquad \underline{5x - 35} \end{array}$$

2. $$\begin{array}{l} x + 3)x^2 - x - 12(x - 4. \\ \quad \underline{x^2 + 3x} \\ \qquad - 4x - 12 \\ \qquad \underline{- 4x - 12} \end{array}$$

3. $$\begin{array}{l} 3x + 2)6x^2 + 13x + 6(2x + 3. \\ \quad \underline{6x^2 + 4x} \\ \qquad 9x + 6 \\ \qquad \underline{9x + 6} \end{array}$$

4. $$\begin{array}{l} 3x + 2)12x^2 + 29x + 14(4x + 7. \\ \quad \underline{12x^2 + 8x} \\ \qquad 21x + 14 \\ \qquad \underline{21x + 14} \end{array}$$

5. $$\begin{array}{l} 3x^2 - 2x + 5)18x^3 - 33x^2 + 44x - 35(6x - 7. \\ \quad \underline{18x^3 - 12x^2 + 30x} \\ \qquad - 21x^2 + 14x - 35 \\ \qquad \underline{- 21x^2 + 14x - 35} \end{array}$$

6. $$\begin{array}{l} x - y)x^4 - y^4(x^3 + x^2y + xy^2 + y^3. \\ \quad \underline{x^4 - x^3y} \\ \qquad x^3y - y_4 \\ \qquad \underline{x^3y - x^2y^2} \\ \qquad\quad x^2y^2 - y^4 \\ \qquad\quad \underline{x^2y^2 - xy^3} \\ \qquad\qquad xy^3 - y^4 \\ \qquad\qquad \underline{xy^3 - y_4} \end{array}$$

Example 6 may be worked differently, thus:

$$\frac{x^4 - y^4}{x - y} = \frac{(x^2 + y^2)(x^2 - y^2)}{x - y} = (x^2 + y^2)(x + y), \therefore \left.\begin{array}{l} x^2 + y^2 \\ x + y \end{array}\right\} \text{by multiplying}$$

$$\overline{\underline{x^3 + xy^2 + x^2y + y^3.}}$$

7. $$\begin{array}{l} x - a)x^4 - ax^3 - 7ax^2 + 8a^2x - a^3(x^3 - 7ax + a^2. \\ \quad \underline{x^4 - ax^3} \\ \qquad - 7ax^2 + 8a^2x \\ \qquad \underline{- 7ax^2 + 7a^2x} \\ \qquad\quad a^2x - a^3 \\ \qquad\quad \underline{a^2x - a^3} \end{array}$$

8. $$\begin{array}{l} x + a)x^2 + (a + b)x + ab(x + b \\ \quad \underline{x^2 + ax} \\ \qquad bx + ab \\ \qquad \underline{bx + ab} \end{array}$$

9. $$\begin{array}{l} 4x^2y + 3xy - 1)8x^4y + 2x^3y - 2x^2 - 3x^2y + x(2x^2 - x. \\ \quad \underline{8x^4y + 6x^3y - 2x^2} \\ \qquad - 4x^3y - 3x^2y + x \\ \qquad \underline{- 4x^3y - 3x^2y + x} \end{array}$$

10. $$\begin{array}{l} x^2 + x - 1)x^6 - x^4 + x^3 - x^2 - 1(x^4 - x^3 + x^2 - x + 1 - \dfrac{2x}{x^2 + x - 1} \\ \quad \underline{x^6 + x^5 - x} \\ \qquad - x^5 + x^3 - x^2 \\ \qquad \underline{- x^5 - x^4 + x^3} \\ \qquad\quad x^4 - x^2 - 1 \\ \qquad\quad \underline{x^4 + x^3 - x^2} \\ \qquad\qquad - x^3 - 1 \\ \qquad\qquad \underline{- x^3 - x^2 + x} \\ \qquad\qquad\quad x^2 - x - 1 \\ \qquad\qquad\quad \underline{x^2 + x - 1} \\ \qquad\qquad\qquad - 2x \quad \text{Remainder.} \end{array}$$

11. Cancelling x, from dividend and divisor, and removing the vincula, the operation is as follows:

$$3x-3)6x^3+9x^2-20(2x^2+5x+5-\frac{4}{3x-3}$$
$$\underline{6x^3-6x^2}$$
$$15x^2-20$$
$$\underline{15x^2-15x}$$
$$15x-20$$
$$\underline{15x-15}$$
$$\underline{-4} \text{ Rem.}$$

12. $$x-a)x^2+px+q(x+a+p+\frac{a^2+pa+q}{x-a}$$
$$\underline{x^2-ax}$$
$$(a+p)x+q$$
$$\underline{(a+p)x-a^2-pa}$$
$$\underline{a^2+pa+q} \text{ Rem.}$$

13. $$x-a)x^3+px^2+qx+r(x^2+(a+p)x+a^2+pa+q+\frac{a^3+pa^2+qa+r}{x-a}$$
$$\underline{x^3-ax^2}$$
$$(a+p)x^2+qx$$
$$\underline{(a+p)x^2-(a^2+pa)x}$$
$$(a^2+pa+q)x+r$$
$$\underline{(a^2+pa+q)x-a^3-pa^2-qa}$$
$$a^3+pa^2+qa+r \text{ Rem.}$$

The final remainder in Example 12 is a^2+pa+q, and that in Example 13 is a^3+pa^2+qa+r; in each case the remainder is the very same expression as we should get by rubbing out the x in the dividend and putting a instead, as observed at page 462. The property is perfectly general: if any polynomial proceeding according to the powers of x be divided by $x-a$, the remainder will always be the same as the polynomial itself when the x is replaced by a. Hence, when a is any given number, you will be able to ascertain, without actual division, whether a proposed polynomial is divisible by $x-a$ or not: thus, suppose it were asked—Is $x^2-2x-35$ divisible by $x-7$? Putting 7 for x in $x^2-2x-35$, we get $49-14-35=0$. Hence, the *remainder* is *nothing*, so that the expression *is* divisible by $x-7$. (See Ex. 1).

In like manner, referring to Ex. 2, and substituting -3 for x in x^2-x-12, it becomes $9+3-12=0$. Hence, x^2-x-12 is divisible by $x+3$. And a glance will serve to show that the division may be performed without remainder in Ex. 7.

SQUARE ROOT OF A SIMPLE QUANTITY. EXAMPLES FOR EXERCISE. PAGE 466.

1. $\sqrt{a^4x^6y}=a^2x^3\sqrt{y}$.
2. $\sqrt[4]{2^4a^4b^8}=\pm 2ab^2$.
3. $\sqrt[3]{8a^3x^6z}=2ax^2\sqrt[3]{z}$.
4. $\sqrt[3]{-8a^4x^3y^2}=-2ax\sqrt[3]{ay^2}$.
5. $\sqrt{-2a^4y^6z^8}=a^2y^3z^4\sqrt{-2}$.
6. $\sqrt{3a^5y^4x}=a^2y^2\sqrt{3ax}$.
7. $(a^2b^3x^4)^{\frac{1}{2}}=abx^2b^{\frac{1}{2}}$.
8. $\sqrt{x^{\frac{1}{2}}y^2z^2}=yz\sqrt[4]{x}$.
9. $\sqrt{\frac{a^2}{bx^2}}=\frac{a}{x\sqrt{b}}=\frac{a\sqrt{b}}{bx}$.
10. $\sqrt{a^3x^{-4}}=ax^{-2}\sqrt{a}$.
11. $\sqrt{a^{-3}x^{-4}y^{-5}}=a^{-\frac{3}{2}}x^{-2}y^{-\frac{5}{2}}$.
12. $\sqrt{\frac{8a^3}{27x^3y^4}}=\sqrt{\frac{4.2a^3}{9.3x^3y^4}}=\frac{2a}{3xy^2}\sqrt{\frac{2a}{3x}}=\frac{2a}{3xy^2}\frac{\sqrt{6ax}}{3x}$.
13. $(-8a^3x^2y^6)^{\frac{1}{3}}=-2ay^2\sqrt[3]{x^2}$.
14. $(9b^4x^2y^3)^{-\frac{1}{2}}=\frac{1}{\sqrt{9b^4x^2y^3}}=\frac{1}{3b^2xy\sqrt{y}}=\frac{\sqrt{y}}{3b^2xy^2}$.
15. $x^2(81x^6y^7z^8)^{-\frac{1}{3}}=\frac{x^2}{\sqrt[3]{81x^6y^7z^8}}=\frac{x^2}{3x^2y^2z^2\sqrt[3]{3yz^2}}=\frac{1}{3y^2z^2\sqrt[3]{3yz^2}}=\frac{(3yz^2)^{\frac{2}{3}}}{9y^3z^4}=\frac{\sqrt[3]{9y^2z}}{9y^3z^3}$.
16. $\sqrt[3]{-16a^5x^6y^{-9}}=-2ax^2y^{-3}\sqrt[3]{2a^2}$.
17. $(32a^{\frac{1}{2}}x^2y^4)^{-\frac{1}{2}}=32^{-\frac{1}{2}}a^{-\frac{1}{4}}x^{-1}y^{-2}=\frac{1}{4xy^2\sqrt{2}.\sqrt[4]{a}}=\frac{\sqrt{2}.\sqrt[4]{a}}{8axy^2}$.
18. $(32a^{-3}x^{-6}y^3)^{-\frac{1}{3}}=32^{-\frac{1}{3}}ax^2y^{-1}=\frac{ax^2}{2y\sqrt[3]{4}}=\frac{ax^2\sqrt[3]{16}}{8y}=\frac{ax^2\sqrt[3]{2}}{4y}$.

REDUCTION OF FRACTIONS. EXAMPLES FOR EXERCISE. PAGE 467.

1. $a+x+\frac{x^2}{a-x}=\frac{a^2-x^2+x^2}{a-x}=\frac{a^2}{a-x}$.
2. $3-y-\frac{2-y^2}{3+y}=\frac{9-y^2-2+y^2}{3+y}=\frac{7}{3+y}$.
3. $\left(\frac{b+c}{b-c}\right)^2-1=\frac{b^2+2bc+c^2-(b^2-2bc+c^2)}{(b-c)^2}=\frac{4bc}{(b-c)^2}$.
4. $\frac{a^3+x^3}{a-x}=$, by actual division, $a^2+ax+x^2+\frac{2x^3}{a-x}$.
5. By actual division, $\frac{a^3-x^3}{a^2+ax+x^2}=a-x$.
6. $x^2-a^2+\frac{x^4+a^4}{x^2+a^2}=\frac{x^4-a^4+x^4+a^4}{x^2+a^2}=\frac{2x^4}{x^2+a^2}$.
7. $\frac{(x+y+z)(x+y-z}{2xy}-1=\frac{[(x+y)+z][(x+y)-z]-2xy}{2xy}=\frac{(x+y)^2-z^2-2xy}{2xy}=\frac{x^2+y^2-z^2}{2xy}$.

8. $\frac{[(x+y)+z][(x+y)-z]}{2xy}-2=\frac{(x+y)^2-z^2-4xy}{2xy}=\frac{x^2-2xy+y^2-z^2}{2xy}=\frac{(x-y)^2-z^2}{2xy}.$

9. $\frac{x^2+y^2-z^2}{2xy}-1=\frac{x^2-2xy+y^2-z^2}{2xy}=\frac{(x-y)^2-z^2}{2xy}=\frac{(x-y-z)(x+y+z).}{2xy}$

10. $x^2-3x-\frac{3x\ (3-x}{x-2}=\frac{x\{(x-3)(x-2)-3(3-x)\}}{x-2}=$

$\frac{x\{(x-3)(x-2)+3(x-3)\}}{x-2}=\frac{x(x-3)(x-2+3)}{x-2}=\frac{x(x-3)(x+1)}{x-2}$

$=\frac{x(x^2-2x-3)}{x-2}=\frac{x(x^2-2x+1-4)}{x-2}=\frac{x\{(x-1)^2-4\}}{x-2}.$

ADDITION AND SUBTRACTION OF FRACTIONS. EXAMPLES FOR EXERCISE. PAGE 468.

1. $\frac{2x-5}{3}+\frac{x-1}{2x}=\frac{4x^2-10x+3x-3}{6x}=\frac{4x^2-7x-3}{6x}.$

2. $\frac{x}{x-3}+\frac{x}{x+3}=\frac{x^2+3x+x^2-3x}{x^2-9}=\frac{2x^2}{x^2-9}.$

3. $\frac{10x-9}{8}-\frac{3x-5}{7}=\frac{70x-63-24x+40}{56}=\frac{46x-23}{56}.$

4. $\frac{2x-3}{7x}-\frac{x-5}{8x}=\frac{16x^2-24x-7x^2+35x}{56x^2}=\frac{9x^2+11x}{56x^2}=\frac{9x+11}{56x}.$

5. $\frac{x-a}{x^2-ax+a^2}+\frac{1}{x+a}=\frac{x^2-a^2+x^2-ax+a^2}{x^3+a^3}=\frac{2x^2-ax}{x^3+a^3}.$

6. $1-\frac{x-a}{x+a}=\frac{x+a-x+a}{x+a}=\frac{2a}{x+a}$ 7. $\frac{a^2z}{xy}-\frac{b^2x}{yz}=\frac{a^2z^2-b^2x^2}{xyz}.$

In this seventh example, the terms of the first fraction are multiplied by z, and those of the second by x; the denominators thus become each equal to xyz.

8. $\frac{1}{x}+\frac{1}{x^2}-\frac{1}{x^n}$. Multiplying the terms of the first fraction by x^{n-1}, and those of the second by x^{n-2}, we have $\frac{x^{n-1}+x^{n-2}-1}{x^n}$

9. $\frac{1}{2x-a}+\frac{1}{2x+a}-\frac{4x^2}{4x^2-a^2}=\frac{2x+a+2x-a-4x^2}{4x^2-a^2}=\frac{4x-4x^2}{4x^2-a^2}.$

10. $\frac{1+x}{1+x+x^2}-\frac{1-x}{1-x+x^2}=\frac{(1+x)(1-x+x^2)-(1+x+x^2)(1-x)}{\{(1+x^2)+x\}\ \{(1+x^2)-x\}}=\frac{(1+x)x^2-x^2(1-x)}{(1+x^2)^2-x^2}=\frac{2x^3}{1+x^2+x^4}$

11. $\frac{a^2+b^2}{a^2-b^2}+\frac{a+b}{a-b}-\frac{a-b}{a+b}+2=\frac{a^2+b^2+a^2-b^2-(a^2-b^2)+2(a^2-b^2)}{a^2-b^2}=\frac{3a^2-b^2}{a^2-b^2}.$

12. $\frac{y}{y-3}-\frac{y-3}{y}+\frac{y}{y+3}-\frac{y+3}{y}.$

The second and fourth fractions united give $-\frac{2y}{y}=-2$, the first and third make $\frac{y^2+3y+y^2-3y}{y^2-9}=\frac{2y^2}{y^2-9}$. Hence the sum of all is $\frac{2y^2}{y^2-9}-2=\frac{2y^2-2y^2+18}{y^2-9}=\frac{18}{y^2-9}.$

13. $\frac{x}{x+y}+\frac{y}{x-y}=\frac{x^2-xy+xy+y^2}{(x+y)(x-y)}=\frac{x^2+y^2}{x^2-y^2}$

and $\frac{x}{x-y}-\frac{y}{x+y}=\frac{x^2+xy-xy+y^2}{(x-y)(x+y)}=\frac{x^2+y^2}{x^2-y^2}$

14. $\frac{x}{x+z}-\frac{y}{y+z}=\frac{xy+xz-xy-yz}{(x+z)(y+z)}=\frac{(x-y)z}{(x+z)(y+z)}$

and $\frac{z}{y+z}-\frac{z}{x+z}=\frac{xz+z^2-yz-z^2}{(y+z)(x+z)}=\frac{(x-y)z}{(x+z)(y+z)}.$

MULTIPLICATION OF FRACTIONS. EXAMPLES FOR EXERCISE. PAGE 469.

1. $\frac{4x}{7}\times\frac{5}{9x}=\frac{4}{7}\times\frac{5}{9}=\frac{20x}{63x}$ 2. $\frac{4x+1}{3}\times\frac{6x}{7}=(4x+1)\frac{2x}{7}=\frac{8x^2+2x}{7}.$

3. $\frac{4x+2}{3}\times\frac{5x}{2x+1}=\frac{2}{3}\times 5x=\frac{10x}{3}.$ 4. $\frac{2x-1}{x+2}\times\frac{3x+1}{x-3}=\frac{6x^2-x-1}{x^2-x-6}.$

5. $\frac{a+b}{b}\times\frac{b^2x}{a^2-b^2}=1\times\frac{bx}{a-b}=\frac{bx}{a-b}.$ 6. $\frac{x^3-a^2x}{a^2}\times\frac{x}{ax-a^2}=\frac{x^4-a^2x^2}{a^3x-a^3}.$

7. $\frac{x^n}{y^m}\times\frac{x^m}{y^n}=\frac{x^{m+n}}{y^{m+n}}.$ 8. $\frac{x^n}{y^m}\times\frac{y^n}{x^m}=\frac{xy^{2n}}{xy^{2m}}.$

9. $\frac{3\sqrt{x}}{y}\times\frac{2y^2}{5\sqrt{x}}=\frac{6y}{5}.$ 10. $\frac{x^2-4a^2}{x-a}\times\frac{x^3-a^3}{x+2a}=(x-2a)(x^2+ax+a^2)=x^3-ax^2-a^2x-2a^3.$

In this tenth example it is seen at once that the numerator of the second fraction is divisible by the denominator of the first, because if a be put for x in x^3-a^3, the result is 0.*

11. $\frac{2x}{7}\times\frac{4x}{9}\times\frac{7}{4x}\times\frac{9x}{5}=2x\times 1\times\frac{x}{5}=\frac{2x^2}{5}.$

12. $\frac{4x+2}{3}\times\frac{5x}{2x+1}\times\frac{9x-3}{x}=2\times 5\times(3x-1)=30x-10.$ 13. $\frac{(x-y)^2}{x^2-y^2}\times\frac{x+y}{x-y}=\frac{x-y}{x-y}=1.$

14. $\frac{(x-y)^2}{x^4-y^4}\times\frac{x+y}{x-y}=\frac{x-y}{(x^2-y^2)(x^2+y^2)}\times(x+y)=\frac{x-y}{(x-y)(x^2+y^2)}=\frac{1}{x^2+y^2}.$

---

* See p. 495.

15. $(a-\frac{b^2}{a})(\frac{a}{b}+\frac{b}{a})=\frac{a^2-b^2}{a}\cdot\frac{a^2+b^2}{ab}=\frac{a^4-b^4}{a^2b}$; Otherwise,

$$(a-\frac{b^2}{a})(\frac{a}{b}+\frac{b}{a})=b(\frac{a}{b}-\frac{b}{a})(\frac{a}{b}+\frac{b}{a})=b(\frac{a^2}{b^2}-\frac{b^2}{a^2})=b\,\frac{a^4-b^4}{a^2b^2}=\frac{a^4-b^4}{a^2b}.$$

DIVISION OF FRACTIONS. EXAMPLES FOR EXERCISE. PAGE 469.

1. $\frac{x}{x-2}\times\frac{x^2+2}{x-1}=\frac{x^3+2x}{x^2-3x+2}$.

2. $\frac{a+1}{a}\times\frac{a}{a^2-1}=\frac{1}{a-1}$.

3. $\frac{x^2-9}{5}\div\frac{x+3}{4}=\frac{x-3}{5}\div\frac{1}{4}=\frac{x-3}{5}\times 4=\frac{4x-12}{5}$.

4. $\frac{6x^2-2x}{4-x^2}\div\frac{x^2}{2+x}=\frac{6x-2}{2-x}\div x=\frac{6x-2}{2x-x^2}$.

5. $\frac{9x^2-4y^2}{x+y}\div\frac{3x-2y}{x^2-y^2}=\frac{3x+2y}{1}\div\frac{1}{x-y}=(3x+2y)(x-y)=3x^2-xy-2y^2$.

6. $\frac{x^2-y^2}{x^2-2xy+y^2}\div\frac{x^2+xy}{x-y}=\frac{x+y}{x-y}\div\frac{x(x+y)}{x-y}=1\div x=\frac{1}{x}$.

SIMPLE EQUATIONS IN GENERAL. EXAMPLES IN EQUATIONS WITH ONLY ONE UNKNOWN QUANTITY. PAGE 470.

1. $\frac{2x}{5}+\frac{x}{2}=22+\frac{x}{5}$. Multiplying the terms of the second fraction by 3,

$$\frac{2x}{5}+\frac{3x}{6}=22+\frac{x}{6}.$$

Transposing, $\frac{2x}{5}+\frac{x}{3}=22$.

Clearing, $6x+5x=330$, that is, $11x=330$ $\therefore x=30$.

This might also have been readily solved by multiplying each side of the proposed equation by 30, the least number divisible by all the denominators; the equation thus cleared of fractions would have been

$$12x+15x=660+5x$$
$$\therefore 27x-5x=660,\ \therefore 22x=660,\ \therefore x=30.$$

2. $\frac{x}{2}+\frac{x}{3}+\frac{x}{4}=6\frac{1}{2}$. Multiplying by 12, the least common multiple of the denominators, we have

$$6x+4x+3x=78,$$
that is, $13x=78$, $\therefore x=6$.

3. $\frac{x}{2}-\frac{x}{4}=\frac{x}{3}-\frac{x}{6}+1$, or $\frac{2x}{4}-\frac{x}{4}=\frac{2x}{6}-\frac{x}{6}+1$; that is,

$$\frac{x}{4}=\frac{x}{6}+1.$$

Multiplying by 12, $3x=2x+12$, $\therefore x=12$.

4. $\frac{18+x}{x}=\frac{6}{x}+5$, that is, $\frac{18}{x}+1=\frac{6}{x}+5$, $\therefore \frac{12}{x}=4\ \therefore 12=4x\ \therefore x=3$.

5. $21+\frac{3x-11}{16}=\frac{5(x-1)}{8}+\frac{97-7x}{2}$. Multiplying by 16,

$$336+3x-11=10x-10+776-56x.$$

Transposing, $56x+3x-10x=776+11-10-336$

$$\therefore 49x=441,\ \therefore x=9.$$

6. $\sqrt{(x^2+7)}+x=7$, $\therefore \sqrt{(x^2+7)}=7-x$.

Squaring, $x^2+7=49-14x+x^2$, $\therefore 14x=42$, $\therefore x=3$.

7. $\sqrt{(x-a)}-b=0$, $\therefore \sqrt{(x-a)}=b$, $\therefore x-a=b^2$, $\therefore x=a+b^2$.

8. $\frac{\sqrt{x}+2}{\sqrt{x}-2}=\frac{3}{2}$. Applying the principle explained at page 468, we have $\frac{\sqrt{x}}{2}=\frac{5}{1}$, $\therefore \sqrt{x}=10$, $\therefore x=100$.

9. $\frac{\sqrt{x}+28}{\sqrt{x}+4}=\frac{\sqrt{x}+38}{\sqrt{x}+6}$. Applying the principle referred to in the last example, we have

$$\frac{\sqrt{x}+16}{12}=\frac{\sqrt{x}+22}{16}.$$ Multiplying by 3.4.4,

$$4\sqrt{x}+64=3\sqrt{x}+66,\ \therefore \sqrt{x}=2,\ \therefore x=4.$$

10. $\frac{\sqrt{x}+2a}{\sqrt{x}+b}=\frac{\sqrt{x}+4a}{\sqrt{x}+3b}$. By the principle at page 468,

$$\frac{2\sqrt{x}+2a+b}{2a-b}=\frac{2\sqrt{x}+4a+3b}{4a-3b};$$ that is,

$$\frac{2\sqrt{x}}{2a-b}+\frac{2a+b}{2a-b}=\frac{2\sqrt{x}}{4a-3b}+\frac{4a+3b}{4a-3b}.$$

Transposing, $\frac{2\sqrt{x}}{2a-b}-\frac{2\sqrt{x}}{4a-3b}=\frac{4a+3b}{4a-3b}-\frac{2a+b}{2a-b}$.

Multiplying by $(2a-b)(4a-3b)$,

$$8a\sqrt{x}-6b\sqrt{x}-4a\sqrt{x}+2b\sqrt{x}=(2a-b)(4a+3b)-(2a+b)(4a-3b)$$
$$\therefore (4a-4b)\sqrt{x}=-8ab+12ab=4ab,$$
$$\therefore \sqrt{x}=\frac{ab}{a-b},\ \therefore x=\left(\frac{ab}{a-b}\right)^2.$$

11. $\frac{\sqrt{ax}-a}{\sqrt{ax}+a}=\frac{3\sqrt{ax}-2a}{3\sqrt{ax}+5a}$. Applying the foregoing principle, $\frac{\sqrt{ax}}{a}=\frac{6\sqrt{ax}+3a}{7a}$,

$$\text{Clearing, } 7\sqrt{ax}=6\sqrt{ax}+3a,\ \therefore\ \sqrt{ax}=3a$$
$$\therefore\ ax=9a^2,\ \therefore\ x=9a.$$

12. $\sqrt{(x-24)}=\sqrt{x}-2$. Squaring each side,

$$x-24=x-4\sqrt{x}+4.$$
$$\text{Transposing, } 4\sqrt{x}=28,\ \therefore\ \sqrt{x}=7,\ \therefore\ x=49.$$

13. $\sqrt{(4x+21)}=2\sqrt{x}+1$. Squaring each side,

$$4x+21=4x+4\sqrt{x}+1.$$
$$\text{Transposing, } 20=4\sqrt{x},\ \therefore\ \sqrt{x}=5,\ \therefore\ x=25.$$

14. $\sqrt[3]{(2x+5)}=3$. Cubing each side,

$$2x+3=27,\ \therefore\ 2x=24,\ \therefore\ x=12.$$

15. $\frac{5x-9}{\sqrt{5x}+3}=\frac{\sqrt{5x}-1}{2}$. The numerator of the first fraction is the difference of the squares of the two quantities in the denominator; therefore, the numerator is actually divisible by the denominator, so that the equation is the same as

$$\sqrt{5x}-3=\frac{\sqrt{5x}-1}{2},\ \therefore\ 2\sqrt{5x}-6=\sqrt{5x}-1,$$
$$\therefore\ \sqrt{5x}=5,\ \therefore\ 5x=25,\ \therefore\ x=5.$$

16. $\frac{\sqrt{(x+1)}-\sqrt{(x-1)}}{\sqrt{(x+1)}+\sqrt{(x-1)}}=\frac{1}{2}$. By the principle at page 468,

$$\frac{\sqrt{(x+1)}}{\sqrt{(x-1)}}=\frac{3}{1},\ \therefore\ \frac{x+1}{x-1}=9$$
$$\therefore\ x+1=9x-9,\ \therefore\ 10=8x,\ \therefore\ x=\frac{10}{8}=1\tfrac{1}{4}.$$

SIMPLE EQUATIONS WITH TWO UNKNOWN QUANTITIES.
EXAMPLES FOR EXERCISE. PAGE 471.

1. $\left.\begin{array}{l}2x+3y=23\\5x-2y=10\end{array}\right\}$ 1st. Proceeding by Rule I., we have from the first equation $x=\frac{23-3y}{2}$; and from the second $x=\frac{10+2y}{5}$; hence equating these two expressions for x,

$$\frac{23-3y}{2}=\frac{10+2y}{5},$$
$$\text{Clearing fractions, } 115-15y=20+4y,$$
$$\text{Transposing, } 95=19y,\ \therefore\ y=5,$$
$$\therefore\ x=\frac{10+2y}{5}=\frac{10+10}{5}=\frac{20}{5}=4.$$

2nd. Proceeding by Rule II., we have from the second equation $x=\frac{10+2y}{5}=2+\frac{2y}{5}$.

Substituting this in the first we get

$$4+\frac{4y}{5}+3y=23,\ \therefore\ \frac{4y}{5}+3y=19,$$
$$\text{Clearing, } 4y+15y=95,\ \therefore\ 19y=95,\ \therefore\ y=5;$$
$$\text{And since } x=\frac{10+2y}{5},\ \therefore\ x=\frac{20}{5}=4.$$

3rd. Proceeding by the third method, multiplying the first equation by 2, the second by 3, and then adding the results, we have

$$19x=76,\ \therefore\ x=4.$$

Again, multiplying the first equation by 5, the second by 2, and subtracting the results, we get

$$19y=95,\ \therefore\ y=5.$$

2. $\left.\begin{array}{l}5x+4y=58\\3x+7y=67\end{array}\right\}$ Multiplying the first equation by 3, and the second by 5, there results

$$\begin{array}{r}15x+12y=174\\15x+35y=335\\\hline\end{array}$$
$$\text{Subtracting,}\quad 23y=161,\ \therefore\ y=\frac{161}{23}=7.$$

And since from the first equation $x=\frac{58-4y}{5}$,

$$\therefore\ x=\frac{58-28}{5}=6.$$

Otherwise, thus: multiplying the first equation by 2, we have

$$\begin{array}{lr}
 & 10x+8y=116\\
 & 3x+7y=\ \ 67\\\hline
\text{Subtracting,} & 7x+\ y=\ \ 49,\ \therefore\ y=49-7x\\
\text{Multiplying by 3,} & 21x+3y=147\\
\text{First equa.} & 5x+4y=\ \ 58\\\hline
\text{Subtracting,} & -16x+y=-89,\ \therefore\ y=16x-89
\end{array}$$
$$\therefore\ 16x-89=49-7x,\ \therefore\ 23x=138,\ \therefore\ x=6,$$
$$\therefore\ y=49-7x=49-42=7.$$

3. $\left.\begin{array}{l}\frac{x}{8}+8y=194\\\frac{y}{8}+8x=131\end{array}\right\}$ Clearing fractions, these equations become

$$x+64y=1552$$
$$y+64x=1048$$

By adding these $65x+65y=2600,\ \therefore\ y+x=\frac{2600}{65}=40$

And by subtracting, $63y-63x=504,\ \therefore\ y-x=\frac{504}{63}=8$

$\therefore$ adding and subtracting, $2y=48$, and $2x=32$,

$$\therefore\ y=24, \text{ and } x=16.$$

NOTE.—The rule has been departed from in the preceding solution; and you perceive that considerable advantage on the score of neatness and simplicity has been gained in consequence. By the rule we should have proceeded thus:

From the first equation $x=1552-64y$

Substituting in the second, $y+64(1552-64y)=1048$;

That is, $64\times1552-1048=(64^2-1)y$

$$\therefore\ y=\frac{64\times1552-1018}{64^2-1}=\frac{64\times1552-1048}{65\times63}$$
$$=\frac{98280}{5.9.7.13}=24$$

And $x=1552-64y=1552-64\times24=16$.

4. $\left.\begin{array}{l}\frac{x+y}{3}=5\\\frac{y-x}{7}=1\end{array}\right\}$ Clearing, these equations become

$$x+y=15$$
$$y-x=\ \ 7$$

Adding and subtracting, we get

$$2y=22, \text{ and } 2x=8,\ \therefore\ y=11,\ x=4.$$

5. $\left.\begin{array}{l}\frac{3x-7y}{3}=\frac{2x+y+1}{5}\\2-\frac{x-y}{5}=0\end{array}\right\}$ Clearing fractions, we have

$$15x-35y=6x+3y+3$$
$$10-x+y=0$$

Or, transposing,
$$9x - 38y = 3 \ldots (1)$$
$$x - y = 10 \ldots (2)$$
$$\therefore 9x - 9y = 90 \ldots (3)$$
Subtracting (1) from (3), $29y = 87, \therefore y = 3$
$$\therefore x = 10 + y = 13.$$

6. $\left.\begin{aligned}\frac{x+2}{3} + 8y &= 31\\ \frac{y+5}{4} + 10x &= 192\end{aligned}\right\}$ Clearing the fractions, we have
$$x + 2 + 24y = 93$$
$$y + 5 + 40x = 768$$
Or, $x + 24y = 91$
$$40x + y = 763.$$
Multiplying the first by 40,
$$40x + 960y = 3640$$
Subtracting, $959y = 2877, \therefore y = \frac{2877}{959} = 3$
$$\therefore x = \frac{763 - y}{40} = \frac{760}{40} = 19.$$

7. $\left.\begin{aligned}ax + by &= 1\\ a'x + b'y &= 1\end{aligned}\right\}$ Equalising the coefficients of x, we have
$$aa'x + a'by = a'$$
$$aa'x + ab'y = a$$
Subtracting, $(ab' - a'b)y = a - a'$
$$\therefore y = \frac{a - a'}{ab' - a'b}.$$
In like manner equalising the coefficients of y,
$$ab'x + b'by = b'$$
$$a'bx + b'by = b$$
Subtracting, $(a'b - ab')x = b - b'$
$$\therefore x = \frac{b - b'}{a'b - ab'}.$$

8. $\left.\begin{aligned}ax + by &= c\\ a'x + b'y &= c'\end{aligned}\right\}$ Equalising the coefficients of x, we have
$$aa'x + a'by = a'c$$
$$aa'x + ab'y = ac'$$
Subtracting, $(ab' - a'b)y = ac' - a'c$
$$\therefore y = \frac{ac' - a'c}{ab' - a'b}.$$
In like manner equalising the coefficients of y, we have
$$ab'x + b'by = b'c$$
$$a'bx + b'by = bc'$$
Subtracting, $(a'b - ab')x = bc' - b'c$
$$\therefore x = \frac{bc' - b'c}{a'b - ab'}.$$

9. $\left.\begin{aligned}\frac{1}{x} - \frac{1}{y} &= 12\\ \frac{3}{x} + \frac{5}{y} &= 2\tfrac{5}{7}\end{aligned}\right\}$ Multiplying the first equation by 3, and then subtracting the second, we have,
$$-\frac{8}{y} = 36 - 2\tfrac{5}{7} = 33\tfrac{2}{7}.$$
Multiplying by $7y$, $-56 = 233y, \therefore y = -\frac{56}{233}.$

Also, $\frac{1}{x} = 12 + \frac{1}{y} = 12 - \frac{233}{56} = \frac{439}{56}, \therefore x = \frac{56}{439}$

10. $\left.\begin{aligned}\frac{x-2}{5} - \frac{10-x}{3} - \frac{y-10}{4} &= 0\\ \frac{2(y+2)}{3} - \frac{2x+y}{8} - \frac{x+13}{4} &= 0\end{aligned}\right\}$ Clearing fractions, these equations become,
$$12x - 24 - 200 + 20x - 15y + 150 = 0$$
$$16y + 32 - 6x - 3y - 6x - 78 = 0.$$
Transposing, $32x - 15y = 74$
$$-12x + 13y = 46.$$
Multiplying the first by 3, and the second by 8, we have,
$$96x - 45y = 222$$
$$-96x + 104y = 368$$
Adding, $59y = 590, \therefore y = 10;$

and since $13y - 46 = 12x, \therefore 130 - 46 = 12x,$
$$\therefore x = \frac{84}{12} = 7.$$

11. $\left.\begin{aligned}\frac{x+6}{x+4} &= \frac{y+2}{y-2}\\ \frac{x+3}{x+1} &= \frac{y-7}{y-13}\end{aligned}\right\}$ Applying to these fractions the general principle at page 468, we have
$$\frac{x+5}{1} = \frac{y}{2}, \therefore 2x + 10 = y$$
$$\frac{x+3}{1} = \frac{y-10}{3}, \therefore 3x + 9 = y - 10.$$
Equating the two expressions for y, we have
$$3x + 19 = 2x + 10, \therefore x = -9$$
$$\therefore y = 2x + 10 = -18 + 10 = -8.$$

12. $\left.\begin{aligned}x + y &= 19\\ x^2 - y^2 &= 95\end{aligned}\right\}$ Dividing the second equation by the first, we have
$$x - y = 5$$
Also, $x + y = 19$

$\therefore$ adding and subtracting, $2x = 24$, and $2y = 14$,
$$\therefore x = 12, \text{ and } y = 7.$$

QUESTIONS IN SIMPLE EQUATIONS. PAGE 472.

1. Find a number such that if it be increased by one-half, one-third, and one-fourth of itself, the sum shall be 50.

Let x be the number; then by the question,
$$x + \frac{x}{2} + \frac{x}{3} + \frac{x}{4} = 50.$$
Multiplying by 12, to clear the fractions,
$$12x + 6x + 4x + 3x = 600,$$
that is, $25x = 600, \therefore x = 24.$

Otherwise.—To avoid fractions, put $12x$ for the number; then by the question,
$$12x + 6x + 4x + 3x = 50,$$
that is, $25x = 50, \therefore x = 2, \therefore 12x = 24.$

2. There is a fraction such that if 4 be added to the denominator, the value is $\frac{1}{4}$; and if 3 be added to the numerator the value is $\frac{3}{4}$: required the fraction.

Let the fraction be $\frac{x}{y}$; then by the question, $\frac{x}{y+4} = \frac{1}{4}$, and $\frac{x+3}{y} = \frac{3}{4}$,

therefore clearing the fractions, $4x = y + 4$
$$4x + 12 = 3y$$
Subtracting $12 = 2y - 4,$
$$\therefore 2y = 16, \therefore y = 8,$$
Also $x = \frac{y}{4} + 1 = 3, \therefore$ the fraction is $\frac{3}{8}$.

3. What number is that, such, that if it be increased by 7, the square root of the sum shall be equal to the square root of the number itself and 1 more?

Let x be the number, then the condition is that
$$\sqrt{(x+7)} = \sqrt{x} + 1;$$
Squaring, $x + 7 = x + 2\sqrt{x} + 1;$

Transposing $6 = 2\sqrt{x}, \therefore 3 = \sqrt{x}, \therefore 9 = x;$

hence the number is 9.

4. Fifty labourers are engaged to remove an obstruction on a railway; some of them are, by agreement, to receive ninepence each, and the others fifteen pence. Just £2 are paid to them; but, no memorandum having been made, it is required to find how many worked for 9*d.*, and how many for 15*d.*

Suppose there are x workmen at 9*d.*, and y at 15*d.*, then the number of pence received by the former is $9x$, and the number received by the latter $15y$; and since by the question the number of pence paid altogether is $2 \times 20 \times 12 = 480$, we must have the equation
$$9x + 15y = 480$$
Moreover, $x + y = 50$ by the question.
$$\therefore 9x + 9y = 450$$
Subtracting, $6y = 30, \therefore y = 5, \therefore x = 45.$

Consequently, 5 of the labourers received 15*d.*, and 45 received 9*d.*

Otherwise.—Let x be the number of labourers at 9*d.*, then by the question $50 - x$ was the number at 15*d.*; consequently the former received $9x$ pence, and the latter $15(50 - x)$ pence; hence, as they received together 480 pence, we must have the equation

$$15(50 - x) + 9x = 480;$$

That is, $750 - 15x + 9x = 480$;

Transposing, $270 = 6x$, $\therefore x = 45$, and $50 - x = 5$;
Consequently, 45 received 9*d*. each, and 5 received 15*d*.

5. A person ordered a quantity of rum and brandy, for which he paid £19 4*s*.; the brandy was 9*s*. a quart, and the rum 6*s*. He has, however, forgotten the exact quantity of each which he has to receive; but he remembers that if his brandy had been rum, and his rum brandy, his outlay would have been £1 13*s*. less. How many quarts of each did he buy?

Suppose he bought x quarts of rum and y quarts of brandy; then, by the question, the number of shillings paid for the two was $6x + 9y$; but if the brandy had been 6*s*. a quart and the rum 9*s*., the number of shillings paid would have been $9x + 6y$. The actual price paid was 384*s*.; the sum that would have been paid in the latter case, we are told, is 33*s*. less than this, that is, 351*s*.; hence we have these two equations—viz.,

$$\begin{aligned} 6x + 9y &= 384 \\ 9x + 6y &= 351 \end{aligned} \quad \therefore \quad \begin{aligned} 2x + 3y &= 128 \\ 3x + 2y &= 117. \end{aligned}$$

By adding these two equations, we have

$$5x + 5y = 245 \;\therefore\; y + x = 49$$

By subtracting, $y - x = 11$

Therefore adding and subtracting, $2y = 60$, $2x = 38$, $\therefore x = 19$, and $y = 30$; so that he had 19 quarts of rum and 30 quarts of brandy.

Otherwise.—Suppose he had x quarts of rum; for this he paid $6x$ shillings by the question; therefore $384 - 6x$ is the number of shillings paid for the brandy; and as 1 quart of brandy cost 9*s*. the number of quarts must have been $\frac{384 - 6x}{9}$, or $\frac{128 - 2x}{3}$. Now, by the question, if these quarts had cost 6*s*. each, and the x quarts 9*s*. each, the number of shillings paid would have been only 351: hence we have the equation

$$\frac{128 - 2x}{3} \times 6 + 9x = 351,$$

or, $256 - 4x + 9x = 351$,

$$\therefore 5x = 95, \;\therefore x = 19, \text{ quarts of rum,}$$

and $\frac{128 - 2x}{3} = \frac{128 - 38}{3} = 30$, quarts of brandy.

It is plain that the former is the easier mode of solution; and it will usually be found that both thought and work are diminished when as many unknown symbols are employed in the solution of a question as there are distinct conditions embodied in that question. It is a mistake to suppose that it is always easier to solve a question with only one unknown quantity than with two, when two are implied in the conditions; the contrary is more frequently true. Some of the present examples will sufficiently show this.

6. A person has spirits at 12*s*. a gallon, and at £1 a gallon; how much of each must he take to make a gallon worth 14*s*.? Let the fractional part of a gallon at 12*s*. be represented by x, and that of a gallon at 20*s*. by y; then

$$x + y = 1,$$

and the price of the mixture $= 12x + 20y = 14$, by the question.

Multiplying the first of these equations by 12, and subtracting

$$8y = 2 \;\therefore\; y = \frac{1}{4}; \text{ and } x = 1 - y = \frac{3}{4}$$

Consequently the mixture must consist of $\frac{1}{4}$ gallon at 20*s*., and $\frac{3}{4}$ gallon at 12*s*.

Otherwise.—Suppose he take x gal. at 12*s*.; then he must take $1 - x$ at 20*s*.; the price of the former is $12x$ shillings, and that of the latter $20\,(1 - x)$ shillings; therefore the price of the whole gallon of the mixture is

$$12x + 20 - 20x = 14, \text{ by the question.}$$

Transposing, $6 = 8x$, $\therefore \frac{3}{4} = x$; $\therefore y = 1 - x = \frac{1}{4}$, so that there must be $\frac{3}{4}$ gal. at 12*s*., and $\frac{1}{4}$ gal. at 20*s*.

7. A merchant has spirits at a shillings a gallon, and at b shillings a gallon; how much of each must he take to make a mixture of d gallons worth c shillings a gallon? Suppose he take x gallons at a shillings, and y at b shillings; then the worth of the mixture of $x + y$ gallons—that is, of d gallons—is

$$ax + by = cd, \text{ by the question;}$$

$$\text{also } x + y = d.$$

Mult. by a, $ax + ay = ad$

Subtract, $(a - b)y = (a - c)d$, $\therefore y = \frac{(a - c)d}{a - b}$.

In like manner, multiplying by b, and subtracting,

$$(a - b)x = (c - b)d, \;\therefore x = \frac{(c - b)d}{a - b}.$$

Otherwise.—Suppose he take x gallons at a shillings, then, by the question, he must take $d - x$ gallons at b shillings: the price of the mixture is,

$$ax + b(d - x) = cd, \text{ by the question; that is,}$$

$(a - b)x = (c - b)d$, $\therefore x = \frac{(c - b)d}{a - b}$, gals. at a shillings,

and $d - x = d - \frac{(c - b)d}{a - b} = \frac{(a - c)d}{a - b}$, gals. at b shillings.

8. In a composition of a certain quantity of gunpowder, two-thirds of the whole + 10 lbs. was nitre; one-sixth of the whole — $4\frac{1}{2}$ lbs. was sulphur; and the charcoal was one-seventh of the nitre, all but 2 lbs. How many lbs. of gunpowder were there?

Suppose there were x lbs. of gunpowder;
then there were $\frac{2x}{3} + 10$ of nitre;
" $\frac{x}{6} - 4\frac{1}{2}$ of sulphur;
" $\frac{1}{7}(\frac{2x}{3} + 10) - 2$ of charcoal;

consequently, adding the ingredients, we have

$$\frac{8}{7}\left(\frac{2x}{3} + 10\right) + \frac{x}{6} + 6\tfrac{1}{2} = x;$$

or, multiplying by 6,

$$\frac{8}{7}(4x + 60) + x + 39 = 6x,$$

$$\therefore \frac{8}{7}(4x + 60) - 39 = 5x.$$

Multiplying by 7,

$$32x + 480 + 273 = 35x,$$

$$\therefore 207 = 3x, \;\therefore x = 69.$$

Consequently there were 69 lbs. of gunpowder.

9. A farmer wishes to mix 28 bushels of barley, at 2*s*. 4*d*. a bushel, with rye at 3*s*. a bushel, and wheat at 4*s*. a bushel, so that the whole may make 100 bushels worth 3*s*. 4*d*. a bushel: how much rye and wheat must he use?

Suppose x bushels of rye, and y of wheat; then $x + y + 28$ must make 100.

Now the price of x bushels of rye is $36x$ pence
" y " wheat is $48y$ "
" 28 " barley is 28×28 pence,

$\therefore$ the price of the $x + y + 28$ bushels is $36x + 48y + 28 \times 28$ pence; which, by the question, is equal to 100×40: hence we have

$$x + y + 28 = 100 \; . \; . \; . \; . \; (1)$$

$$36x + 48y + 28 \times 28 = 100 \times 40;$$

or, dividing the latter equation by 4,

$$9x + 12y + 28 \times 7 = 100 \times 10$$

that is, $9x + 12y + 196 = 1000 \; . \; . \; . \; . \; (2).$

Multiplying (1) by 9, $9x + 9y + 252 = 900$

Subtracting, $3y - 56 = 100$

$$\therefore y = \frac{156}{3} = 52$$

$$\therefore (1),\ x = 100 - 28 - y = 72 - 52 = 20.$$

Hence there must be 20 bushels of rye, and 52 bushels of wheat.

Otherwise.—Suppose there were x bushels of rye; then there must have been $100 - 28 - x$ bushels of wheat. The worth of the x bushels of rye is $36x$ pence, and the worth of the $72 - x$ bushels of wheat is $48(72 - x)$ pence; also the worth of the 28 bushels of barley is 28×28 pence. Hence, because the 100 bushels is worth 4000 pence, by the question, we have

$$36x + 48(72 - x) + 28 \times 28 = 4000$$

Dividing by 4, $\quad 9x + 12(72 - x) + 28 \times 7 = 1000$

that is, $\quad -3x + 864 + 196 = 1000$

$\therefore -3x = 1000 - 1060 = -60$, $\therefore x = 20$, bushels of rye

$\therefore 100 - 28 - x = 72 - 20 = 52$, bushels of wheat.

This latter solution is perhaps somewhat easier than the former: you may vary both by employing shillings throughout instead of pence; representing the 2*s.* 4*d.* and the 3*s.* 4*d.* by $2\frac{1}{3}$*s.*, and $3\frac{1}{3}$*s.* respectively.

10. Two persons, A and B, are engaged on a work which they can finish in 16 days; but after working together 4 days, A is called off; and B alone finishes it in 36 days more In how many days could each do it separately? Suppose A can do it in x days, and B in y days: then in one day they can do the $\frac{1}{x}$ and the $\frac{1}{y}$ part respectively, and consequently in 16 days they can do $\frac{16}{x} + \frac{16}{y}$, which by the question, is the whole.

$$\frac{16}{x} + \frac{16}{y} = 1.$$

Also in 4 days they do the $\frac{4}{x} + \frac{4}{y}$ part, that is, the $\frac{1}{4}$ part; so that after that time the $\frac{3}{4}$ part remains to be done by B. Now, in 1 day B does the $\frac{1}{36}$ part of this; that is, the $\frac{3}{144} = \frac{1}{48}$ of the whole; but he does the $\frac{1}{y}$ of the whole in 1 day; hence

$$\frac{1}{y} = \frac{1}{48}, \therefore y = 48.$$

Substituting this value of y in the former equation, we have

$$\frac{16}{x} + \frac{16}{48} = 1$$

$$\therefore \frac{16}{x} = 1 - \frac{1}{3} = \frac{2}{3}, \therefore 2x = 48, \therefore x = 24.$$

Hence A can finish the work in 24 days, and B in 48 days.

Otherwise, without Algebra.—Since A and B have worked together 4 days, they can complete what is left in 12 days; and, therefore, $\frac{1}{12}$ of it in 1 day, while B alone can do only the $\frac{1}{36}$ in 1 day; so that the part of it done by A in 1 day is

$$\frac{1}{12} - \frac{1}{36} = \frac{1}{18};$$

hence A is twice as good a workman as B, so that A and B together are as good as 3 B's; and, therefore, since 3 B's would do the whole in 16 days, *one* B would take 3 times as long, or 48 days; and, consequently, A would take 24 days—half the time.

Again, with one unknown quantity.—By the question A and B have done $\frac{1}{4}$ of the work before they separate, hence $\frac{3}{4}$ of it remains to be done. Suppose A can do the whole in x days, then in 1 day he can do $\frac{1}{x}$ of it; but A and B together do $\frac{1}{16}$ in a day; hence B's part in a day is $\frac{1}{16} - \frac{1}{x}$; but B's part is also $\frac{1}{36}$ of $\frac{3}{4}$; hence

$$\frac{1}{16} - \frac{1}{x} = \frac{1}{48}$$

$$\therefore \frac{1}{x} = \frac{1}{16} - \frac{1}{48} = \frac{1}{24}, \therefore x = 24, \text{ A's days.}$$

And since B does the $\frac{1}{48}$ part in 1 day, he can do the whole in 48 days.

11. A composition of copper and tin containing 100 cubic inches, weighed 505 ounces; how many ounces of each metal did it contain, supposing a cubic inch of copper to weigh $5\frac{1}{4}$ oz., and a cubic inch of tin to weigh $4\frac{1}{4}$ oz.?

Suppose there were x ounces of copper and y ounces of tin: then $x + y = 505$. Also by the question,

$$\frac{x}{5\frac{1}{4}} + \frac{y}{4\frac{1}{4}} = 100, \therefore \frac{x}{21} + \frac{y}{17} = 25$$

$$\therefore 17x + 21y = 8925$$

Mult. 1st equa. by 17, $\quad 17x + 17y = 8585$

Subtracting, $\quad 4y = 340, \therefore y = 85$

$$\therefore x = 505 - y = 505 - 85 = 420.$$

Hence there were 420 oz. of copper and 85 oz. of tin.

This is solved with only one unknown quantity, by putting x for the number of ounces of copper, and $505 - x$ for the number of ounces of tin.

12. A cask is supplied by three spouts, which can fill it in a minutes, b minutes, and c minutes, respectively; in what time will it be filled if all flow together?

Let x be the number of minutes, then the part of the whole supplied in 1 minute is

$$\frac{1}{x} = \frac{1}{a} + \frac{1}{b} + \frac{1}{c}, \text{ by the question,}$$

Clearing, $abc = (ab + ac + bc)x$

$$\therefore x = \frac{abc}{ab + ac + bc}.$$

Questions of this kind may be treated rather differently, thus: since the first spout can fill the cask in a minutes, it can fill bc such casks in abc minutes. In like manner the second spout can fill ac such casks in abc minutes, and the third ab such casks in the same time; so that when all flow together, they can fill $ab + ac + bc$ casks in abc minutes, and, consequently, *one* cask in

$$\frac{abc}{ab + ac + bc} \text{ minutes.}$$

QUADRATIC EQUATIONS. EXAMPLES FOR EXERCISE.

PAGE 474.

1. $x^2 - 4x = 45$. Completing the square,

$$x^2 - 4x + 4 = 49.$$

Extracting the root, $\quad x - 2 = \pm 7,$

$$\therefore x = 2 \pm 7 = 9 \text{ or } -5.$$

2. $x^2 + 8x = 33$. Completing the square,

$$x^2 + 8x + 16 = 49.$$

Extracting the root, $\quad x + 4 = \pm 7,$

$$\therefore x = -4 \pm 7 = 3 \text{ or } -11.$$

3. $x^2 - 8x = 9$. Completing the square,

$$x^2 - 8x + 16 = 25.$$

Extracting the root, $\quad x - 4 = \pm 5,$

$$\therefore x = 4 \pm 5 = 9 \text{ or } -1.$$

4. $3x^2 + 2x = 161$. Dividing by 3, $x^2 + \frac{2}{3}x = \frac{161}{3}$.

Completing the square, $\quad x^2 + \frac{2}{3}x + \frac{1}{9} = \frac{161}{3} + \frac{1}{9} = \frac{484}{9}.$

Extracting the root, $\quad x + \frac{1}{3} = \pm \frac{22}{3},$

$$\therefore x = -\frac{1}{3} \pm \frac{22}{3} = 7 \text{ or } -\frac{23}{3}.$$

Or, by Rule II., page 474,

$$3x^2 + 2x = 161, \therefore 6x + 2 = \sqrt{(1932 + 4)} = \sqrt{1936}$$
$$= \pm 44,$$

$$\therefore x = \frac{-2 \pm 44}{6} = 7 \text{ or } -\frac{23}{3}.$$

5. $7x^2 - 20x = 32$. Dividing by 7, $x^2 - \frac{20}{7}x = \frac{32}{7}$.

Completing the square, $x^2 - \frac{20}{7}x + \frac{100}{49} = \frac{32}{7} + \frac{100}{49} = \frac{324}{49}.$

Extracting the root, $\quad x - \frac{10}{7} = \sqrt{\frac{324}{49}} = \pm \frac{18}{7}.$

$$\therefore x=\frac{10}{7}\pm\frac{18}{7}=4 \text{ or} -1\tfrac{1}{7}.$$

Or, by Rule II., page 474,

$7x^2-20x=32$, $\therefore 14x-20=\sqrt{(32\times 28+400)}=\pm 36$,

$$\therefore x=\frac{20\pm 36}{14}=4, \text{ or} -1\tfrac{1}{7}.$$

6. $x^2-x-170=40$, or $x^2-x=210$. Completing the square,

$$x^2-x+\frac{1}{4}=210+\frac{1}{4}=\frac{841}{4}.$$

Extracting the root, $x-\frac{1}{2}=\sqrt{\frac{841}{4}}=\pm\frac{29}{2}$,

$$\therefore x=\frac{1}{2}\pm\frac{29}{2}=15, \text{ or} -14.$$

Or by Rule II., page 474,

$x^2-x=210$, $\therefore 2x-1=\sqrt{(840+1)}=\pm 29$,

$$\therefore x=\frac{1\pm 29}{2}=15, \text{ or} -14.$$

7. $5x^2+4x=273$. Dividing by 5, $x^2+\frac{4}{5}x=\frac{273}{5}$

Completing the square, $x^2+\frac{4}{5}x+\frac{4}{25}=\frac{273}{5}+\frac{4}{25}=\frac{1369}{25}$.

Extracting the root, $x+\frac{2}{5}=\sqrt{\frac{1369}{25}}=\pm\frac{37}{5}$.

$$\therefore x=-\frac{2}{5}\pm\frac{37}{5}=7, \text{ or} -7\tfrac{4}{5}.$$

Or, by Rule II., page 474,

$5x^2+4x=273$, $\therefore 10x+4=\sqrt{(273\times 20+16)}=\sqrt{5476}=\pm 74$

$$\therefore x=\frac{-4\pm 74}{10}=7, \text{ or} -7\tfrac{4}{5}.$$

8. $\frac{4x^2-x}{3}=11$. Multiplying by 3, $4x^2-x=33$.

Dividing by 4, $x^2-\frac{1}{4}x=\frac{33}{4}$

Completing the square, $x^2-\frac{1}{4}x+\frac{1}{64}=\frac{33}{4}+\frac{1}{64}=\frac{529}{64}$

Extracting the root, $x-\frac{1}{8}=\sqrt{\frac{529}{64}}=\pm\frac{23}{8}$

$$\therefore x=\frac{1}{8}\pm\frac{23}{8}=3, \text{ or} -2\tfrac{3}{4}.$$

Or, by Rule II., page 474,

$4x^2-x=33$, $\therefore 8x-1=\sqrt{(33\times 16+1)}=\sqrt{529}=\pm 23$,

$$\therefore x=\frac{1\pm 23}{8}=3, \text{ or} -2\tfrac{3}{4}.$$

9. $x+\frac{7x-8}{x}=9$. Multiplying by x, $x^2+7x-8=9x$, $\therefore x^2-2x=8$.

Completing the square, $x^2-2x+1=9$.

Extracting the root, $x-1=\pm 3$, $\therefore x=4$, or -2.

10. $5x^2+3=4x+159$, $\therefore 5x^2-4x=156$. Dividing by 5,

$$x^2-\frac{4}{5}x=\frac{156}{5}.$$

Completing the square,

$$x^2-\frac{4}{5}x+\frac{4}{25}=\frac{156}{5}+\frac{4}{25}=\frac{784}{25}.$$

Extracting the root, $x-\frac{2}{5}=\sqrt{\frac{784}{25}}=\pm\frac{28}{5}$

$$\therefore x=\frac{2}{5}\pm\frac{28}{5}=6, \text{ or} -5\tfrac{1}{5}.$$

Or, by Rule II., page 474,

$5x^2-4x=156$, $\therefore 10x-4=\sqrt{(156\times 20+16)}=\sqrt{3136}=\pm 56$.

$$\therefore x=\frac{4\pm 56}{10}=6, \text{ or} -5\tfrac{1}{5}.$$

11. $6x+\frac{35-3x}{x}-44=0$, or $6x+\frac{35}{x}-3-44=0$;

that is, $6x+\frac{35}{x}-47=0$.

Multiplying by x, $6x^2+35-47x=0$.

$\therefore 6x^2-47x=-35$. Dividing by 6,

$$x^2-\frac{47}{6}x=-\frac{35}{6}.$$

Completing the square,

$$x^2-\frac{47}{6}x+\left(\frac{47}{12}\right)^2=\frac{2209}{144}-\frac{35}{6}=\frac{1369}{144}.$$

Extracting the root,

$$x-\frac{47}{12}=\sqrt{\frac{1369}{144}}=\pm\frac{37}{12},$$

$$\therefore x=\frac{47}{12}\pm\frac{37}{12}=7, \text{ or } \frac{5}{6}.$$

Or by Rule II., page 474,

$6x^2-47x=-35$, $\therefore 12x-47=\sqrt{(-35\times 24+47^2)}=\sqrt{1369}=\pm 37$, $\therefore x=\frac{47\pm 37}{12}=7$, or $\frac{5}{6}$.

12. $\frac{x-2}{x+2}+\frac{x+2}{x-2}=14$. Clearing the fractions,

$$x^2-4x+4+x^2+4x+4=14(x^2-4).$$

Collecting and transposing,

$$64=12x^2, \therefore x=\sqrt{\frac{64}{12}}=\frac{4}{\sqrt{3}}=\frac{4}{3}\sqrt{3}.$$

13. $48x^{-2}+32x^{-1}=11$. Dividing by 48,

$$x^{-2}+\frac{2}{3}x^{-1}=\frac{11}{48}.$$

Completing the square,

$$x^{-2}+\frac{2}{3}x^{-1}+\frac{1}{9}=\frac{11}{48}+\frac{1}{9}=\frac{49}{144}.$$

Extracting the root, $x^{-1}+\frac{1}{3}=\pm\frac{7}{12}$.

$$\therefore x^{-1}, \text{ that is } \frac{1}{x}=-\frac{1}{3}\pm\frac{7}{12}=\frac{1}{4}, \text{ or} -\frac{11}{12}.$$

$$\therefore x=4, \text{ or} -1\tfrac{1}{11}.$$

Or, by Rule II., page 474,

$48x^{-2}+32x^{-1}=11$, $\therefore 96x^{-1}+32=\sqrt{(48\times 44+32^2)}=\sqrt{3136}=\pm 56$,

$$\therefore x^{-1}=\frac{1}{x}=\frac{-32\pm 56}{96}=\frac{1}{4}, \text{ or} -\frac{11}{12},$$

$$\therefore x=4, \text{ or} -1\tfrac{1}{11}.$$

14. $x^4-40x^2+39=0$, or $(x^2)^2-40(x^2)=-39$.

Completing the square, $(x^2)^2-40(x^2)+400=361$.

Extracting the root, $x^2-20=\sqrt{361}=\pm 19$,

$\therefore x^2=20\pm 19=1$ or 39, $\therefore x=\pm 1$, or $\pm\sqrt{39}$.

15. $x^2+ax+b=0$, $\therefore x^2+ax=-b$.

Completing the square.

$$x^2+ax+\frac{1}{4}a^2=\frac{1}{4}a^2-b=\frac{a^2-4b}{4},$$

Extracting the root, $x+\frac{1}{2}a=\frac{\sqrt{(a^2-4b)}}{2}$

$$\therefore x=\frac{-a\pm\sqrt{(a^2-4b)}}{2}.$$

This may be regarded as a general formula for the solution of any quadratic equation whatever; for by putting particular values for a and b in this result, we shall have the proper values of x in the quadratic to which those particular values of the coefficients belong. We further learn from this formula a few general principles well worthy of notice: thus,

1. In every quadratic, put into the form $x^2+ax+b=0$, if $a^2=4b$, the two roots, must be *equal*; since, in this case the general form for the roots is $x=\frac{-a\pm 0}{2}$; so that each root is half the coefficient of x, taken with changed sign.

2. If a^2 be greater than $4b$, the two roots are unequal

and *real;* for a^2-4b, under the radical, is in this case positive.

3. If a^2 be less than $4b$, the two roots must be *imaginary;* for then a^2-4b, under the radical, is negative.

Hence, by examining the coefficients of a quadratic, we may ascertain the character of its roots without actually solving the equation.

16. $\frac{x+a}{x-a}+\frac{x-a}{x+a}=b$. Clearing fractions,

$$(x+a)^2+(x-a)^2=b(x^2-a^2)$$

that is, $2x^2+2a^2=bx^2-a^2b$

Transposing, $(b-2)x^2=a^2(2+b)$,

$$\therefore x^2=\frac{a^2(b+2)}{b-2},$$

$$\therefore x=\pm a\sqrt{\frac{b+2}{b-2}}.$$

17. Put y for $\sqrt{x}$, then multiplying by 6, we have

$$3y^2-2y=133,$$

Dividing by 3, $y^2-\frac{2}{3}y=\frac{133}{3}$.

Completing the square, $y^2-\frac{2}{3}y+\frac{1}{9}=\frac{133}{3}+\frac{1}{9}=\frac{400}{9}$,

Extracting the root, $y-\frac{1}{3}=\sqrt{\frac{400}{9}}=\pm\frac{20}{3}$.

$$\therefore y=\frac{1}{3}\pm\frac{20}{3}=7, \text{ or } -\frac{19}{3}=-6\tfrac{1}{3},$$

$$\therefore y^2=x=49, \text{ or } 40\tfrac{1}{9}.$$

Or, by Rule II., page 474,

$3y^2-2y=133$, $\therefore 6y-2=\sqrt{(1596+4)}=\sqrt{1600}=\pm 40$,

$$\therefore y=\frac{2\pm 40}{6}=7, \text{ or } -6\tfrac{1}{3},$$

$$\therefore y^2=x=49, \text{ or } 40\tfrac{1}{9}.$$

18. $(3x-2)(1-x)=4$; that is,

$$-3x^2+x-2=4, \therefore 3x^2-x=-2.$$

Dividing by 3, $x^2-\frac{1}{3}x=-\frac{2}{3}$,

Completing the square,

$$x^2-\frac{1}{3}x+\frac{1}{36}=\frac{1}{36}-\frac{2}{3}=-\frac{23}{36}.$$

Extracting the root, $x-\frac{1}{6}=\pm\frac{1}{6}\sqrt{-23}$,

$$\therefore x=\frac{1\pm\sqrt{-23}}{6}$$

19. $15x^2-48x+45=0$, or $15x^2-48x=-45$.

Dividing by 15,

$$x^2-\frac{16}{5}x=-3.$$

Completing the square,

$$x^2-\frac{16}{5}x+\frac{64}{25}=\frac{64}{25}-3=-\frac{11}{25}.$$

Extracting the root,

$$x-\frac{8}{5}=\frac{1}{5}\sqrt{-11}, \therefore x=\frac{8\pm\sqrt{-11}}{5}$$

We might have known, without actually solving either of the two equations in Examples 18 and 19, that the roots were imaginary, for these equations being $3x^2-x+2=0$, and $15x^2-48x+45=0$, we see at once that four times the product of the extreme terms exceeds the square of the middle term. (See the principle 3, above.)

20. $\sqrt{\frac{x-2}{x+2}}+\sqrt{\frac{x+2}{x-2}}=4$.

Squaring, $\frac{x-2}{x+2}+2+\frac{x+2}{x-2}=16$,

$$\therefore \frac{x-2}{x+2}+\frac{x+2}{x-2}=14,$$

and this equation has already been solved in Example 12.

QUESTIONS REQUIRING QUADRATIC EQUATIONS.
PAGE 475.

1. Divide the number 33 into two such parts, that their product may be 162.

Let x be one part, then $33-x$ is the other; and by the question,

$$33x-x^2=162; \text{ or } x^2-33x=-162,$$

$\therefore$ Rule II., $2x-33=\sqrt{(1089-648)}=\sqrt{441}=\pm 21$,

$$\therefore x=\frac{33\pm 21}{2}=27, \text{ or } 6.$$

$$\therefore 33-x=6, \text{ or } 27.$$

Hence the parts are 6, and 27.

Otherwise.—Let the two parts be x and y; then by the question

$$x+y=33, \text{ and } xy=162$$
$$\therefore x^2+2xy+y^2=1089$$
$$\text{And } \quad 4xy=648$$

Subtracting, $x^2-2xy+y^2=441$

That is,

$(x-y)^2=441$, $\therefore x-y=\pm 21$

And since $x+y=33$

$\therefore$ adding and subtracting, $2x=33\pm 21$, $\therefore x=27$ or 6

$2y=33\mp 21$, $\therefore y=6$ or 27.

2. Find two numbers whose difference is 9, and which are also such that their sum multiplied by the greater gives 266 for the product.

Let x be the greater number, then $x-9$ is the less, and by the question, $(2x-9)x=266$; that is,

$$2x^2-9x=266$$

$\therefore$ Rule II., $4x-9=\sqrt{(2128+81)}=\sqrt{2209}=\pm 47$

$$\therefore x=\frac{9\pm 47}{4}=14, \text{ or } -\frac{19}{2}=-9\tfrac{1}{2}$$

$$\therefore x-9=5, \text{ or } -18\tfrac{1}{2};$$

hence the numbers are either 5 and 14, or $-9\frac{1}{2}$ and $-18\frac{1}{2}$.

Otherwise.—Let x and y be the numbers; then by the question, $x-y=9$, and $(x+y)x=266$.

From the first of these equations, $x=y+9$, $\therefore$ by substitution in the second, $(2y+9)(y+9)=266$; or

$$2y^2+27y+81=266, \therefore 2y^2+27y=185$$

$\therefore$ Rule II., $4y+27=\sqrt{(1480+729)}=\sqrt{2209}=\pm 47$

$$\therefore y=\frac{-27\pm 47}{4}=5 \text{ or } -18\tfrac{1}{2}$$

$$\therefore x=y+9=14, \text{ or } -9\tfrac{1}{2}$$

Or thus: $x-y=9$

$x+y=\frac{266}{x}$

Adding, $2x=9+\frac{266}{x}$, $\therefore 2x^2-9x=266$,

and the remaining steps as in the first solution.

3. A company at a tavern had £7 4s. to pay; but two of them having left, the others had each 1s. more to pay than his fair share: how many persons were there at first?

Suppose there were x persons, then the fair share of each was $\frac{144}{x}$ shillings; but after two had left, the share to be paid by each of the others was $\frac{144}{x-2}$; and by the question,

$$\frac{144}{x-2}=\frac{144}{x}+1$$

Clearing fractions, $144x=144x-288+x^2-2x$

$\therefore x^2-2x=288$, $\therefore$ completing the square,

$x^2-2x+1=289$, $\therefore$ extracting, $x-1=\pm 17$,

$$\therefore x=18, \text{ or } -16.$$

Consequently there were 18 persons at first. The share of each was therefore 8s.; but when two had left, the share of each of the remaining 16 was 9s.

4. A purse contains 24 coins of silver and copper;

each copper coin is worth as many pence as there are silver coins, and each silver coin is worth as many pence as there are copper coins; and the whole is worth 18s.; how many are there of each?

Suppose there were x of one sort, and therefore $24 - x$ of the other: then the worth of the whole in pence is

$$(24 - x)x + (24 - x)x = 216, \text{ or } 2(24 - x)x = 216$$
$$\therefore 2x^2 - 48x = -216, \therefore x^2 - 24x = -108.$$

Completing the square, $x^2 - 24x + 144 = 36$, $\therefore x - 12 = \pm 6$, $\therefore x = 18$, or -6, $\therefore 24 - x = 6$: hence there were 18 silver coins and 6 copper coins, or 6 silver and 18 copper.

Otherwise.—Let the number of coins be x and y: then

$$x + y = 24, \text{ and } 2xy = 216$$
$$\therefore (x + y)^2 = 576, \text{ and } 4xy = 432.$$

Hence by subtraction, $(x - y)^2 = 144$, $\therefore x - y = \pm 12$.
$\therefore$ by adding to and subtracting from the first equation, we have $2x = 36$, $2y = 12$; $\therefore x = 18$, $y = 6$.

The *negative* values are suppressed, because they are inadmissible, from the nature of the question.

5. Two messengers, A and B, were dispatched to the same place, 90 miles distant. A, by riding one mile an hour more than B, arrives at his destination an hour before him. How many miles did each travel?

Suppose A travels x miles an hour, then he reaches his destination in $\frac{90}{x}$ hours; and B, by travelling 1 mile an hour more—that is, $x + 1$ miles an hour—reaches it in $\frac{90}{x+1}$ hours. And, by the question,

$$\frac{90}{x} = \frac{90}{x+1} + 1 \text{ or } \frac{90}{x} = \frac{91 + x}{x+1}$$

Clearing fractions, $90x + 90 = 91x + x^2$
Transposing, $x^2 + x = 90$

$$\therefore \text{Rule II., } 2x + 1 = \sqrt{(360 + 1)} = \sqrt{361} = \pm 19,$$
$$\therefore x = \frac{-1 + 19}{2} = 9, \therefore x + 1 = 10.$$

Hence A travels 9 miles an hour, and B 10 miles an hour. The negative value of x is suppressed, as it is excluded by the conditions of the question. You will observe that algebra gives *all* the values of the unknown quantity that can satisfy the *equation*: if there are any restrictions in the *question* embodied in that equation, the final results must, of course, conform to those restrictions.

6. A grocer sold 80lbs. of mace and 100lbs. of cloves for £65; but he sold 60lbs. more of cloves for £20, than he did of mace for £10. What was the price of 1lb. of each?

Suppose the price of the mace per lb. was x pounds, and that of the cloves y pounds; then by the question, $80x + 100y = 65$. Also, the number of lbs. of cloves for £20 is $\frac{20}{x}$, and of mace for £10 is $\frac{10}{x}$; and by the question, $\frac{20}{y} = \frac{10}{x} + 60$: hence, the two equations are

$$80x + 100y = 65, \therefore 16x + 20y = 13 \quad . \ . \ . \ (1)$$
$$\text{and } \frac{20}{y} = \frac{10}{x} + 60, \therefore \frac{2}{y} - \frac{1}{x} = 6 \quad . \ . \ . \ (2)$$

Clearing the last of fractions, $\therefore 2x - y = 6xy$ . . . (3)

Substituting in (3) the expression for x given by (1)—viz., $x = \frac{13 - 20y}{16}$, it becomes

$$\frac{13 - 20y}{8} - y = \frac{39y - 60y^2}{8}$$

Multiplying by 8, $\therefore 13 - 20y - 8y = 39y - 60y^2$
Transposing, $60y^2 - 67y = -13$

$$\therefore \text{Rule II., } 120y - 67 = \sqrt{(-13 \times 240 + 67^2)}$$
$$= \sqrt{1369} = \pm 37 \therefore y = \frac{67 \pm 37}{120} = \frac{1}{4}, \text{ or } \frac{13}{15}$$

$\therefore x = \frac{13 - 20y}{16} = \frac{13 - 5}{16} = \frac{1}{2}$; the other value of x is negative: hence the price of 1lb. of mace was £$\frac{1}{2}$, or 10s., and of 1 lb. of cloves £$\frac{1}{4}$, or 5s.

Otherwise.—Multiply (1) and (2) together; we then have

$$32\frac{x}{y} - 20\frac{y}{x} - 16 + 40 = 78, \therefore 32\frac{x}{y} - 20\frac{y}{x} = 54,$$
$$\therefore 16\frac{x}{y} - 10\frac{y}{x} = 27.$$

Multiplying (2) by $8x$, $16\frac{x}{y} - 8 = 48x$

Subtracting, $10\frac{y}{x} - 8 = 48x - 27$

Dividing (1) by $2x$, $8 + 10\frac{y}{x} = \frac{13}{2x}$, $\therefore 10\frac{y}{x} = \frac{13}{2x} - 8$.

Hence, by substitution in the preceding equation,

$$\frac{13}{2x} - 16 = 48x - 27, \text{ or } \frac{13}{2x} = 48x - 11.$$

Clearing the fraction,

$$96x^2 - 22x = 13, \therefore \text{Rule II., } 192x - 22 = \sqrt{(96 \times 52 + 22^2)} = \pm 74$$
$$\therefore x = \frac{22 \pm 74}{192} = \frac{1}{2}, \text{ or } -\frac{13}{48}$$

and, rejecting the negative value of x, we have from (1)

$$y = \frac{13 - 16x}{20} = \frac{13 - 8}{20} = \frac{1}{4}$$

Therefore, the price of 1lb. of mace was £$\frac{1}{2}$, or 10s.; and of 1lb. of cloves £$\frac{1}{4}$, or 5s., as before.

7. The product of two numbers is 240, and they are such that if one of them be increased by 4, and the other diminished by 3, the product of the results is still 240. Find the numbers.

Let x and y represent the numbers; then by the question,

$$xy = 240, \text{ and } (x + 4)(y - 3) = 240,$$
$$\text{That is, } xy - 3x + 4y - 12 = 240$$

Subtracting this from the first equation, $3x - 4y + 12 = 0$, $\therefore x = \frac{4y - 12}{3}$

$$\therefore xy = \frac{4y^2 - 12y}{3} = 240, \therefore 4y^2 - 12y = 720$$
$$\therefore y^2 - 3y = 180, \therefore \text{Rule II., } 2y - 3 = \sqrt{(720 + 9)}$$
$$= \pm 27 \therefore y = \frac{3 \pm 27}{2} = 15, \text{ or } -12$$
$$\therefore x = \frac{240}{y} = 16, \text{ or } -20.$$

Hence the numbers are either 16 and 15, or -20 and -12.

8. A and B set out at the same time for a place 150 miles distant. A travels 3 miles an hour faster than B, and arrives at the place $8\frac{1}{3}$ hours before him. How many miles did each travel per hour?

Suppose A travels x miles per hour, then B travels $x - 3$ miles an hour; and the number of hours occupied by A is $\frac{150}{x}$, the number occupied by B is $\frac{150}{x-3}$; but by the question, this latter number exceeds the former by $8\frac{1}{3}$,

$$\therefore \frac{150}{x} + 8\tfrac{1}{3} = \frac{150}{x-3}$$

Clearing fractions, $450x - 1350 + 25x^2 - 75x = 450x$
Transposing, $25x^2 - 75x = 1350$, $\therefore x^2 - 3x = 54$,

$$\therefore \text{Rule II., } 2x - 3 = \sqrt{(216 + 9)} = \sqrt{225} = \pm 15$$
$$\therefore x = \frac{3 \pm 15}{2} = 9, \text{ or } -6,$$
$$\therefore x - 3 = 6.$$

Hence, A travels at the rate of 9 miles an hour, and B at the rate of 6 miles an hour.

9. What number is that the sum of whose digits is 15, and if 31 be added to their product, the digits will be transposed?

Let x and y denote the two digits; then the number is $10x + y$; and by the question

$$x + y = 15, \text{ and } xy + 31 = 10y + x.$$

From the first, $x = 15 - y$, $\therefore (15 - y)y + 31 = 10y + 15 - y$.

That is, $15y - y^2 + 31 = 9y + 15$, $\therefore y^2 - 6y = 16$.

Completing the square,

$$y^2 - 6y + 9 = 25, \therefore y - 3 = \pm 5, \therefore y = 3 \pm 5 = 8,$$
$$\text{or} -2 \;\therefore x = 15 - y = 7.$$

Hence the digits are 7 and 8, and the number is 78.

10. There is a certain number consisting of two digits. The left-hand digit is equal to three times the right-hand one; and if 12 be subtracted from the number, the remainder will be equal to the square of the left-hand digit. What is the number?

Let x and y represent the two digits; then the number is $10x + y$. And by the question,

$$x = 3y, \text{ and } 10x + y - 12 = x^2$$
$$\therefore \text{ by substitution, } 30y + y - 12 = 9y^2$$
$$\text{Transposing, } 9y^2 - 31y = -12$$
$$\therefore \text{Rule II., } 18y - 31 = \sqrt{(-36 \times 12 + 31^2)}$$
$$= \sqrt{529} = \pm 23 \;\therefore y = \frac{31 \pm 23}{18} = 3, \text{ or } \frac{4}{9}.$$

The fractional value must be rejected, $\therefore x = 3y = 9$; hence the number is 93.

Otherwise.—As above,

$$10x + y - 12 = x^2, \text{ and } x - 3y = 0,$$
$$\text{Multiplying the first by 3, } 30x + 3y - 36 = 3x^2$$
$$\begin{array}{lrcl} \text{Adding the second,} & x - 3y & = & 0 \\ \hline & \therefore\; 31x - 36 & = & 3x^2 \end{array}$$

Transposing, $3x^2 - 31x = -36$, $\therefore$ Rule II., $6x - 31$

$$= \sqrt{(-36 \times 12 + 31^2)} = \pm 23 \therefore x = \frac{31 + 23}{6} = 9,$$
$$\therefore y = \frac{x}{3} = 3;$$

hence the digits are 9 and 3, and the number is 93.

Arithmetical Progression. Examples for Exercise.

Page 478.

1. Find the sum of sixteen terms of the series $1 + 2 + 3 + 4 +$ &c.

By the formula, $S = \frac{1}{2}n\{2a + (n - 1)d\}$, where $a = 1$, $d = 1$, and $n = 16$.

Consequently $S = 8\{2 + 15\} = 136$, the sum required.

2. Find the sum of fourteen terms of the series $4 + 3 + 2 + 1 + 0 - 1 - 2 -$ &c. Here $a = 4$, $d = -1$, and $n = 14$: hence

$$S = \tfrac{1}{2}n\{2a + (n - 1)d\}$$
$$= 7\{8 - 13\} = -35, \text{ the sum.}$$

3. Sum the series $\frac{1}{2} + 1\frac{1}{2} + 2\frac{1}{2} +$ &c. to twenty terms. Here $a = \frac{1}{2}$, $d = 1$, and $n = 20$: therefore

$$S = \tfrac{1}{2}n\{2a + (n - 1)d\}$$
$$= 10\{1 + 19\} = 200, \text{ the sum.}$$

4. Insert three arithmetical means between 2 and 0. By the formula, $l = a + (n - 1)d$, where $a = 2$, $n = 5$, $l = 0$. $\therefore 0 = 2 + 4d$, $\therefore d = -\frac{2}{4} = -\frac{1}{2}$.

Hence, when the means are inserted, the series is

$$2, 1\tfrac{1}{2}, 1, \tfrac{1}{2}, 0.$$

5. Insert five arithmetical means between $\frac{1}{2}$ and $-\frac{1}{2}$.

$$l = a + (n - 1)d,$$
$$\therefore -\tfrac{1}{2} = \tfrac{1}{2} + 6d, \therefore d = -\tfrac{1}{6}.$$

Hence, when the means are inserted, the series is

$$\tfrac{1}{2}, \tfrac{1}{3}, \tfrac{1}{6}, 0, -\tfrac{1}{6}, -\tfrac{1}{3}, -\tfrac{1}{2}.$$

6. The first term is 5, and the fifteenth 47: what is the common difference?

$$l = a + (n - 1)d,$$
$$\therefore 47 = 5 + 14d, \therefore d = \frac{42}{14} = 3.$$

7. How many terms of the series $12 + 11\frac{1}{2} + 11 + 10\frac{1}{2} +$ &c., must be taken to make 55?

$$S = \tfrac{1}{2}n\{2a + (n - 1)d\}$$
$$\therefore 55 = \tfrac{1}{2}n\{24 - (n - 1)\tfrac{1}{2}\} = 12n - \frac{n^2 + n}{4}$$
$$\therefore 220 = 49n - n^2, \therefore n^2 - 49n = -220$$
$$\therefore \text{Rule II., p. 474, } 2n - 49 = \sqrt{(49^2 - 880)} = \sqrt{1521} = \pm 39,$$
$$\therefore n = \frac{49 \pm 39}{2} = 5, \text{ or } 44.$$

Hence, whether five terms, or forty-four terms of the series be taken, the sum will be 55.

8. The first term of an arithmetical progression is 7, and the common difference $-\frac{3}{2}$: required the ninth term.

$$l = a + (n - 1)d,$$
$$\therefore l = 7 - 8 \times \frac{3}{2} = 7 - 12 = -5, \text{ the ninth term.}$$

9. The sum of eight terms of an arithmetical series is 2, and the common difference $-1\frac{1}{2}$; required the first term.

$$S = \tfrac{1}{2}n\{2a + (n - 1)d\}$$
$$\therefore 2 = 4\{2a - 7 \times 1\tfrac{1}{2}\}, \therefore 1 = 4a - 21,$$
$$\therefore 4a = 22, \therefore a = 5\tfrac{1}{2}, \text{ the first term.}$$

10. The first term of an arithmetical series is $-3\frac{1}{3}$, and the common difference $\frac{1}{5}$: required the sum of twenty-one terms.

$$S = \tfrac{1}{2}n\{2a + (n - 1)d\}$$
$$\therefore S = \frac{21}{2}\{-6\tfrac{2}{3} + \frac{20}{5}\} = 21\{-3\tfrac{1}{3} + 2\}$$
$$= -70 + 42 = -28, \text{ the sum.}$$

Geometrical Progression. Examples for Exercise.

Page 479.

1. Required the sum of five terms of the series.

$$1 + 2^2 + 2^4 + 2^6 + \text{\&c.}$$
$$l = ar^{n-1}, S = \frac{rl - a}{r - 1}, \text{ where } a = 1, r = 4, n = 5,$$
$$\therefore l = 256, \therefore S = \frac{1024 - 1}{3} = 341, \text{ the sum.}$$

2. Required the sum of eight terms of

$$1 - \frac{1}{2} + \frac{1}{4} - \frac{1}{8} + \text{\&c.}$$
$$l = ar^{n-1}, S = \frac{rl - a}{r - 1}, \text{ where } a = 1, r = -\frac{1}{2}, n = 8,$$
$$\therefore l = -\frac{1}{128}, \therefore S = \frac{\frac{1}{256} - 1}{-\frac{3}{2}} = \frac{255}{256} \times \frac{2}{3} = \frac{85}{128}, \text{ the sum.}$$

3. Required the sum of ten terms of $1 + 2 + 4 + 8 +$ &c.

$$l = ar^{n-1}, S = \frac{rl - a}{r - 1}, \text{ where } a = 1, r = 2, n = 10,$$
$$\therefore l = 512, \therefore S = \frac{1024 - 1}{1} = 1023, \text{ the sum.}$$

4. What is the geometrical mean between 6 and 54?

$$54 \times 6 = 324, \text{ and } \sqrt{324} = \pm 18, \text{ mean.}$$

Hence when the mean is inserted, the progression is either 6, 18, 54 or 6, -18, 54, the ratio in the former case being 3, and in the latter -3.

5. Insert two geometrical means between 2 and 54. When the two means are inserted there will be four terms, therefore $n = 4$; also $a = 2$, and $l = 54$; and we have to find r. By the formula, $l = ar^{n-1}$, $\therefore 54 = 2r^3$,

$$\therefore r^3 = 27, \therefore r = \sqrt[3]{27} = 3.$$

Hence, supplying the means, the progression is 2, 6, 18, 54.

6. Sum the series $\frac{1}{10} + \frac{1}{10^2} + \frac{1}{10^3} +$ &c. to infinity.

By the formula,

$$\Sigma = \frac{a}{1 - r}, \therefore \Sigma = \frac{1}{10} \div \frac{9}{10} = \frac{1}{9}, \therefore \cdot 111 \ldots = \frac{1}{9}.$$

7. The first term of a geometrical series is 3, the

common ratio 5, and the last term 375: find the sum.

$$S = \frac{rl - a}{r - 1}, \therefore S = \frac{1875 - 3}{4} = 468, \text{ the sum.}$$

8. The first term of a geometrical series is $\frac{5}{2}$, and the common ratio $-\frac{1}{5}$: find the sum to infinity.

By the formula, $\Sigma = \frac{a}{1 - r}$, $\therefore \Sigma = \frac{5}{2} + \frac{6}{5} = 2\frac{1}{12}$, the sum.

9. **Insert three geometrical means between $\frac{1}{2}$ and $\frac{2}{9}$.**

When the means are inserted there will be five terms, therefore $n = 5$; also $a = \frac{1}{2}$, and $l = \frac{2}{9}$; and we have to find r.

By the formula, $l = ar^{n-1}$, $\therefore \frac{2}{9} = \frac{1}{2}r^4$,

$$\therefore r^4 = \frac{4}{9}, \therefore r^2 = \pm\frac{2}{3}, \therefore r = \sqrt{\pm\frac{2}{3}}.$$

Hence the progression is

$$\frac{1}{2}, \frac{1}{2}\sqrt{\pm\frac{2}{3}}, \pm\frac{1}{3}, \pm\frac{1}{3}\sqrt{\pm\frac{2}{3}}, \frac{2}{9}.$$

10. Required the sum of the infinite series

$$1 + \frac{1}{x} + \frac{1}{x^2} + \frac{1}{x^3} + \&c.,$$

and then deduce Σ for $x = 2$, and $x = -2$,

$$\Sigma = \frac{a}{1 - r}, \therefore \Sigma = 1 \div \left(1 - \frac{1}{x}\right) = \frac{x}{x - 1}.$$

$$\text{When } x = 2, \Sigma = 2; \text{ when } x = -2, \Sigma = \frac{2}{3}.$$

QUESTIONS IN WHICH PROPORTION AND PROGRESSION ARE CONCERNED. PAGE 480.

1. Divide 49 into two parts, such, that the greater increased by 6, may be to the less diminished by 11, as 9 to 2.

Let x be the greater, then $49 - x$ is the less, and by the question

$$x + 6 : 38 - x :: 9 : 2.$$

Multiplying extremes and means, we have

$$2x + 12 = 342 - 9x, \therefore 11x = 330, \therefore x = 30,$$

$\therefore 49 - x = 19$: hence the two parts are 30 and 19.

2. Two hundred stones are placed in a straight line, at intervals of 2 feet, the first stone being 20 yards in advance of a basket. Suppose a person, starting from the basket, collects the stones, and returns them, one by one to the basket. How much ground does he go over?

Upon returning the first stone, he will have gone 40 yards; upon returning the second, 40 yards and 4 feet; upon returning the third, 40 yards and 8 feet, and so on; hence we have to find the sum of the arithmetical progression, following, each term being feet.

$$120 + 124 + 128 + 132 + \&c., \text{ to 200 terms.}$$

By the formula, $S = \frac{1}{2}n\{2a + (n - 1)d\}$

$$\therefore S = 100\{240 + 199 \times 4\} = 103,600 \text{ feet,}$$

and 103,600 feet = $34,533\frac{1}{3}$ yards = $19\frac{1}{2}$ miles $213\frac{1}{3}$ yards.

3. The sum of four numbers in geometrical progression is equal to 1 added to the common ratio; and $\frac{1}{17}$ is the first term: required the numbers.

Let r be the common ratio, then since

$$S = a\frac{r^n - 1}{r - 1}, \therefore r + 1 = \frac{r^4 - 1}{17(r - 1)} = \frac{(r^2 - 1)(r^2 + 1)}{17(r - 1)}$$

$$\text{That is, } r + 1 = \frac{(r + 1)(r^2 + 1)}{17}, \therefore 17 = r^2 + 1,$$

$$\therefore r^2 = 16, \therefore r = \pm 4;$$

Hence the progression is $\frac{1}{17}, \pm\frac{4}{17}, \frac{16}{17}, \pm\frac{64}{17}$; that is to say, either of the two progressions, following, will fulfil the conditions, namely,

$$\frac{1}{17}, \frac{4}{17}, \frac{16}{17}, \frac{64}{17};$$

$$\text{or, } \frac{1}{17}, -\frac{4}{17}, \frac{16}{17}, -\frac{64}{17}.$$

4. From two towns, 165 miles apart, A and B set out to meet each other. A travels 1 mile the first day, 2 the second, 3 the third, and so on; B travels 20 miles the first day, 18 the second, 16 the third, and so on: in how many days will they meet?

Suppose they meet in n days, then

$$1 + 2 + 3 + \&c., \text{ to } n \text{ terms} = \tfrac{1}{2}n\{2 + (n - 1)\}$$
$$= \text{A's distance}$$
$$\text{and } 20 + 18 + 16 + \&c., \text{ to } n \text{ terms} = \tfrac{1}{2}n\{40 - 2(n - 1)\}$$
$$= \text{B's distance}$$

$$\therefore \text{ the sum of the distances} = \tfrac{1}{2}n\{42 - n + 1\} = 165$$
$$\therefore 42n - n^2 + n = 330, \therefore n^2 - 43n = -330,$$
$$\therefore \text{Rule II., page 474, } 2n - 43 = \sqrt{(43^2 - 1320)}$$
$$= \sqrt{529} = \pm 23$$
$$\therefore n = \frac{43 \pm 23}{2} = 10, \text{ or } 33.$$

Hence they meet in 10 days. If it were a condition that B is to continue travelling after he meets and passes A, diminishing his distance by two miles daily, he will on the eleventh day travel 0 miles, and therefore on the twelfth day − 2 miles; that is, he will *return back* 2 miles, on the thirteenth day 4 miles, and so on. The second value of n above, shows that in 33 days B will in this way again come up with A, by *overtaking* him. In these 33 days A will have proceeded directly onwards to a distance of 561 miles, while B will have been *following* him for a distance of 396 miles, for B's whole distance is expressed by − 396; and 561 − 396 = 165: so that the *algebraic sum* of the two distances still makes 165 miles; and the only condition implied in the algebraical statement of the question is, that the sum of the two distances shall be 165 miles.

5. The sum of the first and second of four numbers in geometrical progression is 15, and the sum of the third and fourth 60; what are the numbers?

Let the geometrical progression be

$$\frac{x}{y^2}, \frac{x}{y}, x, xy,$$

then, by the question, the conditions are

$$\frac{x}{y^2} + \frac{x}{y} = 15 \quad . \quad . \quad . \quad (1),$$

$$\text{and} \quad x + xy = 60 \quad . \quad . \quad . \quad (2),$$

and since 4 times the first is equal to the second, we have, after dividing each by x,

$$\frac{4}{y^2} + \frac{4}{y} = 1 + y, \therefore \frac{4}{y^2} - 1 = y - \frac{4}{y},$$

or, which is the same thing, $\frac{4}{y^2} - 1 = -y\left(\frac{4}{y^2} - 1\right)$,

that is, transposing, $(y + 1)\left(\frac{4}{y^2} - 1\right) = 0 \quad . \quad . \quad . \quad (3).$

Now a product is 0, *whichever* of the factors is 0; hence we must have either

$$y + 1 = 0, \text{ or } \frac{4}{y^2} - 1 = 0.$$

The first of these conditions cannot be admitted, because it is plain, that for $y = -1$, the equation (2), becoming $0 = 60$, is impossible: hence the condition which is to satisfy (3) is

$$\frac{4}{y^2} - 1 = 0, \therefore 4 - y^2 = 0, \therefore y^2 = 4, \therefore y = \pm 2,$$

$$\therefore (2), x = \frac{60}{1 + y} = \frac{60}{1 \pm 2} = 20, \text{ or } -60.$$

Hence the progression is either

$$5, 10, 20, 60, \text{ or } -15, 30, -60, 120.$$

6. The sum of three numbers in geometrical progression is 35; and the mean term is to the difference of the extremes as 2 to 3; what are the numbers?

Let the three numbers be $\frac{x}{y}$, x, and xy; then by the question

$$\frac{x}{y} + x + xy = 35 \; . \; . \; . \; (1),$$

$$\text{and } x : xy - \frac{x}{y} : : 2 : 3, \; \therefore 3x = 2\left(xy - \frac{x}{y}\right),$$

$$\therefore 3 = 2y - \frac{2}{y} \; . \; . \; . \; (2),$$

$$\therefore 3y = 2y^2 - 2, \; \therefore 2y^2 - 3y = 2,$$

Rule II., page 474, $4y - 3 = \sqrt{(16 + 9)}$
$= \sqrt{25} = \pm 5,$

$$\therefore y = \frac{3 \pm 5}{4} = 2, \text{ or } -\tfrac{1}{2}.$$

Hence, (1) becomes

$$\frac{x}{2} + x + 2x = 35, \text{ or } -2x + x - \frac{x}{2} = 35,$$

that is, $3\frac{1}{2}x = 35$, or $-1\frac{1}{2}x = 35$,

$$\therefore x = 10, \text{ or, } -23\tfrac{1}{3}.$$

Hence the numbers are either

5, 10, and 20 ; or $46\frac{2}{3}$, $-23\frac{1}{3}$, and $11\frac{2}{3}$,

both of which sets satisfy the conditions of the question.

EXTRACTION OF THE SQUARE ROOT. EXAMPLES FOR EXERCISE. PAGE 482.

1.
$$\begin{array}{ll}
 & x^2 + 4bx + 4b^2(x + 2b \\
 & x^2 \\
2x + 2b) & 4bx + 4b^2 \\
 & 4bx + 4b^2.
\end{array}$$

2.
$$\begin{array}{ll}
 & 9x^4 + 12x^3 + 10x^2 + 4x + 1(3x^2 + 2x + 1 \\
 & 9x^4 \\
6x^2 + 2x) & 12x^3 + 10x^2 \\
 & 12x^3 + 4x^2 \\
6x^2 + 4x + 1) & 6x^2 + 4x + 1 \\
 & 6x^2 + 4x + 1
\end{array}$$

3.
$$\begin{array}{ll}
 & 9x^4 + 12x^3 + 34x^2 + 20x + 25)3x^2 + 2x + 5 \\
 & 9x^4 \\
6x^2 + 2x) & 12x^3 + 34x^2 \\
 & 12x^3 + 4x^2 \\

---

[*] The $0x^3$ in the above square is of no value, and has been retained solely to indicate the successive diminution in the value of the exponents of x.—ED.

Otherwise.—$16x^4 + 24x^3 + 89x^2 + 60x + 100(4x^2 + 3x + 10$

$16x^4$ $\quad\therefore$ Root $= 2x^2 + \frac{3}{2}x + 5$

$8x^2 + 3x)$ $\quad 24x^3 + 89x^2$
$\quad 24x^3 + 9x^2$

$8x^2 + 6x + 10$ $\quad 80x^2 + 60x + 100$
$\quad 80x^2 + 60x + 100$

SQUARE ROOT OF A BINOMIAL SURD. EXAMPLES FOR EXERCISE. PAGE 483.

1. Put $\sqrt{(19 + 8\sqrt{3})} = x + y$, $\therefore \sqrt{(19 - 8\sqrt{3})} = x - y$. Taking the product,
$\sqrt{(361 - 192)} = x^2 - y^2$; that is, $13 = x^2 - y^2$. Also,
$19 + 8\sqrt{3} = x^2 + 2xy + y^2$, $\therefore 19 = x^2 + y^2$
$\therefore \overline{32} = 2x^2,\ 6 = 2y^2$
$\therefore x^2 = 16, \therefore x = 4;\ y^2 = 3, \therefore y = \sqrt{3}$
$\therefore \sqrt{(19 + 8\sqrt{3})} = 4 + \sqrt{3}$.

2. $\sqrt{(12 - \sqrt{140})} = x - y$, $\therefore \sqrt{(12 + \sqrt{140})} = x + y$. Taking the product,
$\sqrt{(144 - 140)} = x^2 - y^2$; that is, $2 = x^2 - y^2$.
Also, $12 - \sqrt{140} = x^2 - 2xy + y^2$, $\therefore 12 = x^2 + y^2$
$\therefore \overline{14} = 2x^2,\ 10 = 2y^2$
$\therefore x^2 = 7, \therefore x = \sqrt{7};\ y^2 = 5, \therefore y = \sqrt{5}$.
$\therefore \sqrt{(12 - \sqrt{140})} = \sqrt{7} - \sqrt{5}$.

3. $\sqrt{(7 - 2\sqrt{10})} = x - y$, $\therefore \sqrt{(7 + 2\sqrt{10})} = x + y$. Taking the product,
$\sqrt{(49 - 40)} = x^2 - y^2$; that is, $3 = x^2 - y^2$

Also, $7 - 2\sqrt{10} = x^2 - 2xy + y^2$, $\therefore 7 = x^2 + y^2$
$\therefore \overline{10} = 2x^2,\ 4 = 2y^2$
$\therefore x^2 = 5, \therefore x = \sqrt{5};\ y^2 = 2, \therefore y = \sqrt{2}$
$\therefore \sqrt{(7 - 2\sqrt{10})} = \sqrt{5} - \sqrt{2}$.

4. $\sqrt{(8 + \sqrt{39})} = x + y$, $\therefore \sqrt{(8 - \sqrt{39})} = x - y$. Taking the product,
$\sqrt{(64 - 39)} = x^2 - y^2$; that is, $5 = x^2 - y^2$

Also, $8 + \sqrt{39} = x^2 + 2xy + y^2$, $\therefore 8 = x^2 + y^2$
$\therefore \overline{13} = 2x^2,\ 3 = 2y^2$
$\therefore x^2 = \frac{13}{2}, \therefore x = \frac{1}{2}\sqrt{26};\ y^2 = \frac{3}{2}, \therefore y = \frac{1}{2}\sqrt{6}$
$\therefore \sqrt{(8 + \sqrt{39})} = \frac{1}{2}(\sqrt{26} + \sqrt{6})$.

5. $\sqrt{(76 - 32\sqrt{3})} = x - y$, $\therefore \sqrt{(76 + 32\sqrt{3})} = x + y$. Taking the product, $\sqrt{(5776 - 3072)} = x^2 - y^2$; that is, $52 = x^2 - y^2$.
Also, $76 - 32\sqrt{3} = x^2 - 2xy + y^2$, $\therefore 76 = x^2 + y^2$
$\therefore \overline{128} = 2x^2,\ 24 = 2y^2$;
$\therefore x^2 = 64, \therefore x = 8;\ y^2 = 12, \therefore y = 2\sqrt{3}$,
$\therefore \sqrt{(76 - 32\sqrt{3})} = 8 - 2\sqrt{3}$.

6. $\sqrt{(31 + 12\sqrt{-5})} = x + y$, $\therefore \sqrt{(31 - 12\sqrt{-5})} = x - y$. Taking the product, $\sqrt{(961 + 720)} = x^2 - y^2$; that is, $41 = x^2 - y^2$.

Also, $31 + 12\sqrt{-5} = x^2 + 2xy + y^2$, $\therefore 31 = x^2 + y^2$
$\therefore \overline{72} = 2x^2,\ 10 = -2y^2$;
$\therefore x^2 = 36, \therefore x = 6;\ y^2 = -5, \therefore y = \sqrt{-5}$,
$\therefore \sqrt{(31 + 12\sqrt{-5})} = 6 + \sqrt{-5}$.

TO RATIONALISE BINOMIAL SURDS. EXAMPLES FOR EXERCISE. PAGE 484.

1. Prove that $\frac{3}{2\sqrt{7} - 3\sqrt{2}} = \frac{3}{10}(2\sqrt{7} + 3\sqrt{2})$.

Multiplying numerator and denominator by $2\sqrt{7} + 3\sqrt{2}$,

$$\frac{3}{2\sqrt{7} - 3\sqrt{2}} = \frac{3(2\sqrt{7} + 3\sqrt{2})}{28 - 18} = \frac{3}{10}(2\sqrt{7} + 3\sqrt{2}).$$

2. Prove that $\frac{2 + \sqrt{3}}{3 + \sqrt{3}} = \frac{3 + \sqrt{3}}{6}$. Multiplying the terms by $3 - \sqrt{3}$,

$$\frac{2 + \sqrt{3}}{3 + \sqrt{3}} = \frac{(2 + \sqrt{3})(3 - \sqrt{3})}{6} = \frac{3 + \sqrt{3}}{6}.$$

3. Prove that $\frac{\sqrt{6}}{\sqrt{8}+\sqrt{3}}=\frac{4\sqrt{3}-3\sqrt{2}}{5}$

$$\frac{\sqrt{6}}{\sqrt{8}+\sqrt{3}}=\frac{\sqrt{6}\times(\sqrt{8}-\sqrt{3})}{8\sqrt{\ }+\sqrt{3})\,(\sqrt{8}-\sqrt{3})}=\frac{\sqrt{48}-\sqrt{18}}{5}=\frac{4\sqrt{3}-3\sqrt{2}}{5}.$$

4. Prove that $\frac{2}{\sqrt{3}-\sqrt[3]{2}}=2(\sqrt[3]{9}+\sqrt[3]{6}+\sqrt[3]{4})$.

$$\frac{2}{\sqrt[3]{3}-\sqrt[3]{2}}=\frac{2(\sqrt[3]{9}+\sqrt[3]{6}+\sqrt[3]{4})}{(\sqrt[3]{3}-\sqrt[3]{2})\,(\sqrt[3]{9}+\sqrt[3]{6}+\sqrt[3]{4})}=\frac{2(\sqrt[3]{9}+\sqrt[3]{6}+\sqrt[3]{4})}{3-2}$$
$$=2(\sqrt[3]{9}+\sqrt[3]{6}+\sqrt[3]{4}).$$

5. Prove that $\frac{5}{\sqrt[3]{7}-\sqrt[3]{5}}=\frac{5}{2}(\sqrt[3]{49}+\sqrt[3]{35}+\sqrt[3]{25})$.

Multiplying numerator and denominator by $\sqrt[3]{49}+\sqrt[3]{35}+\sqrt[3]{25}$, we have

$$\frac{5}{\sqrt[3]{7}-\sqrt[3]{5}}=\frac{5(\sqrt[3]{49}+\sqrt[3]{35}+\sqrt[3]{25})}{7-5}=\frac{5}{2}(\sqrt[3]{49}+\sqrt[3]{35}+\sqrt[3]{25}).$$

6. Prove that $\frac{\sqrt{12}-\sqrt{10}}{\sqrt{6}+\sqrt{5}}=11\sqrt{2}-4\sqrt{15}\sqrt{\ }$. Multiplying numerator and denominator by $\sqrt{6}-\sqrt{5}$,

$$\frac{\sqrt{12}-\sqrt{10}}{\sqrt{6}+\sqrt{5}}=\frac{(\sqrt{12}-\sqrt{10})\,(\sqrt{6}-\sqrt{5})}{6-5}=\sqrt{72}-2\sqrt{60}+\sqrt{50}$$
$$=6\sqrt{2}-4\sqrt{15}+5\sqrt{2}=11\sqrt{2}-4\sqrt{15}.$$

EXTRACTION OF THE CUBE ROOT PAGE 486.

1.

$$\begin{array}{lll}
0 & 0 & x^6+9x^5+6x^4-99x^3-42x^2+441x-343(x^2+3x-7^{*} \\
x^2 & x^4 & x^6 \\
x^2 & x^4 & 9x^5+6x^4-99x3 \\
x^2 & 2x^4 & 9x^5+27x^4+27x^3 \\
2x^2 & 3x^4 & -21x^4-126x^3-42x^2+441x-343 \\
x^2 & \quad 9x^3+9x^2 & -21x^4-126x^3-42x^2+441x-343 \\
3x^2 & 3x^4+9x^3+9x^2 & \\
\quad 3x & \quad 9x^3+18x^2 & \\
3x^2+3x & 3x^4+18x^3+27x^2 & \\
\quad 3x & \qquad -21x^2-63x+49 & \\
3x^2+6x & 3x^4+18x^3+6x^2-63x+49 & \\
\quad 3x & & \\
3x^2+9x & & \\
\quad -7 & & \\
3x^2+9x-7 & &
\end{array}$$

Hence the cube root of the proposed polynomial is x^2+3x-7.

2.

$$\begin{array}{lll}
0 & 0 & x^6+6x^5+0x^4\dagger-40x^3+0x^2+96x-64(x^2+2x-4 \\
x^2 & x^4 & x^6 \\
x^2 & x^4 & 6x^5+0x^4-40x^3 \\
x^2 & 2x^4 & 6x^5+12x^4+8x^3 \\
2x^2 & 3x^4 & -12x^4-48x^3+0x^2+96x-64 \\
x^2 & \quad 6x^3+4x^2 & -12x^4-48x^3+0x^2+96x-64 \\
3x^2 & 3x^4+6x^3+4x^2 & \\
\quad 2x & \quad 6x^3+8x^2 & \\
3x^2+2x & 3x^4+12x^3+12x^2 & \\
\quad 2x & \qquad -12x^2-24x+16 & \\
3x^2+4x & 3x^4+12x^3+0x^2-24x+16 & \\
\quad 2x & & \\
3x^2+6x & & \\
\quad -4 & & \\
3x^2+6x-4 & &
\end{array}$$

Hence the cube root is x^2+2x-4.

---

* See the Note appended to the last example in this Key.

† This is of no value, and merely completes the series of exponents of x.

```

In the preceding example the decimals of the root are interminable, since 2 is not an exact cube; it is required to approximate to the cube root as far as eleven or twelve places of decimals only; so that there is no necessity, in carrying on the work of development, to make any provision for decimals beyond this prescribed limit; and, accordingly, in the operation here shown, the decimals in the several columns have been restrained from accumulating to an unnecessary extent. You will, of course, remember that in multiplying a number abridged of final decimals, the *carryings* from the rejected decimals are to be taken account of, as noticed at page 486, ALGEBRA.

Hence the cube root of 2, true as far as eleven places of decimals, is $\sqrt[3]{2} = 1{\cdot}25992104989$. In the third column of the work, the decimals have not been allowed to accumulate after the step marked 5, since more decimals, to the right of those furnished at that step, would have been superfluous, if only eleven or twelve decimals are required in the root; and, in order to provide against this unnecessary increase of decimals, the two preceding columns are curtailed of the decimals which are foreseen to contribute only to that portion of the third column thus rejected. Another decimal—viz., 4, or 5 very nearly—might obviously have been added to those already in the root; so that we may with safety affirm that $\sqrt[3]{2} = 1{\cdot}259921049895$ is true, to the nearest unit, in the twelfth place of decimals. Had the suppression of additional decimals been postponed till another step of the work had been reached, we should have found

$$\sqrt[3]{2} = 1{\cdot}259921049894873 \ldots .$$

which is true as far as fifteen places of decimals.

Such an extent of figures is very rarely, if ever, required in actual practice, and they have been given here merely to show the accuracy with which a cube root may be extracted by the foregoing contracted method.

Hence, the cube root of 959 is 9·8614218, which is true to seven places of decimals.

6. To find the cube root of

$$x^6 - 15x^5y + 69x^4y^2 - 138x^2y^4 - 60xy^5 - 8x^6.$$

From this expression a term was accidentally omitted; but as it is instructive to deal with it as it is, the wanting term is purposely left unsupplied, and the work carried on as in next page.

$$\begin{array}{lll}
 & 0 & x^6 - 15x^5y + 69x^4y^2 - 138x^2y^4 - 60xy^5 - 8x^6(x^2 - 5xy - 2y^2 \\
x^2 & x^4 & x^6 \\
\hline
x^2 & x^4 & -15x^5y + 69x^4y^2 + 0x^3y^3 \\
x^2 & 2x^4 & -15x^5y + 75x^4y^2 - 125x^3y^3 \\
\hline
2x^3 & 3x^4 & -6x^4y^2 + 125x^3y^3 - 138x^2y^4 - 60xy^5 - 8x^6 \\
x^3 & -15x^3y + 25x^2y^2 & -6x^4y^2 + 60x^3y^3 - 138x^2y^4 - 60xy^5 - 8x^6 \\
\hline
3x^3 & 3x^4 - 15x^3y + 25x^2y^2 & 65x^3y^3 \\
-5xy & -15x^3y + 50x^2y^2 & \\
\hline
3x^2 - 5xy & 3x^4 - 30x^3y + 75x^2y^2 & \\
-5xy & -6x^2y^2 + 30xy^3 + 4y^4 & \\
\hline
3x^2 - 10xy & 3x^4 - 30x^3y + 69x^2y^2 + 30xy^3 + 4y^4 & \\
-5xy & & \\
\hline
3x^2 - 15xy & & \\
-2y^2 & & \\
\hline
3x^2 - 15xy - 2y^2 & &
\end{array}$$

Hence the cube root of the proposed polynomial is $x^2 - 5xy - 2y^2$, with $65x^3y^3$ for remainder; so that the expression proposed differs by $65x^3y^3$ from the complete cube of $x^2 - 5xy - 2y^2$. If the remainder be introduced, with changed sign, into the polynomial, it will then become a complete cube: that is,

$$x^6 - 15x^5y + 69x^4y^2 - 65x^3y^3 - 138x^2y^4 - 60xy^5 - 8x^6 = (x^2 - 5xy - 2y^2)^3.$$

And in this way we may always ascertain what expression must be introduced into a proposed polynomial, in order to render it a complete cube.

NOTE.—The process adopted above, in imitation of that at page 485, of the Algebra, occupies a good deal more space than the work by the old method; but it must be observed that *here* there are no bye-operations: the whole is placed fairly before the eye, and every step may be performed with great ease and rapidity, and may be readily revised in case of mistake—advantages not to be overlooked.
